(or *market price*) of a bond is usually its *clean price*, that is, its *gross price* minus the *accrued interest*. When an investor purchases a bond, he is actually entitled to receive all the future cash flows of this bond, until he no longer owns it. If he buys the bond between two coupon payment dates, he logically must pay it at a price reflecting the fraction of the next coupon that the seller of the bond is entitled to receive for having held it until the sale. This price is called the *gross price* (or *dirty price* or *full price*). It is computed as the sum of the clean price and the portion of the coupon that is due to the seller of the bond. This portion is called the *accrued interest*. It is computed from the settlement date on.

The quoted *yield to maturity* of a bond is the discount yield that equalizes its gross price times its nominal amount to the sum of its discounted cash flows. As an illustration, let us consider a French bond paying an annual coupon of 7%, residual maturity 8.5 years and market price 106.459%. The accrued interest is equal to $7\% \times 0.5 = 3.5\%$ (there have been six months since the last coupon payment). The bond annual yield to maturity is such that

$$106.459\% + 3.5\% = \sum_{i=0}^8 \frac{7\%}{(1+R)^{i+0.5}} + \frac{100\%}{(1+R)^{8.5}} \quad (1)$$

which can be solved to yield $R = 6\%$.

The price–yield to maturity relationship is inverse and convex. The inversion property means that the higher (lower) the price, the lower (higher) the yield to maturity. The convexity property means that the previous property is not symmetrical. Actually, for the same absolute change in the yield to maturity, the bond price will increase more than decrease. Convexity is an attractive property that tends to increase with bond maturity.^a A bond price is also dependent on time to maturity. All else being equal, as the bond residual maturity decreases, its price converges to the redemption value. This so-called *pull-to-par phenomenon* is particularly noticeable for bonds with coupons far from their yield to maturity. The price–yield to maturity relationship is given by the following formula [1], where we assume that the

bond has just paid a coupon:

$$P = \sum_{i=1}^{\delta T} \frac{CF_i}{\left(1 + \frac{R}{\delta}\right)^i} \quad (2)$$

Here, P denotes the bond dirty price, T its maturity expressed in years, CF_i its cash flows, R its yield to maturity, δ is 1 for an annual bond, 2 for a semiannual bond, 4 for a quarterly bond, and so forth.

In other words, the yield to maturity is the internal rate of return of the cash flows produced by the bond, using a constant discount rate across all cash flows. The yield to maturity may therefore be interpreted as an “average” discount rate throughout the life of the bond or, equivalently, as the discount rate that would prevail if the yield curve happened to be flat at date t (which of course is not generally the case). It may be easily computed by trial and error or using built-in functions on Excel.

Under certain technical conditions, there exists a one-to-one correspondence between the price and the yield to maturity of a bond. Therefore, giving a yield to maturity for a bond is equivalent to giving a price for the bond. It should be noted that this is precisely what is actually done in the bond market, where bonds are most often quoted in yield to maturity. While bond yield to maturity is a useful concept, it should be approached with some care, given that it represents a weighted average of discount yields across maturities. Indeed, unless the term structure of interest rates is flat, there is no reason why one would consider the yield to maturity on, say, a 10-year bond as the relevant discount rate for a 10-year cash flow horizon. In fact, the relevant discount rate is the 10-year pure discount (or zero coupon) rate.

The yield to maturity, as the name suggests, can be viewed as the expected rate of return on a bond and allows comparison of two bonds of the same issuer with close maturities with each other. Let us consider a 10-year bond and a 10.25-year bond issued by the French treasury, both quoted at par value (i.e., 100%). The former (the latter) yields 4.50% (4.55%). An investor will most likely prefer the second one, as it yields 5 more basis points (0.05%) than the other (a nonnegligible premium) for a maturity that is slightly longer (three months). However, the yield to maturity on an investment will be achieved only under the following constraints:

- Once bought, bond securities have to be held until maturity.
- Bond coupons (equal in our example to the yield to maturity) have to be reinvested at the bond yield to maturity.

The first assumption is restrictive in the sense that it excludes early bond sales. If interest rates go down, an investor will be willing to sell the bond before maturity so as to take advantage of capital gains. This condition is only acceptable for long-term investors (pension funds, insurance companies), who are traditionally buy-and-hold investors. The second assumption is not realistic for two reasons:

- During the life of a bond, interest rates increase and decrease, but never remain unchanged. Consequently, postulating a unique reinvestment rate is not particularly relevant.
- Taking their respective yield to maturity for two bonds as reinvestment rate, that is, assuming that two different cash flows falling on the same date can be reinvested at different interest rates, boils down to questioning the uniqueness of the reinvestment rate at a given time for the same investment horizon [2].

In general, the expected return on a bond nearly always differs from its yield to maturity, except for zero-coupon bonds, which embed no reinvestment risk, as they deliver no intermediary cash flows before maturity. In practice, instead of using the yield to maturity, investors compute the *total rate of return* on a bond, which is equal to the sum of the difference between the sale price and the purchase price and the coupons reinvested at the interest rate corresponding to each reinvestment period, divided by the purchase price. So as to determine the future reinvestment rates as well as the yield at which the bond will be sold, investors often apply various scenarios of evolution of interest rates (worst case, best case, and neutral scenarios)—this is known as *scenario analysis*. To each scenario corresponds a specific total rate of return.

Duration and Convexity

While the concept of yield to maturity has its flaws, it is quite useful in the construction of hedges against interest rate risk. Indeed, as we have seen, the bond

price can generally be written as a unique function of the yield to maturity, so it is sensible to treat the yield to maturity as the main stochastic risk factor driving the price of the bond. If the yield happens to increase, the bond value will decrease, generating (in case of early unwinding) potentially significant losses against which one can choose to be immunized. For this purpose, market participants rely on an interest rate risk measure, whose popularity is inseparable from that of the yield to maturity: duration. This concept, which was developed in 1938 by the American economist Frederick Robertson Macaulay (1882–1970), only became famous in the bond markets from the 1970s onward, a period precisely characterized by a large increase in interest rates and hence a sharp rise in interest rate risk. Macaulay had realized that a bond maturity was an insufficient measure of its effective life because it effectively took only the final cash flow into account. As an alternative to the outright maturity, he suggested that bond interest rate risk be characterized by the average “length” of the bond cash flows—the so-called *Macaulay duration* [3]. These days, a more common measure for interest rate risk is the so-called *modified duration*, which is simply defined as the absolute value of the first derivative of the bond price with respect to its yield, divided by the bond price itself. The Macaulay duration can be computed as the modified duration multiplied by the factor $1 + \frac{R}{\delta}$. A third measure of duration—the *dollar duration*—equals the modified duration times the bond price. Notice that dollar duration measures directly the change in value for a small change in the yield to maturity, whereas modified duration measures percentage change in value.

All duration measures are related to the slope of the bond-yield function at the current yield R , and as such can be interpreted as related to first-order terms of a Taylor expansion of the bond price in its yield. Duration is an appropriate measure of risk for small parallel moves in yield. However, when one wants to quantify the impact of large parallel yield curve moves, it should be accompanied by a second-order measure, called *convexity*, which is the second derivative of the bond price with respect to yield to maturity, divided by the bond price. Formally, we can accomplish this by simply adding another term to the Taylor expansion.

For this, let us denote the bond modified duration by S , its convexity by C , the change in the yield to

maturity by ΔR , and the change in the bond price by ΔP , such that

$$\frac{\Delta P}{P} \sim -S \times \Delta R + 0.5 C \times (\Delta R)^2$$

Duration and convexity, which are based on the flat shape of the term structure of interest rates and on exclusively parallel shifts in interest rates, are faced with two significant hurdles: yield curves are practically never perfectly flat and they are not solely affected by parallel movements.

Interestingly, the Macaulay duration of a bond or bond portfolio is the investment horizon such that investors will not care if interest rates drop or rise as long as changes are small. In other words, capital gain risk is offset by reinvestment risk, as shall be shown now in the following example.

Consider a three-year standard bond with a 5% yield to maturity and a \$100 face value, which delivers a 5% coupon rate. Coupon frequency and compounding frequency are assumed to be annual. The bond price is \$100 and its Macaulay duration is equal to 2.86 years. We assume that the yield to maturity changes instantaneously and stays at this level during the life of the bond. Whatever the change in the yield to maturity, we show in Table 1 that the sum of the bond price and the reinvested coupons after 2.86 years is always the same and equal to 114.972.

The main properties of the three duration measures are as follows:

- The Macaulay duration of a zero-coupon bond equals its time to maturity.
- Holding the maturity and the yield to maturity of a bond constant, the lower a bond coupon rate, the higher its Macaulay or modified or dollar duration.
- Holding the coupon rate and the yield to maturity of a bond constant, its Macaulay or modified

duration increases with time to maturity, as dollar duration decreases.

- Holding other factors constant, the lower a bond yield to maturity, the higher its Macaulay or modified duration and the lower its dollar duration.
- Duration is a linear operator. In other words, the duration of a portfolio P (D_P) invested in n bonds i denominated in the same currency with weights w_i is the weighted average of all bond durations (D_i):

$$D_P = \sum_{i=1}^n w_i D_i \quad (3)$$

This relationship holds for all definitions of duration (Macaulay, modified, dollar).

There are two commonly used measures of second-order interest rate risk. We have already encountered the convexity (C) but market practitioners also use the *dollar convexity*, defined as the bond convexity times the bond price. Dollar convexity is used to quantify the absolute change in a bond price due to convexity for a given change in the yield to maturity.

The main properties of the convexity and dollar convexity measures are as follows:

- For a given bond, the change in value due to the convexity term is always positive.
- Holding the maturity and the yield to maturity of a bond constant, the lower the coupon rate, the higher its convexity and the lower its dollar convexity.
- Holding the coupon rate and the yield to maturity of a bond constant, its convexity and dollar convexity increase with its time to maturity.
- Holding other factors constant, the lower a bond yield to maturity, the higher its convexity and dollar convexity.
- Convexity is a linear operator. In other words, the convexity of a portfolio P invested in n bonds denominated in the same currency with given weights is the weighted average of all bond convexities.

Table 1

Yield to maturity (%)	Bond price	Reinvested coupons	Total
4	104.422	10.550	114.972
4.5	104.352	10.620	114.972
5	104.282	10.690	114.972
5.5	104.212	10.760	114.972
6	104.142	10.830	114.972

End Notes

^aNote that the convexity of a zero-coupon bond is approximately equal to the square of its maturity.

LIBOR Rate

LIBOR stands for London Interbank Offered Rate. It provides a measure of banks' borrowing costs and represents one of the most widely referenced interest rates in the world. LIBOR is owned by the British Bankers' Association (BBA); see [1] for information about BBA and its publications. The *LIBOR rate* is a rate at which contributing banks believe they could raise unsecured funds for a short term. LIBOR panel banks are those with the best credit ratings, and this benchmark describes availability of funds to banks with similar creditworthiness. LIBOR is used as the basis for settlement of interest rate contracts, both those that are traded on the exchanges worldwide (interest rate futures, *see Eurodollar Futures and Options*, and futures options), and the over-the-counter (OTC) transactions. LIBOR supports a swap market estimated at over \$300 trillion and a loan market estimated at over \$10 trillion. All LIBOR rates are the benchmarks set in the London market.

LIBOR is set for 10 different currencies at 11 am London time. The LIBOR rates therefore reflect the relative availability of the corresponding currencies' funds in European markets.

The actual calculation of the LIBOR rates is done by Reuters for the BBA, and the process is overseen by several committees. Sixteen contributor banks are selected for each of the four major currencies: US dollar (USD), sterling (GBP), euro (EUR), and yen (JPY). Between 8 and 12 contributor banks are selected for the other six currencies which are Australian dollar (AUD), Canadian dollar (CAD), Swiss franc (CHF), Danish krone (DKK), New Zealand dollar (NZD), and Swedish krona (SEK).

The process starts with polling the contributor banks. The rate submitted must be formed from the bank's perception of its cost of funds in the interbank market. Hence the quotes are obtained from the money market trading desks (who manage the banks' cash positions), and not from interest rate derivative traders. After the quotes are collected, the 25 percentile of the highest and the 25 percentile of the lowest quotes are discarded. This makes it virtually impossible for a contributor to skew the result. The remaining two quartiles of the quotes are averaged producing the number, which is then published as *LIBOR fixing*.

LIBOR rates are fixed each London business day for a set of short-term maturities up to 12 months. A fixed LIBOR rate refers to a certain interest rate period, starting at the so-called value date and ending at the maturity date (Figure 1). There is an offset between the fixing date and the value date for all currencies except sterling. More details about the rules and conventions governing LIBOR fixing can be obtained from the BBA documentation [1].

Forward Rate Agreements (FRAs)

A forward rate agreement (FRA) is a contract between two parties to fix a future interest rate based on a principal. It is an OTC product and represents an interest rate derivative in which one party (the buyer) pays a fixed interest rate and receives a floating interest rate, which is equal to some underlying rate called the *reference rate*. The most commonly used underlying rate is LIBOR.

FRAs are available for a variety of periods: starting from a few days to terms of several years. However, most of the liquidity in the FRA market is concentrated within 1 year, and those products are regarded as money-market instruments. FRAs are typically agreed on BBA-terms.

FRA's term period is normally specified by a pair of numbers separated by dash, forward slash, or very often by a cross: 0–3, 3/9, 3 × 6, and so on. The first number refers to the starting month and the second number denotes the ending month of the FRA term, counting from the current month. If no day of the month is given, the spot start is assumed; otherwise, the FRA term starts on a given day of the starting month. Figure 2 shows all dates that specify the FRA contract:

Trade date The date on which the contract is traded.

Value date spot Derived in the same way as the value date of the reference rate fixing.

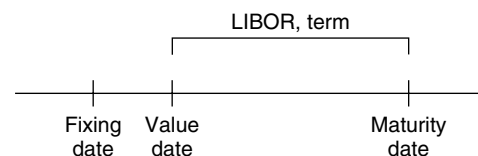

Figure 1 LIBOR rate dates

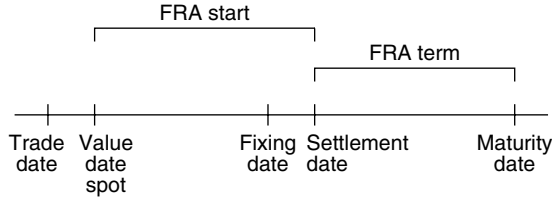

Figure 2 FRA dates

Settlement date The date on which the contract term commences. This is also the date when the amount due is paid by one party to the other.

Fixing date The date on which the reference rate is observed. For a LIBOR FRA, the relationship between the fixing date and the settlement date is the same as that between the fixing date and the value date shown in Figure 1.

Maturity date The end date of the FRA term.

The amount due is determined on the fixing date as a difference between interest rate payments for the buyer and the seller. The payment amount is

$$\frac{(L - R_0) \cdot \tau \cdot (\pm N)}{1 + L \cdot \tau} \quad (1)$$

where L is the reference rate fixing; R_0 is the FRA rate; N is the principal amount ($\pm =$ buy/sell); and τ is the time fraction of the FRA term.

The FRA settlement amount represents the difference in the values of deposits accrued to the maturity date; however, as the payment is exchanged on the settlement date, the appropriate discounting factor is applied, that is, $1 + L \cdot \tau$ in the denominator of (1).

The pricing of an FRA is reduced to forecasting the fixing of the reference rate. The present value of the FRA contract can be written as the expected value—under the pricing measure—of the payoff given by equation (1), assuming that the fixing occurs at T and S is the maturity (per one unit of principal):

$$PV(0) = E \left\{ \frac{P(T, S) \cdot [L(T, T, S) - R_0] \cdot \tau}{B(T)} \right\} \quad (2)$$

where $P(T, S)$ is the value of discount bond at T ; $B(T)$ is the value of a money market account; and $L(t, T, S)$ is the forward reference rate at t .

We observe that since $P(T, S) \cdot L(T, T, S) \cdot \tau \equiv 1 - P(T, S)$, the expression inside the expectation in equation (2) is a linear combination of traded assets of which discounted prices are martingales. Thus the FRA's values today can be expressed in terms of the forward rates:

$$\begin{aligned} PV(0) &= P(0, T) - P(0, S) - R_0 \cdot P(0, S) \cdot \tau \\ &= P(0, S) \cdot [L(0, T, S) - R_0] \cdot \tau \end{aligned} \quad (3)$$

In modeling literature, as in the derivation above, it is common to assume that discounting is done at rates consistent with forward LIBOR rates. In reality, however, discounting should reflect the true cost of financing of the corresponding derivative contract for a given bank. Such financing rate usually differs, and sometimes significantly, from the prevailing LIBOR forward rates. See [2, 3] for further details of derivative pricing using separate forward and discount curves.

SERGEI TRAVEN

Eurodollar Futures and Options

A Eurodollar rate is an interest rate on US dollar deposits that are held in banks outside the United States. The Eurodollar futures contract is a contract whose underlying is the three-month Eurodollar interest rate. When launched in 1981 at the Chicago Mercantile Exchange (CME), the Eurodollar futures were the world's first cash-settled futures contract. Since then, they have become the most actively traded short-term interest rate contract. At the time of writing, an average of more than 1.5 million contracts are traded each day and open interest exceeds 20 million positions (see [2]).

Each futures contract has a notional or “face value” of \$1 000 000. On the expiry date of the contract, the futures price is determined by the London Interbank Offered Rate (LIBOR; see **LIBOR Rate**), which is applied to Eurodollar deposits for a three-month period starting from the third Wednesday of the delivery month. If R is the fixing of the three-month LIBOR at expiration, expressed with quarterly compounding, the futures final settlement price is defined as $100 - R$, and the payoff of one futures contract is $1\,000\,000 \times (1 - 0.25 \times R\%)$. This results in futures price dropping when yield rises.

Eurodollar futures are closely related to the forward rate agreements (FRAs; see **LIBOR Rate**). However, the futures are marked-to-market daily, and for a long Eurodollar futures position, the margin payments are financed at a higher cost when rates rise and invested at a lower rate when rates decline. To compensate for the disadvantage of being long Eurodollar futures against FRA, the futures price must be lower and the futures rate ($= 100 - \text{futures price}$) must be higher than the corresponding forward rates. Empirical study by Burghardt [1] shows that this difference, known as “convexity bias”, may exceed 15 basis points for futures contracts with five years to expire. The exact magnitude of the bias is model dependent, for example, Hull [4] used the approximation $\frac{1}{2}\sigma^2 t_1 t_2$, where σ is the annualized standard deviation of the short-term interest rate, t_1 is the time of maturity of the futures contract, and t_2 is the time of maturity of the deposit. Readers should refer to [5, 6] for the theoretical framework (also see [8] and the reference therein for more results).

Eurodollar futures contracts are listed in a March quarterly expiration cycle. At any given time, there are forty quarterly expiries listed, spanning out 10 years, plus the four nearest serial months (non quarterly months). In addition to the outright individual contracts, the CME also lists a variety of products that enable one to initiate positions more efficiently on a particular segment of the yield curve. Some examples are orders known as *Packs and Bundles*. Packs are the simultaneous purchase or sale of an equally weighted, consecutive series of four Eurodollar futures. Bundles are consecutive series of futures beginning with the front contract. Both packs and bundles are quoted by the average of net price changes from the previous day's close of the constituent contracts.

CME lists American-style call and put options on Eurodollar futures. There are several types of such options. Quarterly Eurodollar options expire in the same month as the underlying futures. Serial options are listed for the two nearest serial months with the next quarterly futures as the underlying contracts. Midcurve options are options with short expiration on longer-dated futures. They expire one, two, or four years before the underlying quarterly futures expire. Option premiums are paid in full at the time of purchase, the so-called “stock-type” settlement.

Eurodollar options can be priced under the Black–Scholes model with dividend yield equal to the risk-free rate (see **Black–Scholes Formula**), and numerical methods are needed to evaluate the early exercise premium (see **American Options**). More complexity arises when considering the underlying futures that are highly correlated with the risk-free rate. We refer interested readers to [3] for a more detailed treatment of this subject.

Eurodollar futures and options are also traded at the Singapore Futures Exchange (SGX) and Euronext. The contracts traded at the CME and SGX are identical. Euronext adopts the “futures-type” settlement for options, where unlike the “stock-type”, premium is not paid up front but marked to market. Oviedo [7] showed that early exercise is not optimal under “futures-type” settlement; therefore, Euronext options can be priced “as if” European-style.

Bond Options

Bond options are contracts giving their buyer the right but not the obligation to buy (call option) or sell (put option) an underlying bond at a prespecified price (the strike price). The strike for options on bond prices is generally quoted in terms of clean price (i.e., not including the accrued interest). Upon exercise, the bond buyer pays the accrued interest to the bond seller. In some cases, the contract for options on bonds may specify a strike yield instead of a strike price. Since price and yields move in opposite directions, a call (put) option on price will correspond to a put (call) option on yield.

Option contracts have a termination date referred to as the *expiration date* and are classified based on the possible dates in which the option holder can exercise the option. European-style options can be exercised only at the contract's expiration date. Bermudan-style options may be exercised on a pre-specified set of dates up to (or including) the expiration date, whereas American-style options can be exercised at any time up to (and including) the expiration date.

Most of the activity for options on cash bonds is over the counter (OTC) and has government bonds as the underlying, with the most common being options on long-term treasury bonds. The exchange-traded market for options on cash bonds is virtually nonexistent. Among the existing contracts, we mention the European options on treasury yields for 13-week treasury bills, 5- and 10-year treasury notes, and 30-year treasury bonds traded on the Chicago Board of Exchange (CBOE). These contracts are cash-settled, that is, there is no delivery of the physical underlying bond at exercise.

Closely related contracts are options on bond futures. These are exchange traded and significantly more liquid than options on cash bonds. In a bond futures contract, the side with the short position can deliver any bond in a predefined basket. For example, in the 30-year US treasury bond futures contract, \$100,000 of any US treasury bond that is not callable for at least 15 years and has a maturity of at least 15 years can be delivered. When a call (put) option on a bond futures is exercised, the buyer receives a cash payoff and is assigned

a long (short) position in the underlying futures contract. The seller is assigned the corresponding opposite position. The most popular options on futures contracts are those on 5- and 10-year US treasury notes and 30-year US treasury bonds traded at the Chicago Board of Trade (CBOT). Exchange-traded options on bond futures are typically American style.

Besides being traded as separate contracts, bond options frequently appear as provisions in the bond contract itself. In this case, because they cannot be traded separately, they are referred to as *embedded options*. The most common types are call provisions, giving the issuer the right but not the obligation to buy back the bond at a predetermined price. Bonds containing a call provision are known as *callable bonds*. Analogously, puttable bonds give the bond holder the right but not obligation to sell the bond back to the issuer at a predetermined strike price. A callable bond buyer is effectively buying the underlying noncallable bond and selling a call option on a bond to the issuer. In the case of a puttable bond, the issuer is selling a put option to the bond holder along with the underlying nonputtable bond. As with regular options, the embedded call and put options can be European, Bermudan, or American style.

Finally, as shown later, there is a close relationship between options on bonds and the most commonly traded OTC options on interest rates, namely, caps, floors, and swaptions. A cap (floor) is equivalent to a portfolio of European put (call) options on zero coupon bonds, whereas a swaption can be seen as an option on a fixed coupon bond.

We restrict our discussion in the following to the pricing of options on default-free bonds. The treatment of options on defaultable bonds is substantially more complex, since it requires consideration of both interest rate and credit components and their interaction. For more information, we refer to [6] and references therein.

European Options

We denote the price of a default-free zero coupon bond at time t maturing at T by $P(t, T)$. Consider European call and put options with strike K and expiration T_e written on a zero-coupon bond with maturity $T_m \geq T_e$. Their payoffs at time T_e are

given as

$$\max\{\omega(P(T_e, T_m) - K), 0\} = [\omega(P(T_e, T_m) - K)]^+ \quad (1)$$

with $\omega = 1$ for a call and $\omega = -1$ for a put.

Default-free bullet bonds pay, with certainty, pre-determined amounts c_i at times $T_i, i = 1 \dots, M$. We assume, for convenience, that the last payment also includes the repayment of principal. Their price can be trivially expressed in terms of prices of zero coupon bonds. More generally, defining for any given time $T, l(T) := \max\{i \in 1, \dots, M : T_i < T\}$, we can express the time $t \leq T$ value of the cash flows to be received after T as

$$B_{cp}(t, T, \{c\}) = \sum_{i=l(T)+1}^M c_i P(t, T_i) \quad (2)$$

Call and put options on this bond expiring at time T and with strike price K are options on a portfolio of zero coupon bonds having payoff

$$\max\{\omega(B_{cp}(T, T, \{c\}) - K), 0\} \quad (3)$$

with $\omega = 1$ for a call and $\omega = -1$ for a put.

Modeling typically proceeds in one of two ways. The first involves directly modeling the stochastic evolution of a finite number of bond prices (or yields) and is in essence an extension of the Black–Scholes–Merton approach [3, 10] to the pricing of option on bonds. The second involves modeling the stochastic evolution of the whole-term structure of interest rates, or equivalently, the simultaneous evolution of zero coupon bonds of all maturities. A rather general framework for term structure modeling was proposed by Heath, Jarrow, and Morton (HJM) [7] (*see also Heath–Jarrow–Morton Approach*), who modeled the instantaneous forward rates as diffusion processes and established the appropriate conditions that need to be satisfied to ensure the absence of arbitrage opportunities. In the term structure modeling approach, the dynamics of bonds and other interest rate instruments follow as a consequence of the stochastic model imposed on the term structure of interest rates.

Black–Scholes Model

Historically, the first approach for valuing bond options made direct use of the Black–Scholes–Merton model (*see also Black–Scholes Formula*). It assumed a geometric Brownian motion process with constant instantaneous volatility for the price process of the underlying bond and a deterministic short-term interest rate. The time 0 price of call and put options on a European bond option with strike price K and expiring at time T_e , under this model, is

$$\begin{aligned} \text{Call}(0, K, T_e, \{c\}) &= e^{-RT_e} \text{Bl}(K, e^{RT_e} B(0, T_e, \{c\}), \sigma_B \sqrt{T_e}, 1) \\ \text{Put}(0, K, T_e, \{c\}) &= e^{-RT_e} \text{Bl}(K, e^{RT_e} B(0, T_e, \{c\}), \sigma_B \sqrt{T_e}, -1) \end{aligned} \quad (4)$$

where

$$\begin{aligned} \text{Bl}(K, F, v, \omega) &:= F \omega \Phi \left(\omega \frac{\ln(F/K) + \frac{1}{2} v^2}{v} \right) \\ &\quad - K \omega \Phi \left(\omega \frac{\ln(F/K) - \frac{1}{2} v^2}{v} \right) \end{aligned} \quad (5)$$

Φ denotes the standard Gaussian cumulative distribution function and R is the continuously compounded spot interest rate for time T_e and σ_B the bond price volatility.

Similar to the convention used in the equity market, option prices are also quoted in terms of their implied volatility, namely, the constant volatility to be imputed in Black's formula so as to reproduce the option price. In some situations, the market quotes implied yield volatilities rather than implied price volatilities. The conversion from a yield volatility to a price volatility is given as

$$\sigma_B = D y \sigma_Y \quad (6)$$

where σ_B is the bond's price volatility, D is its modified duration, and σ_Y is its yield volatility.

There are some obvious drawbacks to the Black–Scholes–Merton approach applied to bond options.

First, contrary to stocks, bond prices tend to their face value at maturity (the so-called “pull to par” effect), implying that their instantaneous volatility must go to zero as they approach maturity. Under a constant volatility assumption, the model is only appropriate in situations where the time to expiration is significantly shorter than the underlying bond’s maturity. Another drawback is that given the lognormal distribution of prices, there is a nonzero probability that the price of the bond will be larger than the sum of the future cash flows, implying negative yields. Finally, the fact that bonds are modeled independently of each other does not guarantee the absence of arbitrage between them.

Black’s 1976 Model

In 1976, Black [2] extended the Black–Scholes–Merton analysis to commodity contracts. An important point was the shift in focus toward forward rather than spot quantities. Under this perspective, one can try and model the underlying bond’s forward price F for delivery at time T_e as a geometric Brownian motion with deterministic volatility $\sigma_F(t)$. Let R be the time 0 continuously compounded spot rate for time T_e . The pricing formulas for European bonds become

$$\begin{aligned} \text{Call}(0, K, T_e, \{c\}) &= e^{-RT_e} \text{Bl}(K, F, \Sigma_F \sqrt{T_e}, 1) \\ \text{Put}(0, K, T_e, \{c\}) &= e^{-RT_e} \text{Bl}(K, F, \Sigma_F \sqrt{T_e}, -1) \end{aligned} \quad (7)$$

with $\Sigma_F^2 := 1/T_e \int_0^T \sigma_F^2(s) ds$ the squared volatility of the bond’s forward price. Note that in equation (4) we take the underlying as the bond’s spot price with its corresponding volatility, whereas in equation (7) the underlying is the bond’s forward price with its corresponding volatility. Since the forward price for time T_e is given by the ratio of the spot price and the zero coupon bond maturing at T_e , these two volatilities are not the same.

A further change in perspective led to the use of Black’s model applied to forward rates rather than to forward prices. In the case of zero coupon bonds, define the simple compounded forward rate:

$$L(t; T_e, T_m) := \frac{1}{\tau} \left[\frac{P(t, T_e)}{P(t, T_m)} - 1 \right], \quad t \leq T_e \quad (8)$$

where τ denotes the year fraction for $(T_e, T_m]$. By using a standard change of measure (*see also Forward and Swap Measures*) it is easy to show that

$$\begin{aligned} P(0, T_e) E^{T_e} \{ [P(T_e, T_m) - K]^+ \} \\ = P(0, T_m) \tau K E^{T_m} \left\{ \left[\frac{1 - K}{\tau K} - L(T_e; T_e, T_m) \right]^+ \right\} \end{aligned} \quad (9)$$

where E^T denotes expectation with respect to a measure having as numeraire the zero coupon bond maturing at T . Therefore, a call option on a zero coupon bond can be regarded as a put option on the forward rate $L(T_e; T_e, T_m)$. We can now use Black’s model on the forward rate L assuming that it follows geometric Brownian motion with volatility $\sigma_L(t)$. The time 0 price of a call option with strike K and time to expiration T_e on a zero coupon bond maturing at T_m can then be written as

$$\begin{aligned} \text{Call}_{zc}(K, T_e, T_m) \\ = \tau K P(0, T_m) \\ \times \text{Bl}(K', L(0, T_e, T_m), \Sigma_L \sqrt{T_e}, -1) \end{aligned} \quad (10)$$

with $K' = \frac{1-K}{\tau K}$ and $\Sigma_L^2 := 1/T_e \int_0^{T_e} \sigma_L^2(s) ds$.

A similar argument can be used to obtain the price of put options on zero coupon bonds in terms of the prices of call options on the forward rate $L(T_e; T_e, T_m)$. In the OTC market for London Interbank Offered Rate (LIBOR) rate based interest rate derivatives, it became market standard to express options in terms of forward rates and to use Black’s formula for valuation (*see also Risk-neutral Pricing*). There is also an analogous relationship between options on coupon bonds and swaptions, which are options on forward swap rates.

Alternative models having the bond price as the only state variable have been proposed to account for some of the shortcomings of the Black–Scholes model. Ball and Torous [1] modeled the rate of return on a discount bond by a Brownian bridge process, which guarantees that the bond price converges to its face value at maturity. Schaefer and Schwartz [13] proposed a model where the price volatility of a coupon bearing bond is proportional to the duration and, therefore, decreases as the bond approaches

maturity. Further attempts in this direction are reviewed by Rady and Sandmann [12].

Term Structure Models

As we have mentioned, the HJM approach is a rather general framework for modeling the full-term structure, guaranteeing no arbitrage. To make progress and obtain explicit results for the price of options on bonds, one needs to choose concrete realizations. Among the most popular are the so-called *short-rate models*, which, as their names indicate, focus on the modeling of the instantaneous short rate $r(t)$ (see also **Term Structure Models**) defined as

$$r(t) = \frac{-d \log P(t, T)}{dT} \Big|_{T=t} \quad (11)$$

These models have a long history, dating back to Merton [10] and Vasicek [14]. In general, the short-rate process is assumed to follow a continuous Markov process, in which case prices of zero coupon bonds become a function of the short rate $r(t)$. The payoff for a European call option expiring at T on a coupon bond can then be written as

$$\left(\sum_{i=1}^n c_i P(r(T), T, T_i) - K \right)^+ \quad (12)$$

If the zero coupon bond price is a continuous decreasing function of $r(t)$, the option will be exercised if and only if $r(T) < r^*$, where r^* is the solution of

$$\sum_{i=1}^n c_i P(r^*, T, T_i) = K \quad (13)$$

In this case, one can decompose the value of the option into a sum of options on zero coupon bonds by rewriting the payoff as

$$\sum_{i=1}^n c_i (P(r(T), T, T_i) - P(r^*, T, T_i))^+ \quad (14)$$

The aforementioned decomposition was discovered by Jamshidian [8] and is sometimes called the *Jamshidian formula*. Several popular term structure models allow for an exact solution for the price of zero coupon bonds in terms of the model

parameters. Among them are the Vasicek/Hull–White [14] (see also **Cox–Ingersoll–Ross (CIR) Model**) and the Cox–Ingersoll–Ross (CIR) [5] (see **Gaussian Interest-Rate Models**) models. In their one-factor version, these two models satisfy the requirement that discount bonds are monotonically decreasing in the short rate, allowing us to obtain the prices of options on coupon bonds in terms of the prices of options on zero coupon bonds.

Bermudan and American Bond Options

The pricing of Bermudan and American options is significantly more complex than their European counterpart. There are typically no closed-form solutions and one needs to resort to numerical methods for computing their value. A common approach is to calibrate a term structure model to European options and subsequently use the calibrated model to price American and Bermudan securities. The latter step would typically involve a numerical scheme such as Monte Carlo simulation or a finite difference method. Among the most popular models used are the one- and two-factor short-rate models (see also **Term Structure Models**) as well as the LIBOR market model (see **LIBOR Market Model**) family [4, 9, 11]).

Caps and Floors

Definitions and Notation

Let us consider a set of times $0 =: T_0, T_1, \dots, T_M$ and denote by $P(t, T)$ the discount factor at time t for the generic maturity T .

A *cap* is a contract that pays at each time $T_i, i = a, \dots, b, a \geq 1$, the difference, if positive, between the LIBOR rate set at the previous time T_{i-1} and a given rate K specified by the contract, which is shortly referred to as a *strike*. In formulas, assuming unit notional, the time- T_i payoff is

$$\tau_i \max\{L(T_{i-1}, T_i) - K, 0\} = \tau_i [L(T_{i-1}, T_i) - K]^+ \quad (1)$$

where τ_i denotes the year fraction for the interval $(T_{i-1}, T_i]$ and the LIBOR rate $L(T_{i-1}, T_i)$ is the simply compounded rate at time T_{i-1} for maturity T_i , namely,

$$L(T_{i-1}, T_i) := \frac{1}{\tau_i} \left[\frac{1}{P(T_{i-1}, T_i)} - 1 \right] \quad (2)$$

(see also **LIBOR Rate**).

Each single option in a cap is called a *caplet*. A cap is then a strip of caplets.

Analogously, a *floor* is a contract that pays at each time $T_i, i = a, \dots, b, a \geq 1$, the difference, if positive, between a strike K and the LIBOR rate set at time T_{i-1} :

$$\tau_i \max\{K - L(T_{i-1}, T_i), 0\} = \tau_i [K - L(T_{i-1}, T_i)]^+ \quad (3)$$

Each single option in a floor is called a *floorlet*. A floor is then a strip of floorlets.

A cap (floor) is said to be at-the-money (ATM) if its price is equal to that of the corresponding floor (cap). It is said to be in-the-money (ITM) or out-of-the-money (OTM) if its price is, respectively, higher or lower than that of the corresponding floor (cap).

As a consequence of the put-call parity, which, on each T_i , reads as

$$\tau_i \max\{L(T_{i-1}, T_i) - K, 0\}$$

$$\begin{aligned} & - \tau_i \max\{K - L(T_{i-1}, T_i), 0\} \\ & = \tau_i [L(T_{i-1}, T_i) - K] \end{aligned} \quad (4)$$

(see also **Put-Call Parity**), the difference between a cap and a floor with the same payment times $T_i, i = a, \dots, b, a \geq 1$, and strike K is an interest rate swap (IRS) where, at each time T_i , the floating rate $L(T_{i-1}, T_i)$ is exchanged for the fixed rate K . Therefore, a cap (floor) is ATM if and only if the related IRS has zero value, that is, if and only if its strike equals the underlying (forward) swap rate:

$$K = K_{\text{ATM}} := \frac{P(0, T_{a-1}) - P(0, T_b)}{\sum_{i=a}^b \tau_i P(0, T_i)} \quad (5)$$

Moreover, the cap is ITM if $K < K_{\text{ATM}}$ and OTM if $K > K_{\text{ATM}}$. The converse holds for a floor.

Pricing Formulas

It is market practice to price caps and floors with sums of corresponding Black's formulas (see **Black-Scholes Formula**). Precisely, if the cap (floor) pays on dates $T_i, i = a, \dots, b, a \geq 1$, and has a strike K , its market formula is given by

$$\begin{aligned} \text{Cap}(K, T_a, T_b; \sigma_b) &= \sum_{i=a}^b P(0, T_i) \tau_i \\ &\quad \times \text{Bl}(K, L(0, T_{i-1}, T_i), \sigma_b \sqrt{T_{i-1}}, 1) \\ \text{Floor}(K, T_a, T_b; \sigma_b) &= \sum_{i=a}^b P(0, T_i) \tau_i \\ &\quad \times \text{Bl}(K, L(0, T_{i-1}, T_i), \sigma_b \sqrt{T_{i-1}}, -1) \end{aligned} \quad (6)$$

where

$$\begin{aligned} \text{Bl}(K, L, v, \omega) &:= L \omega \Phi \left(\omega \frac{\ln(L/K) + \frac{1}{2} v^2}{v} \right) \\ &\quad - K \omega \Phi \left(\omega \frac{\ln(L/K) - \frac{1}{2} v^2}{v} \right) \end{aligned}$$

Φ denotes the standard Gaussian cumulative distribution function, and $L(0, T_{i-1}, T_i)$ is the simply

compounded forward LIBOR rate at time 0 for the interval $[T_{i-1}, T_i]$:

$$L(t; T_{i-1}, T_i) := \frac{1}{\tau_i} \left[\frac{P(t, T_{i-1})}{P(t, T_i)} - 1 \right], \quad t \leq T_{i-1} \quad (7)$$

The parameter σ_b is called the *cap- (floor-) implied volatility*. It is a single volatility parameter that must be inputted in each Black's formula in equation (6) to reproduce the market price.

A cap and a floor with the same maturity and strike must be priced with the same implied volatility, as a consequence of the put-call parity (4).

Justification for the Market Formulas

Practitioners used the market formulas (6) for years without a formal proof that they were indeed arbitrage free. Such a proof was first given by Jamshidian [3], followed by Miltersen *et al.* [4] and Brace *et al.* [1] with their celebrated lognormal LIBOR market models (*see also LIBOR Market Model*).

Let us consider a T_i -maturity caplet with strike K . The floorlet case is analogous. By classic risk-neutral valuation (*see also Risk-neutral Pricing*), the no-arbitrage price of the caplet payoff (1) at time 0 is

$$\begin{aligned} & E \left\{ e^{-\int_0^{T_i} r(t) dt} \tau_i [L(T_{i-1}, T_i) - K]^+ \right\} \\ &= E \left\{ e^{-\int_0^{T_i} r(t) dt} \tau_i [L(T_{i-1}; T_{i-1}, T_i) - K]^+ \right\} \end{aligned} \quad (8)$$

where E denotes the risk-neutral expectation and $r(t)$ the instantaneous short rate at time t . Switching to the T_i -forward measure Q^{T_i} , whose associated numeraire is the zero-coupon bond $P(t, T_i)$ (*see also Forward and Swap Measures*), the caplet price becomes

$$\begin{aligned} & E \left\{ e^{-\int_0^{T_i} r(t) dt} \tau_i [L(T_{i-1}; T_{i-1}, T_i) - K]^+ \right\} \\ &= P(0, T_i) \tau_i E^{T_i} \left\{ [L(T_{i-1}; T_{i-1}, T_i) - K]^+ \right\} \end{aligned} \quad (9)$$

where E^{T_i} denotes expectation under Q^{T_i} . The Black formula for the caplet in question can then be

obtained by assuming that under such a measure:

$$dL(t; T_{i-1}, T_i) = \varsigma_i L(t; T_{i-1}, T_i) dW_i(t) \quad (10)$$

where ς_i is the (constant and deterministic) caplet volatility and W_i is a standard Brownian motion under Q^{T_i} . Assuming a driftless dynamics for the forward rate $L(t; T_{i-1}, T_i)$ under Q^{T_i} is the only admissible choice since, by its own definition (7), the forward rate is a martingale under the T_i -forward measure (tradable asset divided by the numeraire).

A more detailed descriptions of these arguments can be found in **LIBOR Market Model**.

Market Quotes and Smiles

Given the pricing formulas (6), it is also a market practice to quote caps and floors through their implied volatility σ_b . Such a volatility is typically a function of the strike price, too: $\sigma_b = \sigma_b(K)$, meaning that caps (floors) with the same maturities but different strikes can be priced with different implied volatilities. This is called *smile effect*, due to the typical shape of the market implied volatility curves and surfaces.

The market quotes cap-/floor-implied volatilities for a number of maturities (up to 30 years for the main currencies). An example of cap implied volatility surface from the USD market is shown in Figure 1, where payment times are three-month spaced.

Let us denote by T_{j_k} , $k = 1, \dots, N$, the N cap maturities in a given market, and assume that $j_N = M$. From the corresponding cap quotes, one can strip the implied caplet volatilities ς_i , for a given strike K , by recursively solving, for $k = 1, \dots, N$,

$$\text{Cap}(K, T_a, T_{j_k}; \sigma_{j_k})$$

$$\begin{aligned} &= \sum_{i=a}^{j_k} P(0, T_i) \tau_i \text{Cpl}(K, T_{i-1}, T_i; \varsigma_i) \\ &= \sum_{i=a}^{j_k} P(0, T_i) \tau_i \text{Bl}(K, L(0, T_{i-1}, T_i), \varsigma_i \sqrt{T_{i-1}}, 1) \end{aligned} \quad (11)$$

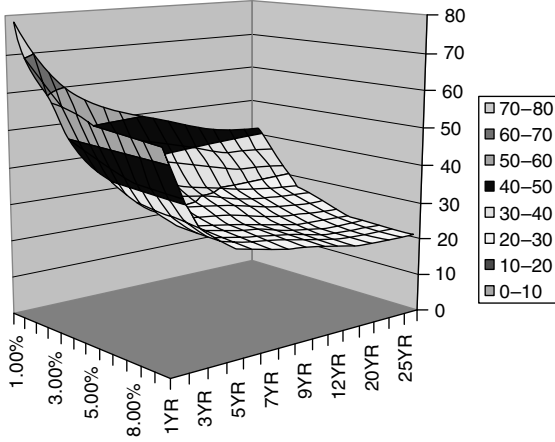

Figure 1 USD cap volatilities as of February 13, 2009. Strikes are in percentage points

Unfortunately, the number N of traded (cap) maturities is typically (much) smaller than the number of underlying (caplet) payments times. Therefore, stripping the caplet volatilities is neither trivial nor uniquely defined. A common approach is based on assuming, for each given strike, specific interpolations along the maturity dimension. The simplest choice is to assume that the ς_i are constant on the intervals defined by the cap maturities, namely, $\varsigma_i = \varsigma_h$ when $T_{j_{k-1}} < T_i, T_h \leq T_{j_k}$. This allows the recursive stripping of caplet volatilities from equation (11) by solving sequences of equations, each with a unique unknown.

The caplet-implied volatilities stripped from the caps of Figure 1 by assuming piece-wise constant interpolation along the maturity dimension are shown in Figure 2 for a limited range of maturities.

Beyond Black's Formula

The lognormal dynamics (10) imply that caplets with the same maturity T_i but different strikes are priced with the same implied volatility ς_i . However, as just seen, the implied volatilities quoted by the market change depending on the strike (smile effect). A popular alternative to equation (10), allowing for implied volatility smiles, is the stochastic alpha beta rho (SABR) model of Hagan *et al.* [2], where each forward LIBOR rate $L(t; T_{i-1}, T_i)$ is assumed to

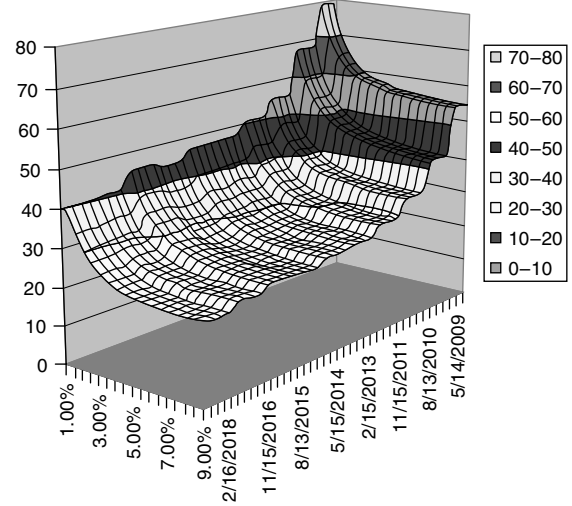

Figure 2 USD caplet volatilities as of February 13, 2009. Strikes are in percentage points

evolve under the corresponding forward measure Q^{T_i} according to

$$\begin{aligned} dL(t; T_{i-1}, T_i) &= V_i(t) L(t; T_{i-1}, T_i)^{\beta_i} dZ_i(t) \\ dV_i(t) &= \epsilon_i V_i(t) dW_i(t) \\ V_i(0) &= \alpha_i \end{aligned} \quad (12)$$

where Z_i and W_i are Q^{T_i} -standard Brownian motions with $dZ_i(t) dW_i(t) = \rho_i dt$ and where $\beta_i \in (0, 1]$, ϵ_i and α_i are positive constants, and $\rho_i \in [-1, 1]$.

Cap prices in the SABR model are given by the following closed form approximation:

$$\begin{aligned} \text{Cap}^{\text{SABR}}(K, T_a, T_b) &= \sum_{i=a}^b P(0, T_i) \tau_i \text{Bl}(K, L(0, T_{i-1}, T_i), \\ &\quad \sigma_i^{\text{SABR}}(K, L(0; T_{i-1}, T_i)) \sqrt{T_{i-1}}, 1) \end{aligned} \quad (13)$$

where

$$\sigma_i^{\text{SABR}}(K, L) = \frac{\alpha_i}{(LK)^{\frac{1-\beta_i}{2}} \left[1 + \frac{(1-\beta_i)^2}{24} \ln^2\left(\frac{L}{K}\right) + \frac{(1-\beta_i)^4}{1920} \ln^4\left(\frac{L}{K}\right) + \dots \right]^{\frac{z}{x(z)}}} \times \left\{ 1 + \left[\frac{(1-\beta_i)^2 \alpha_i^2}{24(LK)^{1-\beta_i}} + \frac{\rho_i \beta_i \epsilon_i \alpha_i}{4(LK)^{\frac{1-\beta_i}{2}}} + \epsilon_i^2 \frac{2-3\rho_i^2}{24} \right] T_{i-1} + \dots \right\} \quad (14)$$

with $z := \frac{\epsilon_i}{\alpha_i} (LK)^{\frac{1-\beta_i}{2}} \ln\left(\frac{L}{K}\right)$ and $x(z) := \ln \left\{ \frac{\sqrt{1-2\rho_i z + z^2} + z - \rho_i}{1-\rho_i} \right\}$. An analogous formula holds for floors.

The success of the SABR model is mainly due to the existence of an analytical formula for the implied volatilities σ_i^{SABR} , which is flexible enough to recover typical market smiles. In fact, it is a widespread practice to construct cap smiles by using the SABR functional form σ_i^{SABR} , assuming specific patterns for the parameters α_i , β_i , ϵ_i , and ρ_i between a caplet maturity and the next (e.g., piece-wise linear interpolation).

FABIO MERCURIO

Constant Maturity Swap

In-arrears swaps, averaging swaps, and constant maturity swaps (CMS) are simple extensions of vanilla interest rate swaps. Unlike vanilla swaps, these securities are sensitive to volatility *via* so-called convexity adjustments (*see* **Convexity Adjustments**). We demonstrate two methods for calculating convexity adjustments: the standard Black–Scholes framework and the replication method.

Market uncertainty is described *via* a filtered probability space $(\Omega, \mathcal{F}, \mathcal{F}_t, Q)$ where $\mathcal{F}_t$ is a filtration associated with a Q -Brownian motion W_t . Q is the so-called risk-neutral probability measure, under which money-market-discounted asset prices are martingales. $\mathbb{E}_t[X] = \mathbb{E}[X|\mathcal{F}_t]$ is the conditional expectation under Q of the integrable random variable X .

Notations

We use the following notations within the article:

- r_t is the short rate at time t .
- $\beta_{t,T} = \exp(\int_t^T r_s ds)$ is the continuously rolled money-market account between t and T . Note that $\beta_{t,T} = \frac{\beta_{0,T}}{\beta_{0,t}}$ and that $\beta_{t,T}$ is $\mathcal{F}_T$ -measurable.
- $P(t, T)$ is the value at t of 1\$ paid at T . We have

$$P(t, T) = \mathbb{E}_t \left[\frac{\beta_{0,T}}{\beta_{0,t}} \right] = \mathbb{E}_t \left[e^{-\int_t^T r_s ds} \right] \quad (1)$$

- $G(w, f, N) = \sum_{i=1}^{f \cdot N} \frac{\delta(f)}{(1 + \delta(f)w)^i}$ is the cash level of the swap, or an approximation to the *present value of a basis-point*, or PV01, of a swap with different payment frequencies $f \in \{1, 2, 4\}$ and different maturities $N \in \mathbb{N}$. Note that $\delta(f) \approx \frac{1}{f}$ is the day-count fraction associated with a given day-count basis such as “Act360”, “30–360”, and so on. Going forward, we assume the frequency to be annual (i.e., $f = 1$), and T to be fixed and equal to N ; then we simply write $G(w, 1, N) = G(w)$.
- $L(t, T_1, T_2)$ is the value at t of the forward LIBOR rate, paid at T_2 , and determined at the settlement date T_1 , as described in **LIBOR Rate**.
- $L^f(t, T_1, T_2)$ is the futures rate with settlement date T_1 . Because of margin calls, the value

$L^f(t, T_1, T_2)$ differs from $L(t, T_1, T_2)$, as detailed in **Eurodollar Futures and Options**.

- Q^T denotes the T -forward probability measure (*see* **Forward and Swap Measures**). It is the risk-neutral probability measure associated with the numeraire $P(t, T)$ (*see* **LIBOR Rate**). For any $\mathcal{F}_T$ -measurable random variable X , the change of measures is given by

$$\mathbb{E}_t \left[\frac{\beta_{0,t}}{\beta_{0,T}} X \right] = P(t, T) \mathbb{E}_t^T[X] \quad (2)$$

where $\mathbb{E}_t^T(\cdot)$ is the conditional expectation under Q^T .

- The Q -Brownian motion, W_t , changes into W_t^T under Q^T *via* the Girsanov theorem.
- $P^f(t, T, T') = \frac{P(t, T')}{P(t, T)}$ is the forward zero-coupon, that is, the t -value of 1\$ paid at T' but borrowed at time $T < T'$. Note that $P^f(t, T, T')$ is a Q^T -martingale as $P(t, T)$ is a traded asset. More details on forward measures can be found in **Forward and Swap Measures** or in [5].
- $w_{t,T}$ is the forward swap rate of an N -year LIBOR swap paying annual coupons at dates $T_1, \dots, T_N$ (*see* **LIBOR Rate for the definition of a LIBOR swap**). We define T_0 to be the fixing date T . We have

$$w_{t,T} = \frac{P(t, T) - P(t, T_N)}{\sum_{i=1}^N \theta_i P(t, T_i)} = \frac{1 - P^f(t, T, T_N)}{\sum_{i=1}^N \theta_i P^f(t, T, T_i)} \quad (3)$$

The quantity θ_i is the day-count fraction for period $[T_{i-1}, T_i]$, $i = 1, \dots, N$.

- $A(t) = \sum_{i=1}^N \theta_i P(t, T_i)$ is the spot annuity paying θ_i at times $T_1, \dots, T_N$.
- $A^f(t, T) = \sum_{i=1}^N \theta_i \frac{P(t, T_i)}{P(t, T)}$ is the forward annuity paying θ_i at time $T_1, \dots, T_N$ forward in time, as of T . Note that $A^f(T, T) = A(T)$.
- The probability measure Q^{A_T} (*see* **Forward and Swap Measures**) associated with the numeraire $A(\cdot)$ is defined *via* the following measure change. For any $\mathcal{F}_T$ -measurable random variable X ,

$$\mathbb{E}_t \left[\frac{\beta_{0,t}}{\beta_{0,T}} A(T) X \right] = A(t) \mathbb{E}_t^{A_T}[X] \quad (4)$$

Q^{A_T} is usually called the *annuity*, or *swap*, measure. Note that for $N = 1$, $Q^{A_{T_1}}$ coincides with Q^{T_1} .

- The Q -Brownian motion, W_t , changes into $W_t^{A_T}$ under Q^{A_T} via the Girsanov theorem.
- A swaption is an option to enter into a swap at a future date T . We define K as the fixed rate in the swap. The price at $t < T$ of a cash-settled swaption is given by $CSS_{t,T}(K, \zeta) = \mathbb{E}_t \left[\beta_{t,T}^{-1} G(w_{T,T}) (\zeta \cdot w_{T,T} - \zeta \cdot K)_+ \right]$ with $\zeta = 1$ for a payer swaption and $\zeta = -1$ for a receiver swaption.
- In this section, we define the payout of a CMS caplet referencing the swap rate $w_{\cdot,T}$ with strike K as $(w_{T,T} - K)_+$, and paying at the fixing date T . So its price is $CMS_{caplet,t,T}(K) = \mathbb{E}_t[\beta_{t,T}^{-1}(w_{T,T} - K)_+]$. We define the CMS floorlet as $CMS_{floorlet,t,T}(K) = \mathbb{E}_t[\beta_{t,T}^{-1}(K - w_{T,T})_+]$. For a definition of standard caps and floors, see **Caps and Floors**: a standard (LIBOR) caplet with maturity T_{i+1} is given by $Caplet_{t,T_{i+1}}(K) = \mathbb{E}_t[\beta_{t,T_{i+1}}^{-1}(L(T_i, T_i, T_{i+1}) - K)_+]$.
- In CMS and LIBOR swaps, we distinguish two different types of payments: the nonstandard case (in-arrears), where the floating cash flow fixes on the same date as it pays, that is, T , and the standard case, (in advance), where the fixing takes place, say, 3 or 6 months before the payment.

Constant Maturity Swaps

Constant maturity swaps, constant maturity treasuries (CMT), and modified schedule LIBOR swaps are extensions of the standard fixed-for-floating swaps. Unlike the standard vanilla interest rate swaps (see **LIBOR Rate**) that specify an exchange of a fixed coupon for a LIBOR rate, CMS instruments pay the swap rate that is reset at each period *versus* either a fixed coupon or a LIBOR rate plus a spread. For CMT swaps, the structure is identical, but instead of the swap rate, the yield of a government bond is referenced. These swaps are often suggested as a way to benefit from a steepening or a flattening of the yield curve, while still being hedged against its parallel moves. To illustrate, let us consider the following CMS instrument: one pays 3-month LIBOR rate and receives the 10-year swap rate, denoted by $CMS_{10Y}(t)$, that is reset (observed) every 6 months. If, during the life of the swap (for instance 10 years)

the curve steepens, so that $CMS_{10Y}(t)$ increases as time t goes by relative to the LIBOR rate, the holder realizes a positive carry, that is, the amount of received cash flows exceeds the amount of paid cash flows. Given that LIBOR and CMS rates are reset at each period, a sudden parallel shift of the curve has no effect on the present value of the swap because of the mutual offset of both legs. As instruments that express views on the nonparallel moves of the yield curve, both CMS and CMT instruments are very popular and generally very liquid, and also often serve as building blocks for more complicated derivatives such as options on CMS rates or CMS spreads (differences between CMS rates of different tenors). Given their widespread use, accurate pricing of the underlying CMS cash flows is important. We describe the nonstandard CMS first, as the standard CMS is the nonstandard CMS adjusted for a payment lag.

There are two main methods for valuing CMS instruments: a standard Black–Scholes approach and a replication method. The first, a more traditional approach, assumes the swap rate to be log-normal, allowing the standard Black–Scholes framework to be used (see **Black–Scholes Formula for this model**). The key benefit of this approach is that it leads to a closed-form formula for the value of a CMS cash flow, also allowing options on CMS rates and other derivatives to be priced with the Black–Scholes formula.

We will show that the value of the CMS rate cash flow differs from the forward swap rate as it depends on volatility. This difference, called *convexity adjustment*, is often explained by the fact that in a CMS cash flow, the rate is paid once, rather than on its “natural” schedule. More details about convexity can be found in [4], [6], and [9].

Before describing these pricing methods in some detail, we introduce some notations. We know that in a CMS cash flow, the swap rate is paid once, at T , so the CMS value at $t < T$ is simply given by

$$\begin{aligned} P(t, T) \cdot CMS_t &= \mathbb{E}_t[\beta_{t,T}^{-1} w_{T,T}] \\ &= P(t, T) \mathbb{E}_t^T[w_{T,T}] \end{aligned} \quad (5)$$

so that

$$CMS_t = \mathbb{E}_t^T[w_{T,T}] \quad (6)$$

Note that $w_{\cdot,T}$ is not a Q^T -martingale, so $\mathbb{E}_t^T[w_{T,T}] \neq w_{t,T}$. The difference between CMS_t and

the forward swap rate $w_{t,T}$ is the convexity adjustment. Let us write the formula under the annuity measure Q^{A_T} , the probability measure under which $w_{\cdot,T}$ is a martingale. Using equation (4), we get

$$CMS_t = \frac{A(t)}{P(t,T)} \mathbb{E}_t^{A_T} \left[\frac{w_{T,T}}{A(T)} \right] \quad (7)$$

We see that CMS_t is a function of both the curve level via $\frac{A(t)}{P(t,T)}$ and the covariance between $A(T)$ and $w_{T,T}$. This strongly hints that the convexity adjustment is a function of the volatility of the forward swap rate $w_{T,T}$.

CMS Convexity Adjustment: the Simple Approach

The aim of this approach is to find a simple, closed-form approximation, assuming that the forward swap rate is log-normal: it is consequently often referred as the *Black* convexity adjustment. As $w_{\cdot,T}$ is a Q^{A_T} -martingale, we have $\frac{dw_{u,T}}{w_{u,T}} = \sigma dW_u^{A_T}$ at any time u between t and T . We assume that the variance of the swap rate under its swap measure is equal to its variance under the T -forward measure, that is, $\mathbb{E}_t^T [w_{T,T} - w_{t,T}]^2 = \sigma^2 (T-t) w_{t,T}^2$ (more precisely, we assume the convexity adjustment to be an adjustment of second order). We further assume that at any time u between t and T , $A^f(u, T) \approx G(w_{u,T})$, so that we approximate $w_{u,T}$ with the par yield of the forward starting bond—a common assumption used by market participants to, for example, compute the swap PV01. Since $A^f(\cdot, T)$ is a Q^T -martingale, so it is approximately $G(w_{\cdot,T})$. Performing a Taylor expansion to second order of $G(w_{T,T})$ around $w_{t,T}$, we obtain

$$\begin{aligned} G(w_{T,T}) &= G(w_{t,T}) + (w_{T,T} - w_{t,T}) G'(w_{t,T}) \\ &\quad + \frac{1}{2} (w_{T,T} - w_{t,T})^2 G''(w_{t,T}) \\ &\quad + o(w_{T,T} - w_{t,T})^2 \end{aligned} \quad (8)$$

Given also that $\mathbb{E}_t^T [G(w_{T,T})] = G(w_{t,T})$, we apply the expected value operator $\mathbb{E}_t^T$ to both sides of (8) to give us

$$CMS_t = w_{t,T} \left(1 - \frac{1}{2} w_{t,T} \cdot \sigma^2 \cdot (T-t) \cdot \frac{G''(w_{t,T})}{G'(w_{t,T})} \right)$$

$$\simeq w_{t,T} \exp \left(-\frac{1}{2} w_{t,T} \cdot \sigma^2 \cdot (T-t) \cdot \frac{G''(w_{t,T})}{G'(w_{t,T})} \right) \quad (9)$$

From the above formula, we see that the convexity adjustment $\exp \left(-\frac{1}{2} w_{t,T} \cdot \sigma^2 \cdot (T-t) \cdot \frac{G''(w_{t,T})}{G'(w_{t,T})} \right) - 1$ is positive given that G is decreasing, convex ($G' < 0$ and $G'' > 0$), and increases with the implied volatility σ .

CMS Convexity Adjustment: the Replication Approach

The simple approach does not capture the fact that the implied volatilities exhibit volatility smile. The replication method we develop in this section captures the smile effect, as noted by Amblard *et al.* [1].

The simple adjustment has a further drawback that it does not provide a way to construct a hedge for a CMS cash flow. Indeed, to hedge the CMS using the Black–Scholes adjustment, one can compute the delta and vega, but this is not a static hedge. The replication approach rectifies this issue as well.

The replication approach has the disadvantage of being nonparametric, but on the other hand, it takes into account the volatility smile and exhibits an explicit static hedge for the CMS rate cash flows and options in terms of payer and receiver swaptions. The computation is done in two steps. First we compute a CMS caplet and a CMS floorlet at a given strike k (see Notations for a definition of CMS caplets and floorlets; *see also Caps and Floors for a definition of caps and floors*). The CMS rate is then obtained *via* the call–put parity.

We use a numerical integration, commonly used to replicate European options with complex payoffs using vanilla European options (see [3]). Indeed, for any real C_2 -function V of the swap rate w and any real number x , we have

$$\begin{aligned} V(w) &= V(x) + (w - x) \cdot V'(x) \\ &\quad + 1_{\{w > x\}} \int_x^w V''(K) (w - K)_+ dK \\ &\quad + 1_{\{w < x\}} \int_w^x V''(K) (K - w)_+ dK \end{aligned} \quad (10)$$

Observing that the boundaries for the integrals can be extended to $+\infty$ and $-\infty$, respectively, we have

$$\begin{aligned} V(w) &= V(x) + (w - x) \cdot V'(x) \\ &\quad + 1_{\{w > x\}} \int_x^{+\infty} V''(K)(w - K)_+ dK \\ &\quad + 1_{\{w < x\}} \int_{-\infty}^x V''(K)(K - w)_+ dK \end{aligned} \quad (11)$$

so by setting $x = 0$

$$\begin{aligned} V(w) &= V(0) + wV'(0) \\ &\quad + 1_{\{w > 0\}} \int_0^{+\infty} V''(K)(w - K)_+ dK \\ &\quad + 1_{\{w < 0\}} \int_{-\infty}^0 V''(K)(K - w)_+ dK \end{aligned} \quad (12)$$

Let $k > 0$ be the strike of CMS caplet or CMS floorlet.

To compute the CMS caplet, let us define $V(w) = \frac{(w - k)_+}{G(w)}$. Then as $V(0) = V'(0) = 0$:

$$\begin{aligned} (w - k)_+ &= 1_{\{w > 0\}} \int_0^{+\infty} V''(K)G(w)(w - K)_+ dK \\ &\quad + 1_{\{w < 0\}} \int_{-\infty}^0 V''(K)G(w)(K - w)_+ dK \end{aligned} \quad (13)$$

Equation (13) expresses the general decomposition of a call payoff $(w - k)_+$ on a continuous set of payoffs $(G(w)(w - K)_+)_{K \geq 0}$ and $(G(w)(K - w)_+)_{K \leq 0}$.

By replacing w with $w_{T,T}$, multiplying both sides by $\beta_{t,T}^{-1}$, taking the $\mathcal{F}_t$ -conditional expectation under the risk-neutral measure, and using the definition of a CMS caplet in the section Notations, we obtain

$$\begin{aligned} CMScaplet_{t,T}(k) &= \int_0^{+\infty} V''(K) \mathbb{E}_t[\beta_{t,T}^{-1} G(w_{T,T})(w_{T,T} - K)_+] dK \\ &\quad + \int_{-\infty}^0 V''(K) \mathbb{E}_t[\beta_{t,T}^{-1} G(w_{T,T})(K - w_{T,T})_+] dK \end{aligned} \quad (14)$$

On the right-hand side, we recognize the prices of cash-settled swaptions as described in the section Notations. Note that $G(w_{T,T})$ is an approximation for $A(T)$ in the cash-settled swaption formula. So we have

$$\begin{aligned} CMScaplet_{t,T}(k) &= \int_0^{+\infty} V''(K) CSS_{t,T}(K, \zeta = 1) dK \\ &\quad + \int_{-\infty}^0 V''(K) CSS_{t,T}(K, \zeta = -1) dK \end{aligned} \quad (15)$$

If we assume $k > 0$, the second integral vanishes as $V''(K) = 0$ if $K < k$. To be tractable, this decomposition must be discretized and the integrals ultimately truncated:

$$CMScaplet_{t,T}(K) \approx \sum_{i=0}^{N_{\text{cap}}} \alpha_i^{\text{cap}} CSS_{t,T}(K_i, x = 1) \quad (16)$$

We start from $K_0 = k + \varepsilon$, with ε very small to avoid the discontinuity at $K = k$, and set $K_i = K_0 + i \Delta K$. The strike step ΔK is also arbitrary. We have $\alpha_i^{\text{cap}} = 2h'(K_i) + (K_i - k)h''(K_i)$ with $h(x) = \frac{1}{G(x)}$. In practice, the choice of N_{cap} or, equivalently, the last payer swaption strike used for replication can be computed dynamically: we add in that case an extra strike until we reach $\alpha_i^{\text{cap}} CSS_{t,T}(K_i, x = 1) < \text{ChosenPrecision}$. Depending on the assumption chosen for the smile extrapolation far out of the money, this can lead to some divergence of the replication algorithm. In that case, we can use an arbitrary cap, for example $K_{\text{max}}^{\text{cap}} = 50\%$.

The CMS floorlet is computed in a similar way, replacing $V(w)$ by $\frac{(k - w)_+}{G(w)}$. Note that we have $V(0) \neq 0$ and $V'(0) \neq 0$, so we have two extra terms:

$$\begin{aligned} CMSfloorlet_{t,T}(k) &= V(0) \mathbb{E}_t[\beta_{t,T}^{-1} G(w_{T,T})] \\ &\quad + V'(0) \mathbb{E}_t[\beta_{t,T}^{-1} w_{T,T} G(w_{T,T})] \\ &\quad + \int_0^{+\infty} V''(K) \mathbb{E}_t[\beta_{t,T}^{-1} G(w_{T,T})(w_{T,T} - K)_+] dK \\ &\quad + \int_{-\infty}^0 V''(K) \mathbb{E}_t[\beta_{t,T}^{-1} G(w_{T,T}) \\ &\quad \times (K - w_{T,T})_+] dK \end{aligned} \quad (17)$$

If we assume that rates cannot be negative, the second integral vanishes. In the current environment, it is not clear that rates cannot go slightly negative, so we should also compute the second part, which has value if we use, for example, a Gaussian model. Assuming $G(w_{T,T})$ as an approximation for $A(T)$ we have $\mathbb{E}_t[\beta_{t,T}^{-1}G(w_{T,T})] \approx A(t)$ and using equation (4), we get $\mathbb{E}_t[\beta_{t,T}^{-1}w_{T,T}G(w_{T,T})] \approx A(t)w_{t,T}$. We start the first integration from $K_0^\alpha = k - \varepsilon$ and set $K_i^\alpha = K_0^\alpha - i\Delta K$, with $\alpha_i^{\text{floor}} = -2h'(K_i^\alpha) + (k - K_i^\alpha)h''(K_i^\alpha)$ until we reach $K_{N_1}^\alpha = 0$. Concerning the receiver swaption, we start from $K_0^\beta = 0$ and set $K_j^\beta = K_0^\beta - j\Delta K$ with $\beta_j^{\text{floor}} = -2h'(K_j^\beta) + (k - K_j^\beta)h''(K_j^\beta)$ until we reach an arbitrary lower bound for the receivers $K_{N_2}^\beta = K_{\min} (< 0)$. Then we have

$$\begin{aligned} & CMS_{\text{floorlet},T}(K) \\ & \approx (V(0) + V'(0)w_{t,T})A(t) \\ & + \sum_{i=0}^{N_1} \alpha_i^{\text{floor}} CSS_{t,T}(K_i^\alpha, \zeta = 1) \\ & + \sum_{j=0}^{N_2} \beta_j^{\text{floor}} CSS_{t,T}(K_j^\beta, \zeta = -1) \quad (18) \end{aligned}$$

To compute the CMS rate, we see from expression (6) that if we assume interest rates to be positive as in the Black–Scholes case, we can value the CMS rate directly from a CMS caplet struck at $k = 0$ as $\mathbb{E}_t[(w_{T,T})_+] = \mathbb{E}_t[w_{T,T}]$:

$$CMS_t = \frac{1}{P(t,T)} CMS_{\text{caplet},T}(k = 0) \quad (19)$$

Alternatively, we use the call–put parity. Note that the choice of the strike k in the caplet and floorlet is arbitrary (a common practice is to set the strike to the forward swap rate $k = w_{t,T}$):

$$\begin{aligned} & CMS_t \\ & = k + \frac{CMS_{\text{caplet},T}(k) - CMS_{\text{floorlet},T}(k)}{P(t,T)} \quad (20) \end{aligned}$$

Alternative pricing methods have been proposed in the literature such as higher order Taylor expansions or chaos expansions (see [2]) or linear swap rate model approximation (see [6–8]).

Computation of the CMS rate in the standard case

In the standard case, fixing is at T , and payment takes place at $T + \theta$, so we have $P(t, T + \theta) \cdot CMS_t^{\text{std}} = \mathbb{E}_t\left[\frac{\beta_{0,t}}{\beta_{0,T+\theta}}w_{T,T}\right]$. We see that we can no longer apply the change of probability as in equation (4) because of the presence of $\beta_{0,T+\theta}$ instead of $\beta_{0,T}$: we artificially introduce $\beta_{0,T}$ in order to use equation (4). We have

$$\begin{aligned} \mathbb{E}_t\left[\frac{\beta_{0,t}}{\beta_{0,T+\theta}}w_{T,T}\right] &= \mathbb{E}_t\left[\frac{\beta_{0,t}}{\beta_{0,T}}\frac{\beta_{0,T}}{\beta_{0,T+\theta}}w_{T,T}\right] \\ &= \mathbb{E}_t\left[\frac{\beta_{0,t}}{\beta_{0,T}}w_{T,T}B(T, T + \theta)\right] \\ &= P(t, T)\mathbb{E}_t^T[w_{T,T}B(T, T + \theta)] \quad (21) \end{aligned}$$

There are at least two methods for computing the above quantity.

The first method consists in replacing $B(T, T + \theta)$ with a function involving $w_{T,T}$ plus a spread s . For example, we could write $B(T, T + \theta) = \frac{1}{1 + \theta(w_{T,T} + s)}$ so that $\mathbb{E}_t^T[w_{T,T}B(T, T + \theta)] = \mathbb{E}_t^T[f(w_{T,T})]$ with $f(w) = \frac{w}{1 + \theta(w + s)}$. We then use the replication formula (12) by replacing $V(w)$ with $V(w) = \frac{f(w)}{G(w)}$.

Alternatively, we can replace $B(T, T + \theta)$ with $B(T, T + \theta) = \frac{1}{1 + \theta L(T, T, T + \theta)}$. The approximation:

$$\frac{1}{1 + \theta L(T, T, T + \theta)} \approx 1 - \theta L(T, T, T + \theta) \quad (22)$$

together with a correlation assumption $\rho = \text{corr}^{Q^T}(L(T, T, T + \theta), w_{T,T})$ between the forward LIBOR and the forward swap rate under measure Q^T give us

$$\begin{aligned} & \mathbb{E}_t^T[w_{T,T}B(T, T + \theta)] \\ & \approx CMS_t - \theta CMS_t \mathbb{E}_t^T[L(T, T, T + \theta)] \\ & \quad - \theta \rho \sqrt{\text{Var}^{Q^T}(w_{T,T})} \sqrt{\text{Var}^{Q^T}(L(T, T, T + \theta))} \quad (23) \end{aligned}$$

where CMS_t is the nonstandard CMS rate computed previously and $\mathbb{E}_t^T[L(T, T, T + \theta)]$ is a convexity-adjusted forward LIBOR (see the next section for

more details). The variances under Q^T of the forward swap and LIBOR rates can be both valued *via* replication or approximated with the variances under their “natural” measures, respectively, Q^A and $Q^{T+\theta}$. Under Black–Scholes assumptions, they are simply $w_{t,T}^2(e^{(T-t)\sigma_w^2(T)} - 1)$ and $L(t, T, T + \theta)^2(e^{(T-t)\sigma_L^2(T)} - 1)$, respectively.

On the one hand, the second method involves more computations, themselves involving approximations, and uses an input ρ not explicitly given by the market. However, it better illustrates the “negative” convexity in the standard CMS case, that is, the presence of a negative second term in the formula.

In-arrears Swaps

In this section, we deal with LIBOR swaps, the CMS case having been described previously. As defined in the section Notations, *in-arrears* swaps are interest rate swaps that differ from vanilla swaps by the absence of a payment lag in the floating leg. More precisely, in a vanilla swap, the floating rate $L(T_{i-1}, T_{i-1}, T_i)$ fixes at T_{i-1} and is paid at T_i , that is, payment at T_i is $\theta_i L(T_{i-1}, T_{i-1}, T_i)$ while in an in-arrears swap, the floating rate is fixed and paid the same date at the end of the period, that is, the payment at T_i is $\theta_{i+1} L(T_i, T_i, T_{i+1})$. As we will see, this change also creates a positive convexity adjustment in the valuation of the floating leg. The valuation of in-arrears swaps can be done by at least two different methods: the traditional Black–Scholes adjustment and the replication technique. For the replication method, the underlying replication instruments are caplets/floorlets as opposed to swaptions for the CMS cash flows described in the previous section.

The time t -value of the in-arrears payment at T_i is

$$\begin{aligned} & \mathbb{E}_t \left[\frac{\beta_{0,t}}{\beta_{0,T_i}} \theta_{i+1} L(T_i, T_i, T_{i+1}) \right] \\ &= \theta_{i+1} P(t, T_i) \mathbb{E}_t^{T_i} [L(T_i, T_i, T_{i+1})] \end{aligned} \quad (24)$$

As the forward LIBOR rate $L(\cdot, T_i, T_{i+1})$ is a $Q^{T_{i+1}}$ -martingale, we have

$$\mathbb{E}_t^{T_{i+1}} [L(T_i, T_i, T_{i+1})] = L(t, T_i, T_{i+1}) \quad (25)$$

but

$$\mathbb{E}_t^{T_i} [L(T_i, T_i, T_{i+1})] \neq L(t, T_i, T_{i+1}) \quad (26)$$

To use the martingale property of $L(\cdot, T_i, T_{i+1})$ under $Q^{T_{i+1}}$, we discount $\theta_{i+1} L(T_i, T_i, T_{i+1})$ from date T_{i+1} . Obviously, the cash flow must be capitalized between T_i to T_{i+1} to compensate for this “late” discounting:

$$\begin{aligned} & \mathbb{E}_t \left[\frac{\beta_{0,t}}{\beta_{0,T_i}} \theta_{i+1} L(T_i, T_i, T_{i+1}) \right] \\ &= \mathbb{E}_t \left[\frac{\beta_{0,t}}{\beta_{0,T_{i+1}}} \theta_{i+1} L(T_i, T_i, T_{i+1}) \frac{\beta_{0,T_{i+1}}}{\beta_{0,T_i}} \right] \\ &= \mathbb{E}_t \left[\frac{\beta_{0,t}}{\beta_{0,T_{i+1}}} \theta_{i+1} L(T_i, T_i, T_{i+1}) \right. \\ & \quad \left. \times (1 + \theta_{i+1} L(T_i, T_i, T_{i+1})) \right] \\ &= P(t, T_{i+1}) \theta_{i+1} L(t, T_i, T_{i+1}) \\ & \quad + P(t, T_{i+1}) \theta_{i+1}^2 \mathbb{E}_t^{T_{i+1}} [L^2(T_i, T_i, T_{i+1})] \end{aligned} \quad (27)$$

Now we can compute $\mathbb{E}_t^{T_{i+1}} [L^2(T_i, T_i, T_{i+1})]$ either using a standard Black–Scholes adjustment or *via* replication on caplets. In the first case, assuming that the at-the-money implied volatility of the forward rate $L(\cdot, T_i, T_{i+1})$ is σ_i , we find $\mathbb{E}_t^{T_{i+1}} [L^2(T_i, T_i, T_{i+1})] = L(t, T_i, T_{i+1})^2 e^{\sigma_i^2(T_i-t)}$. In the second case, we can use formula (12) to find that

$$x^2 = 2 \int_0^{+\infty} (x - K)_+ dK \quad (28)$$

so that using the caplet definition given in the section Notations

$$\begin{aligned} & \mathbb{E}_t^{T_{i+1}} [L^2(T_i, T_i, T_{i+1})] \\ &= 2 \int_0^{+\infty} \mathbb{E}_t^{T_{i+1}} [(L(T_i, T_i, T_{i+1}) - K)_+] dK \\ &= \frac{2}{P(t, T_{i+1})} \int_0^{+\infty} \text{Caplet}_{t, T_{i+1}}(K) dK \end{aligned} \quad (29)$$

To be tractable, this integral must be discretized and capped as previously described in the CMS case.

Averaging Swaps

As nonstandard fixed-for-floating interest rate swaps, *averaging* swaps are somewhat less common than

CMS and in-arrears swaps. The floating leg of such a swap pays at each coupon date T_i the average of the LIBOR rates observed over a predetermined period. Let us consider a set of dates $T_{i(k)}$ with $i(k) < i$. The cash flow at date T_i is given by

$$\frac{1}{N} \sum_{k=1}^N \theta_{i(k)+1} L(T_{i(k)}, T_{i(k)}, T_{i(k)+1}) \quad (30)$$

So assuming that under the “terminal measure” Q_{T_i} , we know the drift $\mu_{i(k)}$,

$$\frac{dL(t, T_{i(k)}, T_{i(k)+1})}{L(t, T_{i(k)}, T_{i(k)+1})} = \mu_{i(k)}(t) dt + \sigma_{i(k)} dW_t^{T_i} \quad (31)$$

the averaging formula has a value at time t given by

$$\begin{aligned} & \mathbb{E}_t \left[\beta_{t, T_i}^{-1} \frac{1}{N} \sum_{k=1}^N \theta_{i(k)+1} L(T_{i(k)}, T_{i(k)}, T_{i(k)+1}) \right] \\ &= P(t, T_i) \sum_{k=1}^N \theta_{i(k)+1} L(t, T_{i(k)}, T_{i(k)+1}) \\ & \quad \times \exp \left(\int_t^{T_{i(k)}} \mu_{i(k)}(u) du \right) \end{aligned} \quad (32)$$

The convexity adjustments $\exp \left(\int_t^{T_{i(k)}} \mu_{i(k)}(u) du \right)$ can either be computed by Black–Scholes formula, or by replication. Alternatively, a term structure model such as a LIBOR market model (see **LIBOR Market Model**) or a Cheyette model (see **Markovian Term Structure Models**) could be used to obtain the required drifts. (See also **Change of Numeraire**; **Forward and Swap Measures**; **Convexity Adjustments**.)

Bermudan Swaptions and Callable Libor Exotics

In this article we give an overview of callable interest rate products, a product class that includes Bermudan swaptions as well as callable Libor exotics (CLE). The main contractual features of these securities are discussed, and an outline of valuation algorithms is provided. CLEs are among the most complicated fixed income exotics derivatives traded, combining state-dependent coupons with other features such as a Bermudan-style callability option. As a consequence, these securities are particularly challenging to price and risk-manage.

Market Overview

CLEs most often start their life as callable structured notes. In a callable structured note, a *note issuer* receives the principal from an *investor* and pays a coupon, which is typically a function of interest rates, in return. In addition, the issuer retains the right to *call*, or *cancel*, the note on particular days, often coupon fixing days, after some initial *lock-out* (or *noncall*) period. When a note is called by the issuer, the principal is returned to the investor and the issuer stops paying the coupons.

As the principal received by the issuer is invested and typically yields a Libor rate (plus or minus a spread), a cancelable note is equivalent to a *cancelable swap*, that is, a swap of structured coupons against Libor rate payments that can be canceled on specified dates. Alternatively, it can be viewed as a noncancelable swap plus an option to *enter*, on a given set of dates, into a reverse swap. A CLE is typically defined to be such a *Bermudan-style option* to enter an exotic swap.

An investor granting the issuer the right to cancel the structured note is essentially selling a Bermudan-style right to enter an exotic swap. In return, the issuer compensates by making the coupon more attractive, which is often the motivation for adding the callability feature in the first place.

Types of Structured Coupons

CLEs are defined by the structured coupon they are paying, plus other features such as callability. In this

section we review some common types of coupons that one can encounter in a CLE. Coupons are usually structured to let the investors take speculative views on the interest rate market or to provide protection against adverse scenarios. For example, a floored payoff can be chosen if an investor desires protection against a fall in interest rates.

A structured coupon can be any function of observed interest rates (such as Libor or constant maturity swap (CMS); *see* **LIBOR Rate; Constant Maturity Swap**) on or before its fixing date. Many types are available. They can roughly be split into four categories: Libor-based, CMS-based, spread-based, and range-accruals.

To provide some detail, we assume in the following sections that a tenor structure is defined:

$$0 = T_0 < T_1 < \dots < T_N, \quad \tau_n = T_{n+1} - T_n \quad (1)$$

Typically, the rate observations, or fixings, for the n th coupon are made at T_n , and the coupon pays at T_{n+1} , $n = 1, \dots, N - 1$.

Libor-based Exotic Swaps

A Libor-based structured coupon is a function of a single Libor rate. Let us denote the n th coupon as a function of the n th Libor rate observed on its fixing date by

$$C_n = C_n(L_n(T_n)) \quad (2)$$

There is a large variety of structured coupons $C_n(\cdot)$ that can be used. For example^a

- *Standard swap*: For fixed coupon k ,

$$C_n(x) = k \quad (3)$$

- *Capped and floored floaters*: For strike s , gearing g , cap c , and floor f ,

$$C_n(x) = \max(\min(g \times x - s, c), f) \quad (4)$$

- *Capped and floored inverse floaters*: For spread s , gearing g , cap c , and floor f ,

$$C_n(x) = \max(\min(s - g \times x, c), f) \quad (5)$$

- *Digitals*: For strike s and coupon k ,

$$C_n(x) = k \times 1_{\{x > s\}} \quad (6)$$

- “Flip-flops” or “tip-tops”: For strike s and two coupons, k_1 and k_2 , “low” and “high” coupons, the coupon is

$$C_n(x) = \begin{cases} k_1, & x \leq s \\ k_2, & x > s \end{cases} \quad (7)$$

Different coupon types can be added together to create new types of structured coupons.

CMS-based Coupons

The same payoffs can be applied to CMS rates. Structured coupons are then deterministic functions of CMS rates. If an m -period rate is used, and we denote by $S_{n,m}(\cdot)$ the forward swap rate that fixes at T_n and covers m periods, then a structured coupon for period n is defined by

$$C_n = C_n(S_{n,m}(T_n)) \quad (8)$$

with $C_n(x)$ as defined in the previous section.

Spread-based Coupons

Spread-based structured coupons differ from Libor- or CMS-based ones in that they involve more than one market rate, Libor or CMS, in the calculation of structured coupons. The most common example is a CMS spread coupon. Let $S_{n,a}(\cdot)$ and $S_{n,b}(\cdot)$ be two collections of CMS rates, fixing on T_n , $n \geq 0$, and covering a and b periods, respectively. A CMS spread coupon with gearing g , spread s , cap c , and floor f is then defined by

$$C_n = \max(\min(g \times (S_{n,a}(T_n) - S_{n,b}(T_n)) + s, c), f) \quad (9)$$

A more general example can be obtained by using one of the payoff functions $C_n(x)$ defined in section Libor-based Exotic Swaps when applied to the spread $x = S_{n,a}(T_n) - S_{n,b}(T_n)$. In particular, digital and flip-flop CMS spread swaps are popular.

Spread-based exotic swaps typically cannot be decomposed into “standard” instruments, such as standard swaps, caps, and so on. Therefore, they, as a rule, cannot be valued by replication arguments, and a model is required.

More than two rates can be used in the definition of a coupon. Relatively recently, the so-called “curve

caps” became popular. In a curve cap, a coupon rate (Libor or CMS) is capped at a level that is given by a function (typically a spread) of two (other) rates. Often, the coupon rate is also floored at (another) function of two (yet other!) rates. Thus, the definition of a curve cap coupon can involve up to five rates. If the coupon rate is itself a spread, six rates define the coupon.

Range-accruals

A range-accrual structured coupon is defined as a fixed (or, sometimes, floating; see below) rate that only accrues when a reference rate is within a certain range. Let $X(t)$ be such a reference rate, and let l be the low bound and u be the upper bound. Let k be a fixed rate. A range-accrual coupon pays

$$C_n = k \times \frac{\#\{t \in [T_n, T_{n+1}] : X(t) \in [l, u]\}}{\#\{t \in [T_n, T_{n+1}]\}} \quad (10)$$

where $\#\{\cdot\}$ is used to denote the number of days that a given criterion is satisfied.

The fixed coupon k can be replaced with, for example, a Libor rate or, much less commonly, a CMS rate or any other structured coupon. Similarly, the reference rate $X(t)$ can be any market-observable rate such as a Libor rate fixing at t , a CMS rate fixing at t , or even a CMS spread.

A fixed-rate range-accrual coupon can be decomposed into simpler coupons, because

$$\begin{aligned} & \#\{t \in [T_n, T_{n+1}] : X(t) \in [l, u]\} \\ &= \sum_{t \in [T_n, T_{n+1}]} 1_{\{X(t) \in [l, u]\}} \end{aligned} \quad (11)$$

The sum on the right-hand side is over all business days in the period $[T_n, T_{n+1}]$. Thus, the range-accrual coupon can be seen as a collection of digitals on the reference rate. A similar decomposition can be applied to floating range-accruals.

Bermudan Swaptions and Callable Libor Exotics

Definition

A *Bermudan swaption* is a Bermudan-style option to enter a fixed-for-floating swap, that is, a swap with

the “structured” coupon paying fixed rate, $C_n(x) = k$. Bermudan swaptions on payer (pay-fixed, receive-floating) swaps are called *payer Bermuda swaptions*; similar conventions hold for receiver swaps. Bermudan swaptions are actively traded in both the US and European markets, with well-developed interdealer market in the United States for shorter-dated Bermudan swaptions.

If the underlying swap is an exotic swap, that is, a swap paying a structured coupon as in the previous section, then the Bermuda-style option to enter it is called a *CLE*.

For a CLE on an exotic swap with structured coupons $\{C_n\}_{n=0}^{N-1}$, we denote the value of the exotic swap that one can exercise on date T_n , the so-called *exercise value*, by

$$E_n(t) = \beta(t) \sum_{i=n}^{N-1} \tau_i \mathbf{E}_t(\beta^{-1}(T_{i+1}) \times (C_i - L_i(T_i))),$$

$$t \leq T_n \quad (12)$$

where β is a numeraire and E_t denotes time t expectation in the probability measure associated with β (see **Forward and Swap Measures**).

Types of Callable Libor Exotics

Any exotic swap can be used as an underlying for a CLE. The “taxonomy” of CLEs follows closely that of structured coupons; see the section Types of Structured Coupons. As we already mentioned, the simplest type of a CLE is a Bermudan swaption, with the underlying being a fixed-for-floating swap. We can generally distinguish four types of CLEs, Libor-based, CMS-based, spread-based, and callable range-accruals. If the underlying is an inverse floating swap, the CLE is called a *callable inverse floater*, and so on.

CLEs Accreting at Coupon Rate

Typically the notional of the underlying swap of a CLE is the same throughout the life of the deal, but occasionally this is not the case. A notional can vary deterministically by, for example, increasing or decreasing by the same amount or at a certain rate each period. Such deterministic accretion rarely adds extra complications from a modeling prospective. Sometimes, however, a contract specifies that the

notional of the swap increases, or accretes, at the structured coupon rate. As the structured coupon is not known in advance, the accretion rate is not deterministic. For such CLEs, definition (12) has to be amended. For this, let q_i be the notional to be applied to the coupon paid at the end of the period $[T_i, T_{i+1}]$. q_i is obtained from the notional over the previous period q_{i-1} by multiplying it by the structured coupon over the previous period. Formally,

$$E_n(t) = \beta(t) \sum_{i=n}^{N-1} \tau_i \mathbf{E}_t(\beta^{-1}(T_{i+1}) \times q_i \times (C_i - L_i(T_i))),$$

$$q_i = q_{i-1} \times (1 + \tau_{i-1} C_{i-1}) \quad (13)$$

The initial notional q_0 is contractually specified.

Snowballs

In a *snowball*, the structure coupon is not just a function of the interest rate, but of the previous coupon as well. The most common snowball is of inverse floating type. In particular, the n th coupon C_n is defined by

$$C_n = (C_{n-1} + s_n - g_n \times L_n(T_n))^+ \quad (14)$$

for $n = 1, \dots, N-1$ (with C_0 usually being a simple fixed-rate coupon). Here $\{s_n\}$ and $\{g_n\}$ are contractually specified deterministic sequences of spreads and gearings. With this particular type of coupon, a snowball is sometimes called a *callable inverse ratchet*.

Many variants on the snowball idea have appeared recently, all variations on the theme of using a previous coupon in the definition of the current one. For example, a *snowrange* is typically defined by

$$C_n = C_{n-1} \times \frac{\#\{t \in [T_n, T_{n+1}] : X(t) \in [l, u]\}}{\#\{t \in [T_n, T_{n+1}]\}} \quad (15)$$

Multitranches

As we discussed previously, the more optionality an investor can sell to the issuer, the better coupon he/she can receive. The option to call the note is already present in a callable structured note. Another

option that is sometimes embedded is the right for the issuer to increase the size of the note, or put more of the same note to the investor, whether he/she wants it or not. The name of this feature, a *multitranche* callable structured note, comes from the fact that these possible notional increases are formalized as tranches of the same note that the issuer has the right to put to the investor.

The times when the issuer has the right to increase the notional of the note typically come before the times when the issues can cancel the note altogether. Callability usually applies jointly to all “tranches” of the note.

Valuation of Callable Libor Exotics

The valuation of multicable securities, such as Bermudan or American options, requires a solution of the optimal exercise problem, a type of a dynamic programming problem (*see Binomial Tree*). If we denote by $H_n(t)$ the value, at time t , of a CLE that has only the dates $\{T_{n+1}, \dots, T_{N-1}\}$ as exercise opportunities, then the value of a CLE, the value $H_0(0)$, is defined recursively by

$$\begin{aligned} H_{n-1}(T_{n-1}) &= \beta(T_{n-1}) \mathbf{E}_{T_{n-1}} (\beta(T_n)^{-1} \\ &\quad \times \max\{H_n(T_n), E_n(T_n)\}), \\ n &= N-1, \dots, 1, \\ H_{N-1} &\equiv 0 \end{aligned} \tag{16}$$

Bermudan swaptions are the most liquid interest rate exotics. As their values are mostly derived from up- and down-moves of the yield curve, they are often valued in low-dimensional short-rate models such as developed in **Term Structure Models**, using lattice or PDE numerical methods (*see* articles in **Partial Differential Equations**). The value of the “switch” option built into a Bermudan swaption, that is, the option to change which swap is entered into, can be captured by a model parameter responsible for rate autocorrelations, such as mean reversion in a

one-factor Gaussian model, *see* [1]. To value other types of CLEs, a more involved setup is usually required. Complicated dependence of coupons on one or more underlying rates, combined with the need to account for callability, typically necessitates an application of a realistic, multifactor model of interest rates such as the Libor market model (*see LIBOR Market Model*). Owing to the high dimension of such a model, Monte Carlo methods become a necessity (*see LIBOR Market Models: Simulation*) and must be complemented by methods for estimating exercise boundaries of Bermudan-style options in Monte Carlo simulation (*see Bermudan Options; Exercise Boundary Optimization Methods; Early Exercise Options: Upper Bounds*). Additional details are available in [2].

End Notes

^aNote that in all definitions we ignore day counting fractions.

Trigger Swaps

We discuss two classes of exotic interest rate derivatives: trigger swaps and targeted accrual redemption notes (TARNs). Subsequently, we outline possible valuation methodologies and assess the impact on the quality of risk estimates.

A trigger swap features an underlying swap. Cash flows of this underlying swap only start to be exchanged from the moment that a certain trigger condition is met. An example trigger condition is that some trigger index should be within a prespecified range. These are barrier type options, *see* **Barrier Options**.

The above-described trigger swap is of *knock-in* type, as opposed to a *knock-out* feature with which a swap is cancelled when the trigger index ends up in a prespecified range. There is a simple relation between an underlying swap and its knock-in and knock-out variants:

$$\begin{aligned}\text{value of swap} &= \text{value of knock-in swap} \\ &\quad + \text{value of knock-out swap}\end{aligned}$$

The above relation shows that the ability to value knock-out swaps also yields the ability to value knock-in swaps. Hence in the remainder of the article, we restrict the discussion to knock-out swaps.

A TARN is a trigger swap where the trigger index is the cumulative sum of structured coupons paid, typically of knock-out type. In this case, the barrier is referred to as a *lifetime cap*.

Example term sheets of a knock-in swap and a TARN are displayed in Tables 1 and 2, respectively. Both term sheets feature structured coupons that are exchanged for IBOR plus spread—this is more or less the general rule. There are several variations often applied to the basic TARN design:

1. The form in Table 2 is referred to as *partial final coupon* in order to exactly attain the lifetime cap.
2. The latter is in contrast to a *full-final coupon* where an excess over the lifetime cap is allowed.
3. If the sum of coupons is below target at maturity, then a *lifetime floor* dictates that a make up coupon be paid to attain the target.

Valuation

We focus the discussion primarily on valuation methods, such as a Markovian grid or Monte Carlo simulation. The presentation is more or less independent of model choice, unless explicitly mentioned otherwise.

It is well known that simulation-based risk estimates for derivatives with discontinuous payoff are less efficient than for those with continuous payoff. In contrast, a Markovian grid naturally provides high-quality risk estimates, as the backward induction expectation operator has a smoothing effect—as long as interpolation is dealt with properly. Knock-out features can be easily valued on a grid as the value of a knock-out swap is simply 0 for those state nodes for which the trigger index is within the knock-out range. Path-dependent aspects such as the cumulative coupon trigger index of TARNs may be incorporated by adding a dimension to the Markovian grid that keeps track of the cumulative coupon.

Although a Markovian grid has excellent credentials, the alternative of simulation may also successfully be applied. Its drawback—as mentioned above—lies in less than efficient estimates of risk sensitivities. The remainder of the article outlines four techniques to improve risk estimates for trigger swaps in a simulation framework: (i) large shifts, (ii) importance sampling (IS), (iii) conditioning, and (iv) smoothing.

All of the described methods may also be found in the article overview paper of Piterbarg (2004, [1]).

Large Shift Sizes

Ordinary simulation, without further enhancements, remains a viable technique of obtaining risk estimates. In the general case, risk sensitivities are calculated *via* finite differences, for which we must specify a shift size. For continuous payoffs, it is more efficient to use “smaller” shift sizes (say of the order 10^{-8}). However, for discontinuous payoffs, this is not the case as small shift sizes mostly ignore the risk component due to the digital option embedded in the knock-out structure. With discontinuous payoffs, it is more efficient to use somewhat larger shift sizes, say of the order of 1 basis point.

Importance Sampling (IS)

IS is typically used to reduce the variance of the simulation estimate. (For an overview of variance

Table 1 Example knock-in swap

Product	CMS spread knock-out
Currency	CCY
Maturity	X years
Receive	Float funding plus margin
Pay	$Y \times (\text{CCY CMS10} - \text{CMS2})$ Annually, floor at 0% If on any day the spread $\text{CCY CMS10} - \text{CMS2} \geq B\%$ then from the next coupon period onwards a fixed rate of $Z\%$ knocks in until maturity of the trade

Table 2 Example TARN

Product	Guaranteed inverse floater swap
Currency	CCY
Maturity	X years
Receive	Float funding plus margin
Pay	$Y - Z \times \text{CCY 6M IBOR in arrears}$ Semi-annually, floor at 0% If on any day the sum of structured coupons $\geq B\%$ then pay $B\% - [\text{sum of coupons}]$ and the trade cancels thereafter

reduction techniques, *see* **Variance Reduction**.) For knock-outs; however, the simulation value estimate is usually of desirable quality. It is, however, a side effect of IS that we are interested in. With IS, we sample conditional on knocking out or in. Realizations of these conditional samples then need to be multiplied by the likelihood ratio, which is a measure for the probability of the conditional event. These likelihood ratios smoothen the valuation and cause the discontinuity to disappear. Hence, we obtain efficient risk. See Glasserman and Staum [2].

Conditioning

Conditioning is specifically geared toward TARNs. With TARNs, each cash flow is contingent on a sum of index rates being within range. We focus on the valuation of one TARN cash flow, since we may value the whole TARN if we can value all cash flows. We halt the simulation when the penultimate index rate is determined. Subsequently, the remaining cash flow is a digital option with underlying rate the final index rate that determines whether or not we obtain the TARN cash flow. This digital option may

be valued analytically with a Black-type formula—the latter provides smoothing, from which we obtain more efficient risk estimates.

Smoothing

For knock-outs, we observe a trigger index x . If the trigger is outside of the survival range $[L, U]$, then the trade knocks out. We assume $L \leq U$. We consider the survival ratio A_i for each cash flow i . The survival ratio A_i is either 0 or 1. It evolves from cash flow to cash flow as follows:

$$A_{i+1} = A_i \times (1 - R_i^{\text{KO}}) \quad (1)$$

The quantity R_i^{KO} is the knock-out ratio. For the remainder of the presentation, we omit the cash flow index i for convenience. The knock-out ratio R^{KO} is either 0 or 1, and is given by:

$$R^{\text{KO}} = 1\{x < L\} + 1\{x > U\} \quad (2)$$

A smoothed version of the function in equation (2) is easily devised. An example is given in Figure 1. The smoothed function may be parameterized. For “small” parameters, the smoothed version is hardly distinguishable from the original discontinuous function. The use of “large” parameters leads to an intolerable bias in the derivative value. Experience and testing may provide guidance in selecting a parameter that bares acceptable bias yet sufficiently improves risk sensitivity estimates.

We test smoothing for a trade such as given in Table 1. We use 10^{-6} bps (“small”) shift for smooth and 0.5 bps (“large”) for nonsmooth. The terminology

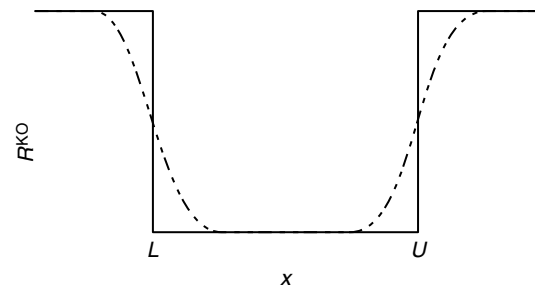

Figure 1 Knock-out ratio *versus* trigger index x , with lower and upper knock-out barriers L and U . Discontinuous, according to contract (full line) and smoothed (dotted line)

Table 3 P&L prediction results

	-10 bps	-1 bps	0 bps	1 bps	10 bps
Nonsmooth, large shifts					
NPV	1 005 251	994 113	992 594	990 804	981 537
P&L	-1266	-1519		-1790	-1106

RAOUL PIETERSZ

CMS Spread Products

According to recent estimates, the volume of traded contracts involving euro-denominated options on the spread between two *constant maturity swap* (CMS) rates (see **Constant Maturity Swap**) amounted to €240 billions in 2007 in the interbank market alone. This makes CMS spread options the most rapidly growing interest-rate derivatives market.

The underlying of any option on CMS spread is the CMS rate. By definition, the CMS rate that fixes and settles at a generic time T (associated to a swap of maturity T_n and starting at T) is equal to the swap rate of the associated swap. At any time prior to T , the value of that rate is then formally given by $CMS(t) = E_t^T(S(T, T_n))$, by absence of arbitrage. Here, the expectation $E_t^T(\cdot)$ is intended at time t with respect to the T —*forward measure* Q^T (see **Forward and Swap Measures**), where the zero coupon bond $B(t, T)$ is the associated *numéraire*. The variable leg of a CMS swap pays a stream of CMS rates at any settlement date. In turn, the payout $f_T = f(CMS_1(T), CMS_2(T); K)$ of a European call (respectively, put) option on a CMS spread expiring at time T reads as $f_T = (CMS_1(T) - CMS_2(T) - K)^+$, (respectively $f_T = (K - CMS_1(T) + CMS_2(T))^+$), where we have defined, as usual, $(\cdot)^+ = \text{Max}(\cdot, 0)$.

Generally speaking, CMS spread options are simple and liquid financial instruments that allow to take a view on the future shape of the yield curve (or immunizing a portfolio against it). In the most commonly traded combination, we have that $CMS_{1,2}(T) = CMS_{10Y,2Y}(T)$ (i.e., the two CMS rates are associated with a 10Y and 2Y swap, respectively). The buyer of a call (respectively, put) CMS spread option will then benefit from a future curve steepening (respectively, flattening) scenario. More complex option strategies involving CMS spreads are actively traded in the over-the-counter (OTC) market, as well. They include, to name a few, digitals, barrier options, and Bermudan-style derivatives.

Option Pricing without Smiles

The fair value at time t of the most generic call option is formally given by $C(t, T; K) = B(t, T)E_t^T(\alpha_1 CMS_1(T) - \alpha_2 CMS_2(T) - K)^+$, by arbitrage,

with α_1 and α_2 being constants. This expression is obviously reminiscent of an option on the spread between two assets and reduces to a simple *exchange option* (see **Exchange Options**) when $K = 0$. In the simplest case, one assumes that each CMS rate follows a simple arithmetic or geometric Brownian motion under the relevant martingale measure. In the former case, a closed-form formula for $C(t) = C(t, T; K)$ can be given [3], while in the latter the price can be only expressed in integral form unless $K = 0$, in which case a closed-form formula can be exhibited [9]. Some authors propose to use the first approach as an approximation for the second one [3, 11] for a generic $K \neq 0$. One must be, however, warned against these oversimplifications as market bid/offer spreads are relatively tight. Further risk sensitivities are very different in the two settings with profound implications as long as portfolio replication quality is concerned.

Differently from the single asset case, the process difference of two asset prices is now allowed to take negative values. Therefore, the arithmetic Brownian motion framework is generally considered as the simplest viable approach. Since, by definition, the CMS rate is a Q^T -martingale, we assume that the two rates $CMS_{1,2} = X_{1,2}$ evolve according to the following Gaussian processes under Q^T : $dX_{1,2}(t) = \sigma_{1,2} dW_{1,2}^T(t)$ with constant volatility $\sigma_{1,2}$ and where $d\langle W_1^T, W_2^T \rangle_t = \rho dt$ for some constant correlation coefficient ρ . In this case, it is easy to verify that the price of the option $C(t)$ is given by the modified *Bachelier formula* (see **Bachelier, Louis (1870–1946)**) $C(t) = B(t, T)[\sigma\sqrt{\tau}n(d(F_t, \tau)) + (F_t - K)N(d(F_t, \tau))]$ where $\tau = T - t$, $F_t = \alpha_1 X_1(t) - \alpha_2 X_2(t)$, $\sigma^2 = \alpha_1^2 \sigma_1^2 - 2\rho\alpha_1\alpha_2\sigma_1\sigma_2 + \alpha_2^2 \sigma_2^2$ and $d(F_t, \tau) = (F_t - K)/(\sigma\sqrt{\tau})$. Here, $n(\cdot)$ and $N(\cdot)$ stand for the standard Gaussian density and cumulative distribution function, respectively. In the lognormal case, one has to resort to a quasi-closed form formula (see [3] for a review).

The advantage of the above formula, similarly to Black–Scholes (BS) model (see **Black–Scholes Formula**) for European options on single assets, is its simplicity. However, while in the BS case inverting the market price provides a unique *implied volatility*, here the situation is more complex. There are now three (as opposed to one) free parameters of the theory, that is, ρ , σ_1 , and σ_2 . In a perfectly liquid market, one could, in principle, infer σ_1 and σ_2 by inverting the Bachelier formula for the two respective

options on $CMS_{1,2}$, and then use the correlation as the unique free parameter of the theory. Interestingly, this indicates that buying or selling spread options is, in principle, equivalent to trading *implied spread correlation*.

Unfortunately, the above approach relies on the assumption that CMS rates dynamics are well modeled by an arithmetic Brownian motion. In practice, this is not the case. The main reason has to do with the presence of the volatility smile rather than with the request of positivity of CMS rates. As it is well known, a CMS rate settling at time T , and associated to a swap of length τ , can be statically replicated through a linear combination of European swaptions (of different strike) expiring at T to enter into a swap of length τ . The sum is actually infinite, that is, it is an integral over all possible swaptions for that given maturity [1, 6]. Because it is well known that implied swaption volatilities are different at different strikes (i.e., a volatility smile is present) it means that the swaption underlying—the forward swap rate—cannot follow a simple Gaussian process in the relevant martingale measure. Consequently, the CMS rate, viewed as a linear combination of swaptions, must evolve accordingly. Needless to say that using a model for spread options where the underlying process is inconsistent with the market available information on plain-vanilla instruments has important consequences on the quality of the risk management [4, 5].

Option Pricing with Smiles

There are essentially three possible ways to quote CMS spread options so as to ensure partial or full consistency with the underlying (CMS) implied dynamics.

Stochastic volatility models are very popular among academics and practitioners as they provide a simple and often effective mechanism of static generation as well as dynamic smile evolution [10]. The first approach consists of assuming that each CMS rate in the spread follows a diffusion with its own stochastic volatility. The Stochastic Alpha Beta Rho (SABR) model, for instance, has become the market standard for European options on interest rates [7]. By coupling two SABR diffusions, one can easily calibrate each parameter set on the respective market-implied CMS smile. The method has, however, two

major drawbacks. First, neither known formula nor simple approximation exists on options for multivariate SABR models. Second, there are six independent correlations to specify and several among them are not directly observable (e.g., the correlation between the first CMS rate and the volatility of the second one). In addition, it is easy to verify that some of those parameters are fully degenerate with respect to the price of a spread option of given strike.

The second approach resorts to using arbitrage-free dynamic models for the whole yield curve dynamics, in the Heath-Jarrow-Morton (HJM) sense [8], *see Heath–Jarrow–Morton Approach*. Dynamics of the spread between any two CMS rates is then inferred from dynamics of the whole curve. This second method allows pricing and risk managing all spread options on different pairs (e.g., 10Y–2Y, 10Y–5Y, 30Y–10Y, etc.) within a unique modeling setup rather than treating them as separate problems. This offers the great advantage of measuring and aggregating correlation exposures across all pairs at once and correlation risk diversification can be achieved. Also, exotic derivatives can be priced in this framework. On the negative side, it is very difficult to reproduce the implied smile of each CMS rate unless very complex models are introduced (e.g., a multifactor HJM model with possibly multivariate stochastic volatility).

Finally, a third possibility consists of disentangling the marginal behavior and the dependence structure between the two CMS rates. One can infer the marginal probability density from plain-vanilla swaptions, that is, match their respective individual smiles, and then “recombine” them *via a copula-based method* [2], and references therein) to get the bivariate distribution function. In [2], a simple numerical trick to reduce the dimensionality of the necessary integration routines is also described. The great advantage of this approach is its simplicity and the guarantee that, by construction, the price of the spread option is, at a given time, consistent with the current swaption market. On the negative side, the approach is purely static, since no simple method exists to assign a dynamics on a bivariate process such that the associated density is consistent with the chosen copula function at any time. In addition, the choice of the copula itself is, to a large extent, arbitrary.

Implied Correlation and Normal Spread Volatility

Similar to the BS case, practitioners often prefer to measure and compare spread option prices through homogeneous quantities. For simple options, people use implied volatility. For spread options, the natural equivalent is the concept of implied correlation.

Assume that a spread option is being priced through a Gaussian copula-based method. Put simply, this amounts to inferring the two CMS marginal densities from each respective swaption market and then coupling them *via* a Gaussian copula function. It should be mentioned that a Gaussian copula is parameterized by a single correlation ρ and that a spread option price is monotonically decreasing as a function of ρ . Therefore, given the market price of a generic call spread option $C(t, T; K)$ struck at K , and given the two marginal CMS underlying densities, there exists a unique $\rho(K)$ such that the market price is matched by a copula method with correlation $\rho(K)$. This unique number is termed *implied copula correlation*. As for simple options, the function $\rho(K)$ displays a significant dependence on the strike. This is the correlation smile phenomenon (Figure 1).

Interestingly, it is possible to analyze the situation from a different, albeit similar, angle. In a previous

section, we showed that the simplest way to price options on CMS spread consists of coupling two simple Gaussian processes. The resulting closed-form formula is of Bachelier type with a modified normal volatility given by $\sigma^2 = \alpha_1^2 \sigma_1^2 - 2\rho\alpha_1\alpha_2\sigma_1\sigma_2 + \alpha_2^2 \sigma_2^2$. Given the option price $C(t, T; K)$, one can then invert the Bachelier-like formula to get a unique *implied normal spread volatility* $\sigma(K)$. Once more, function $\sigma(K)$ displays a smile. This alternative approach is still very popular among some practitioners.

It must be noticed, however, that the two above smile generation methods are not equivalent. In fact, only the first one is fully consistent with the underlying swaption smile observed in the market. In addition, the former approach concentrates on correlation, while the latter on the normal spread volatility that corresponds to the covariance of the joint process. Therefore, the first method is better suited if one considers volatility and correlation markets as evolving separately so that correlation movements are partly unrelated to price changes for swaptions. On the other side, the second method assumes that correlation and volatility markets are essentially indistinguishable to the extent that only the product of volatility and correlation (i.e., the

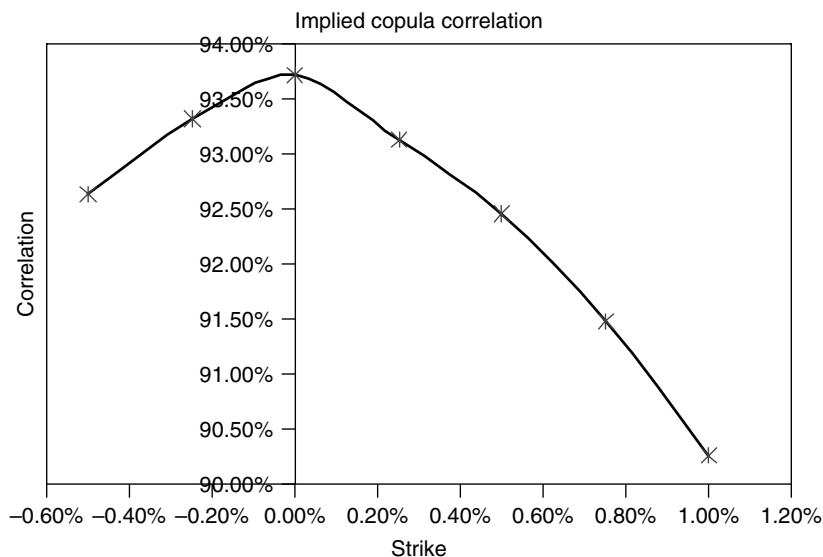

Figure 1 The figure displays the typical pattern of the implied copula correlation smile associated to a contract on the 10Y–2Y CMS spread. Volatility is associated to a 7×10 cap on CMS spread, starting 7 years from today and maturing 10 years from today. [Source: BNP Paribas]

covariance) is the relevant quantity as far as risk management is concerned.

CMS Spread Derivatives

In recent times, a whole range of financial products has been introduced where the underlying is a spread between two CMS rates. In the broker market, option on CMS spreads are usually quoted as a cap/floor comprising a given number of caplets/floorlets with quarterly frequency. This is completely equivalent to caps/floors written on LIBOR rates. Plain options on spreads are also commonly traded in the interbank market (mainly on maturities less than three years). These are referred to as *single-look* (or *one-look*) options on CMS spread.

Investors can benefit by taking a view on the future evolution of the difference between two swap rates, that is, by taking a view on the shape of the yield curve. This can be best captured by structuring financial derivatives written on the spread. Here, we limit ourselves to briefly mention a few important examples.

A digital option on a CMS spread gives the purchaser the right to receive one unit of notional should the spread exceed the strike price at expiry and nothing otherwise. For instance, an investor who believes that the level of the current 10Y swap rate will always be larger than the 2Y, one can buy a digital (call) option on the 10Y–2Y CMS spread with strike set to 0. Similarly, a range accrual option on the same spread gives the holder the right to receive one unit of notional times the number of days the 10Y swap exceeds the 2Y swap between two given dates. Both digital and range accrual options are relatively simple instruments. More complex derivatives written on CMS spreads have also appeared in the market and enjoyed vast success: Bermudan options, target redemption notes (TARNs), knockout options as well as multiple underlying derivatives, to name a few. A simple example of multiple underlying derivatives is a digital option that pays a variable coupon (e.g., a LIBOR rate) if the spread between two CMS rates fixes above a given strike.

It is worth reminding that the pricing and risk management of all structured derivatives on CMS spreads are, by construction, heavily dependent on the correlation smile. Further, for Bermudan and

path-dependent derivatives, they also depend on the yield curve/forward volatility assumptions that are associated to a given model for interest rates dynamics.

Yield Curve Construction

The objective of an interest rate model is to describe the random movement of a curve of zero-coupon bond prices through time, starting from a known initial condition. In reality, however, only a few short-dated zero-coupon bonds are directly quoted in the market at any given time, a long stretch from the assumption of many models that an initial curve of zero-coupon bond prices is observable for a continuum of maturities. Fortunately, a number of liquid securities depend, in relatively straightforward fashion, on zero-coupon bonds, opening up for the possibility of uncovering zero-coupon bond prices from prices of such securities. Still, as only a finite set of securities are quoted in the market, constructing a continuous curve of zero-coupon bond prices will require us to complement market observation with an interpolation rule, based perhaps on direct assumptions about functional form or perhaps on a regularity norm to be optimized on. A somewhat specialized area of research, discount curve construction relies on techniques from a number of fields, including statistics and computer graphics. We discuss the basic topics in detail and refer the reader to appropriate sources for advanced applications. In the same spirit, we pay scant attention to the subtle intricacies of actual swap and bond market conventions.

Discount Curves

Let $P(t, T)$ be the time t price of a zero-coupon bond maturing at time T . Going forward, we use the abbreviated notation $P(T) = P(0, T)$ where $P : [0, T] \rightarrow (0, 1]$ is a continuous, monotonically declining *discount curve*. T denotes the maximum maturity considered, typically given as the longest maturity in the set of securities the curve is built to match. Let there be N such securities—the *benchmark set*—with observable prices $V_1, \dots, V_N$. We fundamentally assume that the time 0 price $V_i = V_i(0)$ of security i can be written as a linear combination of zero-coupon bond prices at different maturities,

$$V_i = \sum_{j=1}^M c_{ij} P(t_j), \quad i = 1, \dots, N \quad (1)$$

where $0 < t_1 < t_2 < \dots < t_M \leq T$ is a given finite set of dates, in practice obtained by merging together

the cash-flow dates of each of the N benchmark securities. Securities that satisfy relationship (1) include coupon bonds, forward rate agreements (FRAs), as well as fixed-floating interest rate swaps. For instance, consider a newly issued unit-notional fixed-floating swap, paying a coupon of $c\tau$ at times $\tau, 2\tau, 3\tau, \dots, n\tau$. If no spread is paid on the floating rate, the time 0 total swap value V_S to the fixed-rate payer is

$$V_S = 1 - P(n\tau) - \sum_{j=1}^n c\tau P(j\tau) \Rightarrow$$

$$1 - V_S = P(n\tau) + \sum_{j=1}^n c\tau P(j\tau) \quad (2)$$

which is in the form (1) once we interpret $V_i = 1 - V_S$.

The choice of the securities to be included in the benchmark set depends on the market under consideration. For instance, to construct a treasury bond curve, it is natural to choose a set of treasury bonds and T-bills. On the other hand, if we are interested in constructing a discount curve applicable for bonds issued by a particular firm, we would naturally use bonds and loans used by the firm in question. In many applications, the most important yield curve is the *Libor curve*, constructed out of market quotes for Libor deposits, swaps, and Eurodollar futures. In the construction of this curve, most firms would use a few certificates of deposit for the first 3 months of the curve, followed by a strip of Eurodollar futures^a (with maturities staggered 3 months apart) out to 3 or 4 years. Par swaps are then used for the rest of the curve, often going out to 30 years or more.

Matrix Formulation & Transformations

Define the M -dimensional discount bond vector

$$\mathbf{P} = (P(t_1), \dots, P(t_M))^T \quad (3)$$

and let $\mathbf{V} = (V_1, \dots, V_N)^T$ be the vector of observable security prices. Also let $\mathbf{c} = \{c_{ij}\}$ be an $N \times M$ dimensional matrix containing all the cash flows produced by the chosen set of securities. $\mathbf{c}$ would typically be quite sparse.

In a friction-free market without arbitrage, the fundamental relation

$$\mathbf{V} = \mathbf{cP} \quad (4)$$

must be satisfied, giving us a starting point to find $\mathbf{P}$. In practice, however, we normally have $M > N$, in which case equation (4) is insufficient to uniquely determine $\mathbf{P}$. The problem of curve construction essentially boils down to supplementing equation (4) with enough additional assumptions to allow us to extract $\mathbf{P}$ and to determine $P(T)$ for values of T not in the cash-flow timing set $\{t_j\}_{j=1}^M$.

As it is normally easier to devise an interpolation scheme on a curve that is reasonably flat (rather than exponentially decaying), it is common to perform the curve-fitting exercise on *zero-coupon yields*, rather than directly on discount bond prices^b. Specifically, we introduce a continuous yield function $y : [0, T] \rightarrow \mathbb{R}_+$ given by

$$e^{-y(T)T} = P(T) \Rightarrow y(T) = -T^{-1} \ln P(T) \quad (5)$$

such that in equation (4) $\mathbf{P} = (e^{-y(t_1)T_1}, \dots, e^{-y(t_M)T_M})$. The mapping $T \mapsto y(T)$ is known as the *yield curve*; it is related to the discount curve by the simple transformation (5). Of related interest is also the *instantaneous forward curve* $f(T)$, given by

$$P(T) = e^{-\int_0^T f(u)du} \Rightarrow f(T) = y(T) + \frac{dy(T)}{dT}T \quad (6)$$

For more transformations of the discount curve—and a discussion of relative merits in curve construction—see [1, 14]. For simplicity, in this article we work primarily with $y(T)$ unless otherwise noted.

Construction Principles

We have at least three options for solving equation (4).

1. We can introduce new and unspanned securities such that $N = M$ and equation (4) allows for exactly one solution.
2. We can use a parameterization of the yield curve with precisely N parameters, using the N equations in equation (4) to recover these parameters.
3. We can search the space of all solutions to equation (4) and choose the one that is “optimal” according to a given criterion.

Let us provide some comments to these three ideas. First, in option 1, introduction of new securities might not truly be possible—such securities may simply not exist—but sometimes interpolation rules applied to the given benchmark set may allow us to provide reasonable values for an additional set of “fictitious” securities. Although it can occasionally be useful in preprocessing to pad an overly sparse benchmark set, this idea will often require some quite *ad hoc* decisions about the specifics of the fictitious securities, and excessive use may ultimately lead to odd-looking curves and suboptimal hedge reports. When an interpolation rule is to be used, it is typically better to apply it to fundamental quantities such as zero-coupon yields or forward rates, thereby maintaining a higher degree of control over the resulting yield curve.

In option 2 above, parametric functional forms such as that in [9] are sometimes used, but it is far more common to work with a spline representation with N user-selected knots (typically at the maturity dates of the benchmark securities), with the level of the yield curve at these knots constituting the N unknowns to be solved for. We discuss the details of this approach in the section Yield Curve Fitting with N -knot Splines, using a number of different spline types. We assume some knowledge of spline theory here—classical references are [2, 11].

Option 3 is covered in the section Nonparametric Optimal Yield Curve Fitting and constitutes the most sophisticated approach. It can often be stated in completely nonparametric terms, with the yield curve emerging naturally as the solution to an optimization problem. If carefully stated, this approach can be set up to also handle the situation where the system of equations (4) is (near-) singular, in the sense that either no solutions exist or all solutions are irregular and nonsmooth.

Yield Curve Fitting with N -Knot Splines

In this section, we discuss a number of yield Curve algorithms based on polynomial and exponential (tension) splines of various degrees of differentiability. Throughout, we assume that we can select and arrange our benchmark set of securities to guarantee that the maturities of the benchmark securities satisfy

$$T_i > T_{i-1}, \quad i = 2, 3, \dots, N \quad (7)$$

where the inequality is strict. Equation (7) constitutes a “spanning” condition and allows us to select the N deal maturities as distinct knots in our splines.

Bootstrapping

A simple—and widely used—approach involves assuming that the yield curve $y(T)$ is a continuous piecewise linear spline. This assumption allows for a straightforward solution procedure, known as *bootstrapping*. Specifically, we proceed according to the algorithm:

1. Let $y(t_j)$ be known for $t_j \leq T_{i-1}$, such that prices for benchmark securities $1, \dots, i-1$ are matched.
2. Make a guess for $y(T_i)$; linearly interpolate to find $y(t_j)$, $T_{i-1} < t_j < T_i$.
3. Compute V_i from the known values of $P(t_j)$, $t_j \leq T_i$.
4. If V_i equals the market value, stop. Otherwise return to equation (4).
5. If $i < N$, set $i = i + 1$ and repeat.

The updating of guesses when iterating over steps 4 and 6 can be handled by a standard one-dimensional root-search algorithm (e.g., the Newton–Raphson or secant methods).

With $y(T)$ being piecewise linear, the forward curve $f(T)$ (see equation 6) takes on a discontinuous saw-tooth shape, as shown in Figure 1. It may be tempting to replace the assumption of continuous piecewise linear yields with an assumption of continuous piecewise linear forwards, but such an interpolation rule turns out to be numerically unstable and prone to oscillations. However, we may

instead assume that the forward curve is piecewise flat—or, equivalently, that $\log P(T)$ is piecewise linear—which again allows for stable application of the bootstrapping principle. For reference, the forward curve resulting from this idea is also shown in Figure 1.

Catmull–Rom Splines

To ensure that the forward curve stays continuous, we need a yield curve that is at least once differentiable, that is, in C^1 . A common assumption involves setting $y(T)$ equal to a once differentiable Hermite cubic spline:

$$y(T) = a_{3,i}(T - T_i)^3 + a_{2,i}(T - T_i)^2 + a_{1,i}(T - T_i) + a_{0,i}, \quad T \in [T_i, T_{i+1}] \quad (8)$$

for a series of constants $a_{3,i}$, $a_{2,i}$, $a_{1,i}$, $a_{0,i}$ to be determined from exogenously given values of $y(T_i)$, $y(T_{i+1})$, $y'(T_i)$, and $y'(T_{i+1})$. In practice, the first derivatives $y'(T_i) = dy(T_i)/dT$ are most often specified as finite difference coefficients $y'(T_i) = (y(T_{i+1}) - y(T_{i-1})) / (T_{i+1} - T_{i-1})$, giving rise to the so-called *Catmull–Rom spline* [3].

Solving for the Catmull–Rom spline that satisfies equation (4) involves an iterative search for the unknown levels $y(T_1), \dots, y(T_N)$, with each iteration involving a construction of the spline and a computation of $\mathbf{P} = (e^{-y(t_1)t_1}, \dots, e^{-y(t_M)t_M})$. Any standard multidimensional root-search algorithm can be applied here. We notice that the Catmull–Rom spline links values of $y(T)$, $T \in (T_i, T_{i+1})$ to only four knots, namely, $y(T_{i-1})$, $y(T_i)$, $y(T_{i+1})$, $y(T_{i+2})$,

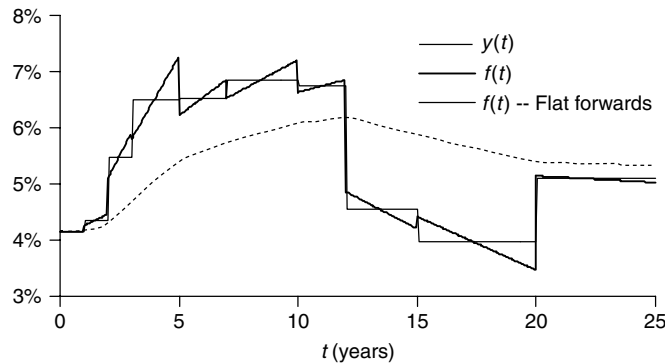

Figure 1 Yield and forward curve (linear yield bootstrap)

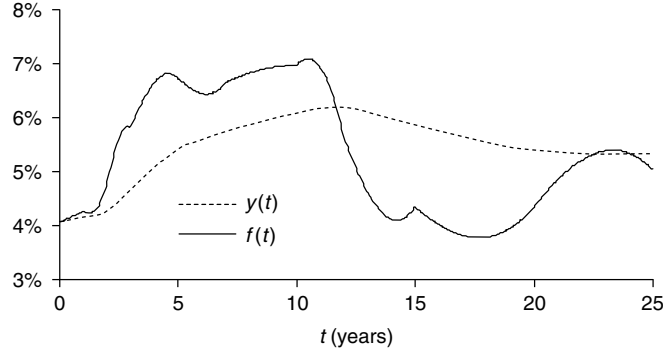

Figure 2 Yield and forward curve (Catmull–Rom spline)

which simplifies the causality structure in the model and allows for application of “near-bootstrap” methods. Figure 2 shows typical yield and forward curves generated by the Catmull–Rom spline approach, using the same benchmark set as was used to construct Figure 1.

We can easily extend the procedure above beyond Catmull–Rom splines to more complicated C^1 cubic splines in the Hermite class; for instance, it is relatively straightforward to add *tension* to the Catmull–Rom spline. See [7] for details.

C^2 Cubic Splines

While the spline method introduced in the previous section often produces acceptable yield curves, the method is heuristic in nature and ultimately does not produce a smooth forward curve. To improve on the latter, one alternative is to remain in the realm of cubic splines, but now insist that the curve is twice differentiable everywhere on $[T_1, T_N]$. The resulting spline equations are

$$\begin{aligned}
 y(T) = & \frac{(T_{i+1} - T)^3}{6h_i} y_i'' + \frac{(T - T_i)^3}{6h_i} y_{i+1}'' \\
 & + (T_{i+1} - T) \left(\frac{y_i}{h_i} - \frac{h_i}{6} y_i'' \right) + (T - T_i) \\
 & \times \left(\frac{y_{i+1}}{h_i} - \frac{h_i}{6} y_{i+1}'' \right), \quad T \in [T_i, T_{i+1}]
 \end{aligned} \tag{9}$$

where $y_i'' = d^2 y(T_i)/dT^2$, $y_i = y(T_i)$, and $h_i = T_{i+1} - T_i$. Continuity of the second derivative across

the $\{T_i\}$ knots requires that y_i'' and y_i , $i = 1, \dots, N$, are connected through a tri-diagonal linear system of equations; see [2, 10] for the well-known details. Full specification of this system of equations requires exogenous characterization of behavior at the boundaries T_1 and T_N . The most common—and often best—specification is that of the *natural spline*, where we set $y_1'' = y_N'' = 0$.

As for the Catmull–Rom spline, solving the C^2 cubic spline yield curve that satisfies equation (4) involves a numerical search for the unknown levels^c $y_1, \dots, y_N$. The fitting problem is typically good-natured, and virtually all standard root-search packages can tackle it successfully. References [1, 14] use a simple Gauss–Newton scheme, whereas [6] applies a fixed-point-type iteration. Both these simple suggestions are most likely outperformed by the backtracking Newton method or the Broyden method, both of which are described in Press *et al.* [10]. An example of the forward curve arising from this approach can be seen in Figure 3 (the case $\sigma = 0$).

While the C^2 cubic spline discussed here has attractive smoothness, it is not necessarily an ideal representation of the yield curve. As discussed in [1, 6], among others, twice differentiable cubic spline yield curves are often subject to oscillatory behavior, spurious inflection points, poor extrapolation behavior, and nonlocal behavior when prices in the benchmark set are perturbed. In particular, perturbation of a single benchmark price can cause a slow-decaying “ringing” effect on the C^2 cubic yield curve, with the effect of the perturbation of the benchmark instrument price spilling into the entire yield curve. This behavior is a nuisance in risk-management applications, and is much less present in curves constructed by

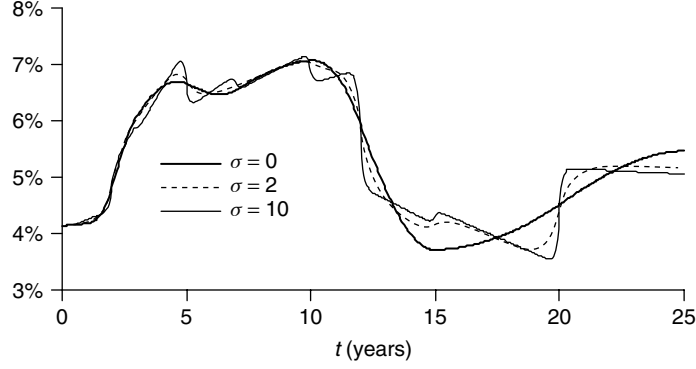

Figure 3 Forward curve (tension spline)

bootstrapping or by the Hermite spline approach.^d A pragmatic, but inherently inconsistent, approach is to use a C^2 cubic spline for pricing purposes only, but use bootstrapping when stability to perturbations is required. A more sophisticated approach is discussed below.

C^2 Tension Splines

Hermite cubic splines are less prone to nonlocal perturbation behavior than C^2 cubic splines, but accomplish this in a somewhat *ad hoc* fashion by giving up one degree of differentiability. Rather than taking such an extreme step, one wonders whether there may be a way to retain the C^2 feature of the cubic spline, yet still allow control of the curve locality and “stiffness”. As it turns out, an attractive remedy to the shortcomings of the pure C^2 cubic spline is to insert some *tension* in the spline, that is, to apply a tensile force to the end points of the spline. Details about this idea can be found in [12]; when applied to the yield Curve setting, the construction involves a modification of the cubic equation (9) for $y(T)$ to

$$\begin{aligned}
 y(T) = & \left(\frac{\sinh(\sigma(T_{i+1} - T))}{\sinh(\sigma h_i)} - \frac{T_{i+1} - T}{h_i} \right) \frac{y_i''}{\sigma^2} \\
 & + \left(\frac{\sinh(\sigma(T - T_i))}{\sinh(\sigma h_i)} - \frac{T - T_i}{h_i} \right) \frac{y_{i+1}''}{\sigma^2} \\
 & + y_i \frac{T_{i+1} - T}{h_i} + y_{i+1} \frac{T - T_i}{h_i}, \\
 & T \in [T_i, T_{i+1}]
 \end{aligned} \tag{10}$$

where $\sigma \geq 0$ is the *tension factor*, and where we recall the definition $h_i = T_{i+1} - T_i$.

Among the properties of the tension splines are the facts that setting $\sigma = 0$ will recover the ordinary C^2 cubic spline, whereas letting $\sigma \rightarrow \infty$ will make the tension spline uniformly approach a linear spline (i.e., the spline we used in the section Bootstrapping). Loosely, we can thus think of a tension spline as a twice differentiable hybrid between a cubic spline and a linear spline. Equally loosely, as we increase σ , inflections and ringing in the cubic spline are gradually “stretched” out of the curve, accompanied by rising (absolute values of) second derivatives at the knots.

More details on tension splines in yield Curve application can be found in [1], which also contains a discussion of computationally efficient local spline bases and the usage of T -dependent tension factors for additional curve control. For our purposes here, it suffices to note that equation (10) is structurally similar to equation (9), and also allows for a tri-diagonal matrix equation linking y_i'' and y_i , $i = 1, \dots, N$. The solution procedure for the yield curve is therefore the same as in the section C^2 Cubic Splines. Figure 3 illustrates the effect of varying the tension factor on the shape of the instantaneous forward curve $f(t)$; notice how increasing the tension parameter gradually moves us from smooth cubic spline behavior to bootstrap behavior. Examples of how the tension parameter dampens ringing in the forward curve after input perturbations can be found in [1].

Nonparametric Methods

The techniques we outlined so far generally suffice for the construction of a discount curve from a “clean” set of non-duplicate benchmark securities, including the carefully selected set of liquid staggered-maturity deposits, futures, and swaps, that most banks assemble for the purpose of constructing a Libor yield curve. In some settings, however, the benchmark set may be significantly less well structured, involving illiquid securities with little order in their cash-flow timing and considerable noise in their prices. This situation may, say, arise when one attempts to construct a yield curve from corporate bonds.

When the input benchmark set is noisy, a straight solution of (4) may be erratic or may not exist. To overcome this, and to reflect that noise in the input data may make us content to solve (4) only to within certain error bounds, we now proceed to replace this equation by minimization of a penalized least-squares norm. Specifically, define the space $\mathcal{A} = C^2[t_1, t_M]$ of all twice differentiable functions $[t_1, t_M] \rightarrow \mathbb{R}$ and introduce the M -dimensional discount vector

$$\mathbf{P}(y) = (e^{-y(t_1)t_1}, \dots, e^{-y(t_M)t_M}) \quad (11)$$

Also, let $\mathbf{W}$ be a diagonal $N \times N$ weighting matrix. Then, as our best estimate $\hat{y}$ of the yield curve we may use

$$\hat{y} = \arg \min_{y \in \mathcal{A}} \mathcal{I}(y) \quad (12)$$

$$\begin{aligned} \mathcal{I}(y) \equiv & \frac{1}{N} (\mathbf{V} - \mathbf{cP}(y))^\top \mathbf{W}^2 (\mathbf{V} - \mathbf{cP}(y)) \\ & + \lambda \left(\int_{t_1}^{t_M} [y''(t)^2 + \sigma^2 y'(t)^2] dt \right) \end{aligned} \quad (13)$$

where λ and σ are positive constants. The norm $\mathcal{I}(y)$ consists of three separate terms:

- A least-squares penalty term

$$\begin{aligned} & \frac{1}{N} (\mathbf{V} - \mathbf{cP}(y))^\top \mathbf{W}^2 (\mathbf{V} - \mathbf{cP}(y)) \\ & = \frac{1}{N} \sum_{i=1}^N W_i^2 \left(V_i - \sum_{j=1}^M c_{ij} e^{-y(t_j)t_j} \right)^2 \end{aligned} \quad (14)$$

where W_i is the i th diagonal element of $\mathbf{W}$. This term is an outright precision-of-fit norm and measures the degree to which the constructed discount curve can replicate input security prices. The weight-matrix $\mathbf{W}$ can be used to express the relative importance of the various securities in the benchmark set, or to turn price errors into yield errors.

- A weighted smoothness term $\lambda \int_{t_1}^{t_M} y''(t)^2 dt$, penalizing high second-order gradients of y to avoid kinks and discontinuities.
- A weighted curve-length term $\lambda \sigma^2 \int_{t_1}^{t_M} y'(t)^2 dt$, penalizing oscillations and excess convexity/concavity.

To construct the yield curve, we have replaced the nonlinear root-search problems encountered in the section Yield Curve Fitting with N -knot Splines with the functional optimization problem (12). Fortunately, the latter approach can be linked to that of the former by the following result, which can be shown by variational methods.

Proposition 1 *The curve $\hat{y}$ that satisfies equation (12) is a natural exponential tension spline with tension factor σ and knots at all cash-flow dates $t_1, t_2, \dots, t_M$.*

Proposition 1 establishes that the curve we are looking for is a tension spline with tension factor σ , but does not, in itself, allow us to identify the optimal spline directly, beyond the fact that (i) it is a natural spline with boundary conditions $y''(t_1) = y''(t_M) = 0$; (ii) it has knots at all t_i . Identification of the correct tension spline involves solving for unknown levels $y(t_1), y(t_2), \dots, y(t_M)$ to directly optimize equation (13). This optimization problem can be solved by standard methods, for example, by use of the Levenberg–Marquardt method, or the Gauss–Newton method in [1, 14].

Remark 1 If we let $\sigma = 0$, the solution to the optimization problem becomes a *cubic smoothing spline*; see [14] for more details on this case.

Choice of Smoothing Parameter

The parameter λ may be specified exogenously by the user, as a way to provide a trade-off between pricing accuracy and curve regularity. In practice, however, a good magnitude of λ may sometimes be

hard to ascertain by inspection, and a procedure to estimate λ directly from the data is often useful. One possibility is to use a cross-validation approach, either outright or through the more efficient generalized cross-validation (GCV) criterion in [4]. Some results along these lines can be found in [14], for instance. A more pragmatic approach is to specify a target value for the least-squares term in equation (13), iterating on λ until the target is met; in general, we would expect the least-squares error term to increase monotonically with λ . Most trading desks should have little difficulty specifying a meaningful least-squares target error directly from, say, observed bid–offer spreads. We note that the target error value may be set to zero, if a perfect fit to benchmark securities is required.

Special Topics

While our discussion of curve construction algorithms generally relied on the notion that the forward curve should ideally be *smooth*, there may be circumstances where we want to make exceptions. For instance, it may be reasonable to expect instantaneous forwards to jump on or around meetings of monetary authorities, such as the Federal Reserve in the United States. In addition, other “special” situations may exist that might warrant introduction of discontinuities into the forward curve. A well-known example is the turn-of-year (TOY) effect where short-dated loan premiums spike for loans between the last business day of the year and the first business day of the next year. One common way of incorporating TOY-type effects is to exogenously specify an *overlay curve* $\epsilon_f(t)$ on the instantaneous forward curve. Specifically, the forward curve $f(t)$ is written as

$$f(t) = \epsilon_f(t) + f^*(t) \quad (15)$$

where $\epsilon_f(t)$ is user-specified—and most likely contains discontinuities around special events dates—and $f^*(t)$ is unknown. The yield curve construction problem is then subsequently applied to the construction of $f^*(t)$, using algorithms such as those discussed earlier.

We should note that the curve construction algorithms outlined in this article are meant only for single-currency applications. In a setting with multiple currencies, care must be taken to ensure that discount curves in different currencies are properly

related, in the sense that they together replicate the prices for foreign exchange forward agreements, as well as cross-currency floating–floating basis swaps. In general, the ability to match currency markets requires that the discount curve and the forward rate curve (e.g., the Libor curve) be separated into two entities separated by a cross-currency spread; see [5]. It is normally straightforward to embed a single-currency yield curve solver into a cross-currency setting, for instance, by means of an iterative adjustment to the price vector $\mathbf{V}$ in equation (4). Similar techniques can be used to accommodate the so-called *tenor* basis, that is, the fact that different Libor tenors (e.g., 3-month versus 6-month) in practice do not swap flat against each other.

End Notes

^aOwing to their daily mark-to-market provision, Eurodollar futures contracts do not allow for a pricing expression of the form (1), so a preprocessing step is normally employed to convert the futures rate quote to a forward rate quote. See **Eurodollar Futures and Options**.

^bSee, for example, [13] for a discussion of the pitfalls associated with curve interpolators that work directly on the discount function $P(T)$ (as in [8]).

^cA more contemporary approach replaces this search with a search for coefficients in a local spline basis. Andersen [1] contains more details on this.

^dIntuitively, this is because linear and Hermite splines link values of $y(T)$ to only a few (2 and 4, respectively) of the values $y(T_i)$, $i = 1, \dots, N$. The C^2 cubic spline, on the other hand, links $y(T)$ to *all* $y(T_i)$, $i = 1, \dots, N$.

Stochastic Volatility Interest Rate Models

Stochastic volatility has been widely used to model implied volatility smiles for European caps and swaptions. We discuss models of the yield curve that incorporate stochastic volatility, defined as randomness in the volatility of the bond prices that is not spanned by movements in the yield curve. We argue that it is difficult to specify short rate models that exhibit unspanned stochastic volatility and that a more natural choice for construction of stochastic volatility models is the Heath, Jarrow, and Morton (HJM) or Libor Market Model framework. We then consider the specification of stochastic volatility interest rate models and survey some of the stochastic volatility models found in the literature.

“Unspanned” Stochastic Volatility

Stochastic volatility interest-rate models are models that prescribe moves in the volatility of rates that cannot directly be inferred from the shape or the level of the yield curve. Let $P(t, T)$ be the time t price of a zero-coupon bond maturing at time T and let the time t continuously compounded forward rate for deposit over the interval $[T, T + dT]$ be given by

$$f(t, T) = -\frac{\partial \ln P(t, T)}{\partial T}, t \leq T \quad (1)$$

Assume that interest rates evolve continuously. As shown by Heath *et al.* [9], absence of arbitrage implies that the forward rates have to evolve according to (see **Heath–Jarrow–Morton Approach** for the HJM model)

$$df(t, T) = \sigma(t, T) \cdot \left(\int_t^T \sigma(t, s) ds \right) dt + \sigma(t, T) \cdot dW(t) \quad (2)$$

where W is a vector Brownian motion under the risk-neutral measure, and $\{\sigma(t, T)\}_{t \leq T}$ some family of vector processes.

A “true” stochastic volatility model has the property that there exists some stochastic process z and at least one maturity U , so that

$$\frac{\partial \sigma(t, U)}{\partial z(t)} \neq 0 \quad (3a)$$

and

$$\frac{\partial f(t, T)}{\partial z(t)} = 0 \quad (3b)$$

for all T .

In other words, “true” or “unspanned” stochastic volatility is when there is uncertainty in the volatility of the rates, which cannot be fully hedged by taking positions in bonds. There is considerable empirical evidence of unspanned stochastic volatility in interest rates and interest rate options markets (see, e.g., Casassus *et al.* [5]).

It is very difficult to specify a traditional short-rate model that can be categorized as a true stochastic volatility model. This is so because stochastic short-rate volatility will tend to show up as a second factor that the bond prices will depend on. Consider, for example, the model by Fong and Vasicek [7]:

$$\begin{aligned} dr(t) &= \kappa(\theta - r(t)) dt + \sqrt{v(t)} dW_1(t) \\ dv(t) &= \beta(\alpha - v(t)) dt + \varepsilon \sqrt{v(t)} dW_2(t) \\ dW_1(t) \cdot dW_2(t) &= \rho dt \end{aligned} \quad (4)$$

where $\kappa, \theta, \beta, \alpha, \varepsilon, \rho$ are constants, and W_1 and W_2 Brownian motions under the risk-neutral measure. In this model, we have

$$\begin{aligned} P(t, T) &= E_t \left[e^{-\int_t^T r(u) du} \right] \\ &= E \left[e^{-\int_t^T r(u) du} | r(t), v(t) \right] \\ &\equiv P(t, T; r(t), v(t)) \end{aligned} \quad (5)$$

So the bond price becomes a function of two stochastic variables. Hence, we can invert the system and infer the level of both the short rate and the short rate volatility from any two points on the yield curve. Thus, the model is not a true stochastic volatility model. This is also the case for the Longstaff and Schwartz [13] model and other early attempts to produce stochastic volatility yield curve model.

In fact, it is also the case for attempts to formulate a stochastic volatility yield curve model in the context of the Markov functional approach by Hunt *et al.* [12] (see **Markov Functional Models** for the Markov functional models).

So, as observed by Andreasen *et al.* [4], the most straightforward way of formulating a stochastic volatility yield curve model is to directly use the

HJM approach, or equivalently the Libor market model approach, and directly specify the stochastic nature of the bond or forward rate volatility structure (see **LIBOR Market Model** for the Libor market model). In the HJM modeling approach, we see that it is easy to specify a volatility structure satisfying equation (3a,b). We could, for example, set $\sigma(t, T) = c \cdot \sqrt{z(t)}$ for some constant c and some Markov process z .

Intuitively, if the volatility is nondeterministic, then the minimal number of state variables in a HJM model is two, so with the addition of stochastic volatility the number of state variables in a “true” stochastic volatility HJM model is at least three. In fact, Dufresne and Goldstein [6] provide a partial differential equation (PDE)-based argument to justify that the minimal number of state variables for a “true” stochastic volatility interest rate model is three.

Model Specifications

In the following, we present some examples of stochastic volatility interest-rate models. A Libor market model is based on a discrete time grid $0 = t_0 < t_1 < \dots$. Let

$$L_k(t) = \frac{1}{t_{k+1} - t_k} \left(\frac{P(t, t_k)}{P(t, t_{k+1})} - 1 \right) \quad (6)$$

be the forward Libor rate over the period $[t_k, t_{k+1}]$. Under absence of arbitrage, we have

$$\begin{aligned} dL_k(t) = & \vartheta_k(t) \cdot \sum_{j=i+1}^k \frac{\delta_j \vartheta_j(t)}{1 + \delta_j L_j(t)} dt \\ & + \vartheta_k(t) \cdot d\tilde{W}(t), t_{i-1} \leq t < t_i \end{aligned} \quad (7)$$

for a discrete set of vector processes $\{\vartheta_k(t)\}_{t \leq t_k}$ and $\tilde{W}$ being a vector Brownian motion under the martingale measure with $B(t) = \left(\prod_{j=0}^{n-1} P(t_j, t_{j+1}) \right) \times P(t, t_{n+1})$, $t_n \leq t < t_{n+1}$ as numeraire.

Andersen and Brotherton-Ratcliffe [3] consider an uncorrelated stochastic volatility extended constant elasticity of variance (CEV) Libor market model

$$\begin{aligned} \|\vartheta_k(t)\| &= \sqrt{z(t)} \lambda_k(t) L_k(t)^\beta \\ dz(t) &= \theta(1 - z(t)) dt + \varepsilon \sqrt{z(t)} dZ(t) \\ dL_k(t) \cdot dz(t) &= 0 \end{aligned} \quad (8)$$

where Z is a Brownian motion, λ_k is a time-dependent function, and θ, ε are constants. Andersen and Brotherton-Ratcliffe suggest asymptotic expansions for solving for European swaption prices based on approximation of the swap rate dynamics.

Piterbarg [16] replaces the CEV assumption for the forward rate volatility with a linear one:

$$\begin{aligned} \|\vartheta_k(t)\| &= \sqrt{z(t)} \lambda_k(t) [\beta_k(t) L_k(t) \\ &\quad + (1 - \beta_k(t)) L_k(0)] \\ dz(t) &= \theta(1 - z(t)) dt + \varepsilon \sqrt{z(t)} dZ(t) \\ dL_k(t) \cdot dz(t) &= 0 \end{aligned} \quad (9)$$

Piterbarg shows that using time- and tenor-dependent skew coefficients ($\beta_k(t)$) improves the simultaneous fit to implied cap and swaption skews and smiles. Piterbarg solves for European swaption prices using Markovian projection techniques applied to the process for the swap rate.

Andersen and Andreasen [2] present a one-factor Markov HJM model with uncorrelated stochastic volatility:

$$\begin{aligned} P(t, T) &= \frac{P(0, T)}{P(0, t)} e^{-G(t, T)x(t) - \frac{1}{2}G(t, T)^2 y(t)} \\ G(t, T) &= \frac{1 - e^{-\kappa(T-t)}}{\kappa} \\ dx(t) &= (-\kappa x(t) + y(t)) dt + \eta(t) dW(t) \\ dy(t) &= (\eta(t)^2 - 2\kappa y(t)) dt \\ \eta(t) &= \lambda(t) \sqrt{z(t)} [\beta R(t, s, T) \\ &\quad + (1 - \beta) R(0, s, T)] \\ dz(t) &= \theta(1 - z(t)) dt + \varepsilon \sqrt{z(t)} dZ(t) \\ dW(t) \cdot dZ(t) &= 0 \end{aligned} \quad (10)$$

where W, Z are Brownian motions under the risk-neutral measure and

$$R(t, s, T) = -\frac{1}{T - s} \ln \frac{P(t, T)}{P(t, s)} \quad (11)$$

is a continuously compounded zero-coupon forward rate that is linked to the choice of calibration instruments. Piterbarg’s Markovian projection techniques are used for calibration of the model. Owing to the limited number of state variables (equation 3), the model allows for finite difference solution and efficient simulations.

Andreasen [1] presents a multifactor Markov HJM model that extends equation (10) and allows for time- and tenor-dependent skew as in equation (9). For a selected set of (continuously compounded) forward rates with tenors, the dynamics are similar to the forward rate dynamics in equation (9) (*see also Markovian Term Structure Models*).

The models discussed so far are all based on zero correlation between the interest rates and the stochastic volatility process. The reason for this choice is mainly technical: if it were not the case, then the stochastic volatility process would be different for different annuity measures (*see Forward and Swap Measures*) and it would often include complicated terms in its drift. This would, in turn, make approximation of the swaption prices and thereby calibration more complicated.

The reason for the choice of square-root process for the stochastic volatility is also tractability. The square-root process admits computation of exponential moments in closed form and this can either be used for approximation of at-the-money option prices as in Piterbarg [16] or for direct computation of option prices *via* numerical inversion of Fourier transforms. An example of the latter is the model in equation (10) with level independent but correlated volatility:

$$\begin{aligned}\eta(t) &= \lambda(t)\sqrt{z(t)} \\ dW(t) \cdot dZ(t) &= \rho(t) dt\end{aligned}\quad (12)$$

where ρ is a time-dependent function. For this model, the processes for the maturity U forward bond price $P(t, U)/P(t, T)$ and the stochastic volatility factor, z , are

$$\begin{aligned}\frac{d(P(t, U)/P(t, T))}{(P(t, U)/P(t, T))} &= \lambda(t)\sqrt{z(t)}(G(t, T) \\ &\quad - G(t, U)) dW^T(t) \\ dz(t) &= \theta(1 - z(t)) dt + \varepsilon\sqrt{z(t)} dZ^T(t) \\ &\quad - \rho\varepsilon z(t)\lambda(t)G(t, T) dt\end{aligned}\quad (13)$$

where W^T, Z^T are correlated Brownian motions under the maturity T forward measure. So, essentially, the processes in equation (13) are similar to the single-asset stochastic volatility model of Heston [11] but with time-dependent parameters. So, as shown by Dufresne and Goldstein [6], this means that the prices of caplets and options on zero-coupon bonds can be

found by numerical inversion of Fourier transforms in the same way as for the Heston model. Swaption prices can, in turn, be found by approximating swaptions as options on zero-coupon bonds by duration matching as suggested by Munk [14].

As an alternative to the square-root process for the stochastic volatility, Rebonato [15] and Henry-Labordere [10] consider the SABR-based stochastic volatility Libor market models with correlated stochastic volatility of the form (*see [8] for the SABR model*).

$$\begin{aligned}dL_k(t) &= z\lambda_k(t)L_k(t)^{\beta_k} dW_k(t) + O(dt), \\ k &= 1, \dots, n \\ dz(t) &= v z(t) dW_{n+1}(t) \\ dW_i(t) \cdot dW_j(t) &= \rho_{ij}(t) dt, \\ i, j &= 1, \dots, n+1\end{aligned}\quad (14)$$

where v is a constant and $\{\rho_{ij}(t)\}$ is time dependent. Henry-Labordere provides asymptotic expansion results for the prices of caplets and swaptions based on hyperbolic geometry methods.

JESPER ANDREASEN

Heath–Jarrow–Morton Approach

Basics

We consider a financial market model living on a filtered probability space $(\Omega, \mathcal{F}, F, P)$, where $F = \{\mathcal{F}_t\}_{t \geq 0}$ and P is the objective probability measure. The basis is assumed to carry a standard m -dimensional P -Wiener process $\bar{W}$.

Our main object of study is the zero coupon bond market, and we denote the price by $p(t, T)$, at t , of a zero coupon bond maturing at T .

We define, as usual, the *instantaneous forward rate with maturity T , contracted at t* , by

$$f(t, T) = -\frac{\partial \log p(t, T)}{\partial T} \quad (1)$$

The instantaneous *short rate at time t* is defined by $r(t) = f(t, t)$.

The HJM Framework

We now turn to the specification of the Heath–Jarrow–Morton (HJM) framework (see [13]). We start by specifying everything under a given objective measure P .

Assumption 1 We assume that, for every fixed $T > 0$, the forward rate $f(\cdot, T)$ has a stochastic differential, which, under the objective measure P , is given by

$$df(t, T) = \alpha(t, T) dt + \sigma(t, T) d\bar{W}_t \quad (2)$$

$$f(0, T) = f_{\text{in}}(0, T) \quad (3)$$

where, for each fixed T , $\alpha(\cdot, T)$ and $\sigma(\cdot, T)$ are adapted processes. The curve f_{in} is the initially observed forward rate curve.

It is important to note that the HJM approach to model the evolution of interest rates is not a proposal of a specific *model*, like, for example, the Cox–Ingersoll–Ross model (see **Cox–Ingersoll–Ross (CIR) Model**). It is, instead, a *framework* that is used for analyzing interest-rate models. In fact, every interest-rate model can be equivalently formulated in forward rate terms. To turn the HJM

framework into a *model*, we have to specify the volatility and drift structure, that is, we have to specify σ and α .

There are two main advantages of the HJM approach: First, the forward rate volatility structure $\sigma(t, T)$ is an *input* to the model, whereas in a factor model such as a short rate model (see **Term Structure Models**), it would be an output. Second, by using the observed forward rate curve as an initial condition, we automatically obtain a perfect fit to the observed yield curve.

The first main result shows how the bond price dynamics are determined by the forward rate dynamics.

Proposition 1 *If the forward rate dynamics are given by equation (2) then the induced bond price dynamics are given by*

$$\begin{aligned} dp(t, T) = & p(t, T) \{ r(t) + A(t, T) \\ & + \frac{1}{2} \|S(t, T)\|^2 \} dt \\ & + p(t, T) S(t, T) d\bar{W}_t \end{aligned} \quad (4)$$

where $\|\cdot\|$ denotes the Euclidean norm, and

$$\begin{cases} A(t, T) = -\int_t^T \alpha(t, s) ds \\ S(t, T) = -\int_t^T \sigma(t, s) ds \end{cases} \quad (5)$$

Absence of Arbitrage

Using proposition 1 above, an application of the Girsanov Theorem gives us the following basic result concerning absence of arbitrage.

Theorem 1 (HJM Drift Condition). *Assume that the family of forward rates is given by equation (2). Then the induced bond market is arbitrage free if and only if there exists a d -dimensional column-vector process $\lambda(t) = [\lambda_1(t), \dots, \lambda_d(t)]^*$ with the property that for all $T \geq 0$ and for all $t \leq T$, we have*

$$\alpha(t, T) = \sigma(t, T) \int_t^T \sigma(t, s)^* ds - \sigma(t, T) \lambda(t) \quad (6)$$

In these formulas $*$ denotes transpose.

Martingale Modeling

In many cases, the specification of the forward rate dynamics is done directly under a martingale

measure Q as

$$\begin{aligned} df(t, T) &= \alpha(t, T) dt + \sigma(t, T) dW_t \\ f(0, T) &= f_{\text{in}}(0, T) \end{aligned} \quad (7)$$

where W is a (d -dimensional) Q -Wiener process. In this setting, absence of arbitrage is no longer an issue, but we have to give conditions that guarantee that all the induced bond price processes have the correct martingale dynamics, that is, short rate as their local rate of return. This directly follows from the earlier result by setting $\lambda = 0$.

Proposition 2 (HJM Drift Condition). *Under the martingale measure Q , the processes α and σ must satisfy the following relation, for every t and every $T \geq t$.*

$$\alpha(t, T) = \sigma(t, T) \int_t^T \sigma(t, s)^* ds \quad (8)$$

Thus when specifying the forward rate dynamics, (under Q) we may freely specify the volatility. The drift is then uniquely determined. In practical applications, one thus has to specify the number d of Wiener processes as well as the volatility structure.

It is common to assume a deterministic volatility structure, and then try to estimate this as well as the number d by principal component analysis. The deterministic volatility is very tractable since it will lead to Gaussian forward rates (see **Gaussian Interest-Rate Models**) and lognormal bond prices. Analytical formulas for bond options are easily available.

The HJM approach has been extended to include a driving marked point process in [4], a random measure [3], a Levy process [8], a Gaussian random field [15], and a Levy field [1].

The Musiela Parameterization

In many applications, it is more natural to use time to maturity, rather than time of maturity, to parameterize bonds and forward rates, and this approach was first described in [6] and [16]. If we denote time to maturity by x , then we have $x = T - t$, and in terms of x , the forward rates are defined as follows.

Definition 1 *For all $x \geq 0$ the forward rates $r_t(x)$ are defined by the relation*

$$r_t(x) = f(t, t + x) \quad (9)$$

and we denote by r_t the forward rate curve $x \mapsto r_t(x)$ at time t . We can thus view r as a process taking values in some Hilbert space $\mathcal{H}$ of forward rate curves.

Suppose now that we have the standard HJM-type model for the forward rates under a martingale measure Q

$$df(t, T) = \alpha(t, T) dt + \sigma_0(t, T) dW_t \quad (10)$$

where σ_0 denotes the HJM volatility structure. The question is to find the Q -dynamics for $r(t, x)$, and we have the following result.

Proposition 3 (Musiela parameterization). *Assume that the forward rate dynamics under Q are given by (10). Then*

$$dr_t(x) = \left\{ \frac{\partial}{\partial x} r_t(x) + D(t, x) \right\} dt + \sigma(t, x) dW_t \quad (11)$$

where

$$\begin{aligned} \sigma(t, x) &= \sigma_0(t, t + x) \\ D(t, x) &= \sigma(t, x) \int_0^x \sigma(t, s)^* ds \end{aligned} \quad (12)$$

If the volatility σ is of the simple deterministic form $\sigma_t(x) = \sigma(x)$, then the Musiela equation mentioned above takes the form

$$dr_t = \{\mathbf{F}r_t + D\} dt + \sigma dW_t$$

where $D(x) = \sigma(x) \int_0^x \sigma(s) ds$ and the operator $\mathbf{F}$ is given by $\partial/\partial x$. In this case, the forward rate equation is an infinite dimensional linear stochastic differential equation (SDE) on $\mathcal{H}$ with formal solution

$$r_t = e^{\mathbf{F}t} r_0 + \int_0^t e^{\mathbf{F}(t-s)} D ds + \int_0^t e^{\mathbf{F}(t-s)} \sigma dW_s \quad (13)$$

where the semigroup $e^{\mathbf{F}t}$ is left translation, that is, $e^{\mathbf{F}t} f(x) = f(t + x)$.

Geometric Interest Rate Theory

Assume that the volatility process σ is of the Markovian form $\sigma_t(x) = \sigma(r_t, x)$. Then the Musiela equation for the r process is an infinite dimensional SDE and we write it compactly as

$$dr_t = \mu(r_t) dt + \sigma(r_t) dW(t) \quad (14)$$

where

$$\begin{aligned} \mu(r, x) &= \frac{\partial}{\partial x} r(x) + D(r, x) \\ D(r, x) &= \sigma(r, x) \int_0^x \sigma(r, s) ds \end{aligned} \quad (15)$$

We can thus view μ and σ as vector fields on $\mathcal{H}$, and we now formulate a couple of natural problems:

1. Consider a given parameterized family $\mathcal{G}$ of forward rate curves, such as the Nelson–Siegel family, where forward rates are parameterized as

$$G(z, x) = z_1 + z_2 e^{-z_3 x} + z_4 x e^{-z_3 x} \quad (16)$$

where $z_1, \dots, z_4$ are the parameters. The question is now under which conditions this family is *consistent* with the dynamics of the interest-rate model mentioned above? Here consistency is interpreted in the sense that, given an initial forward rate curve in $\mathcal{G}$, the interest-rate model will (with probability 1) produce forward rate curves belonging to the given family $\mathcal{G}$.

2. When does the given, inherently infinite dimensional, interest-rate model admit a *finite dimensional Markovian state space realization*, that is, when can the r process be realized by a system of the form

$$\begin{aligned} dZ_t &= a(Z_t) dt + b(Z_t) dW_t \\ r_t(x) &= G(Z_t, x) \end{aligned} \quad (17)$$

where Z (interpreted as the state vector process) is a finite dimensional diffusion, $a(z)$, $b(z)$ and $G(z, x)$ are deterministic functions and W is the same Wiener process as in equation (11).

Consistency

A finitely parameterized family of forward rate curves is a real-valued function of the form $G(z, x)$ where

z lies in some open subset of R^k , that is, for each fixed parameter vector z , we have the forward rate curve $x \mapsto G(z, x)$. A typical example is the Nelson–Siegel forward curve family in equation (16). The mapping G can also be viewed as a mapping $G : \mathcal{Z} \rightarrow \mathcal{H}$, and we now define the *forward curve manifold* $\mathcal{G}$ as the set of all forward rate curves produced by this family, that is., $\mathcal{G} = \text{Im}(G)$. The main result concerning consistency is as follows (see [2]).

Theorem 2 (Consistency). *The forward curve manifold $\mathcal{G}$ is consistent with the forward rate process if and only if,*

$$\begin{aligned} G'_x(z) + D(r) - \frac{1}{2} \sigma'_r(r) \sigma(r) &\in \text{Im}[G'_z(z)] \\ \sigma(r) &\in \text{Im}[G'_z(z)] \end{aligned} \quad (18)$$

hold for all $z \in \mathcal{Z}$ with $r = G(z)$, where D is defined in equation (15)

Here, G'_z and G'_x denote the Frechet derivative of G with respect to z and x , respectively.

The invariance problem was originally posed and studied in [2] and then extended and studied in great depth in [9] and [10]. In particular, it is shown in [9] that no nondegenerate arbitrage-free forward rate model is consistent with the Nelson–Siegel family.

Finite Dimensional Markovian Realizations

The existence of finite dimensional Markovian realizations (FDR) was first studied in [7] and [17] where sufficient conditions were given for particular choices of volatility structures (see **Markovian Term Structure Models**) for a detailed discussion of these special cases and more references. General necessary and sufficient results were first obtained in [5] and extended in [11]. For an arbitrary SDE in Hilbert space (with the forward rate SDE as a special case) of the form

$$dr_t = \mu(r_t) dt + \sigma(r_t) dW_t \quad (19)$$

the main general result is as follows.

Theorem 3 *The infinite dimensional SDE above admits an FDR if and only if the Lie algebra generated by the vector fields $\mu - 1/2 \sigma' \sigma$ and σ (where σ' denotes the Frechet derivative) has finite dimension*

(evaluated pointwise) in a neighborhood of the initial point r_0 .

All known examples in the literature are easy consequences of this general result, which can also be extended to stochastic volatility.

A special case of a finite dimensional realization is when a HJM model generates a Markovian short rate process. This corresponds to the case of a two-dimensional realization with running time and short rate as Z-factors. For the case of a short rate dependent volatility, it was shown in [14] that this occurs if and only if the model is affine. This result has a remarkable extension in [12], where it is shown that all models admitting finite dimensional realizations are, in fact, affine.

Forward and Swap Measures

Forward and swap measures are instances of general numeraire measures and are useful in interest-rate modeling and derivatives valuation. They take a zero-coupon bond and an annuity as the numeraire, respectively. Accordingly, the forward price of any asset and the instantaneous and Libor forward rates are martingales under the forward measure. Likewise, the forward swap rate is a martingale under the swap measure.

Assuming deterministic forward Libor or swap rate volatility leads to industry-standard Black–Scholes type pricing formulae for caplets and swaptions, respectively. The forward measure has other interesting applications in option pricing and in the Libor market model.

The forward measure was implicit in Merton’s [7] extension of the Black–Scholes model to stochastic interest rates. Early development and application of the concept appeared in [4] and [2]. The swap measure was discussed heuristically in [8] and formalized in [5]. Forward and swap measures are instances of the change of numeraire, as described heuristically in [6] and formalized in [3].

Numeraire Measures

We take as given a stochastic basis $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t \geq 0}, \mathbb{P})$ and a family $(A^i)_{i \in I}$ of semimartingales. Each A^i is viewed as the observable price process of a traded zero-dividend asset. We assume that this family is *arbitrage free* in that there exists a positive semimartingale $S = (S_t)$ such that $S_- > 0$, $S_0 = 1$, and SA^i is a martingale for every $i \in I$. Such a process S is called a *state price density* (or sometimes a *state price deflator*, cf. Duffie [1]), and we fix one such process. (In a complete market, it is unique.)

For our purposes here, we define an *asset* as a *semimartingale* C such that there exist a finite subset $J \subset I$ and bounded predictable processes δ^j satisfying $C = \sum_{j \in J} \delta^j A^j$ and $dC = \sum_{j \in J} \delta^j dA^j$. As such, an asset is the price process of a dynamic self-financing portfolio, for example, a (static) linear combination of A^i . The δ^j are called the *deltas* or the *hedge ratios*.

It can be shown that SC is a martingale for any asset C . This implies *the law of one price*: if two assets have almost surely the same prices at some time T , then they will have identical prices at all times $t < T$.

Let N be a *numeraire*, that is, a positive asset. For each $T > 0$ define the measure $\mathbb{P}^{N,T}$ on $\mathcal{F}_T$ via its Radon–Nikodym derivative by

$$\frac{d\mathbb{P}^{N,T}}{d\mathbb{P}} = \frac{S_T N_T}{N_0} \quad (1)$$

This is an equivalent probability measure and is called the associated *equivalent martingale measure* or *numeraire measure*. Since SN is a martingale, for any $s < T$, the restriction of $\mathbb{P}^{N,T}$ to $\mathcal{F}_s$ equals $\mathbb{P}^{N,s}$. (In an incomplete market, $\mathbb{P}^{N,T}$ depends on the choice of S .)

By an easy and well-known consequence of the Bayes’ rule, given a process C , the process SC is a $\mathbb{P}$ -martingale on $[0, T]$ if and only if C/N is a $\mathbb{P}^{N,T}$ -martingale on $[0, T]$. In particular, this holds for all assets C , yielding for $t \leq T$ the pricing formula,

$$C_t = N_t \mathbb{E}^{\mathbb{P}^{N,T}} \left[\frac{C_T}{N_T} \mid \mathcal{F}_t \right] \quad (2)$$

A useful technique is the *change of numeraire*. Suppose B is another numeraire and M is a $\mathbb{P}^{N,T}$ -martingale. Note that both $F := N/B$ and MF are $\mathbb{P}^{B,T}$ -martingales. Hence, using Itô’s product rule, $\int F_- dM + [M, F]$ is a $\mathbb{P}^{B,T}$ -local martingale. (Here, $[M, F]$ denotes the quadratic covariation of M and F .) Thus, dividing by F_- , so is $M + \int d[M, F]/F_-$. In particular, if F is continuous, then the $\mathbb{P}^{B,T}$ -drift of M equals $-d[M, \log F]$.

The Forward Measure

For a fixed maturity T , let us assume there exists an asset P^T such that $P_T^T = 1$. Such an asset, called the *T-maturity zero-coupon bond*, is necessarily positive and unique on $[0, T]$ by the law of one price. Its associated numeraire measure on $\mathcal{F}_T$ is called the *T-forward measure* and denoted $\mathbb{P}^T$. Its expectation operator is denoted $\mathbb{E}^T$. Since $P_T^T = 1$, by equation (1)

$$\frac{d\mathbb{P}^T}{d\mathbb{P}} = \frac{S_T}{P_0^T} \quad (3)$$

By equation (2), the T -forward price C/P^T of any asset C is a $\mathbb{P}^T$ -martingale on $[0, T]$ and

$$C_t = P_t^T \mathbb{E}^T[C_T | \mathcal{F}_t] \quad (4)$$

The price of a European thus equals the discounted expected value of its payoff.

Another important property is that *forward interest rates* are martingales under the forward measure. The simple (or Libor) T -forward rate $L^{T,\varepsilon}$ of length $\varepsilon > 0$ is defined by

$$L^{T,\varepsilon}_t := \frac{P^{T-\varepsilon}_t - P_t^T}{\varepsilon P_t^T} \quad (5)$$

Assuming that $P^{T-\varepsilon}$ is an asset, $P^{T-\varepsilon}/P^T$, and with it, $L^{T,\varepsilon}$ is a $\mathbb{P}^T$ -martingale.

As ε approaches zero, $L^{T,\varepsilon}_t$ approaches the instantaneous forward rate f_t^T defined by

$$f_t^T := -\frac{\partial \log(P_t^T)}{\partial T} \quad (6)$$

As such, in the limit, the instantaneous forward rate process f^T is also a $\mathbb{P}^T$ -martingale.

Option Pricing and Hedging

Consider a T -expiry option on an asset A (e.g. a stock or a bond) with time T -payoff $g(A_T)$, where $g(x)$ is a Borel function of linear growth. For example, $g(x) = \max(x - K, 0)$ for a call option struck at K . We wish to construct an asset C satisfying $C_T = g(A_T)$. From equation (4), we know that the only possible candidate is $C = P^T F$, where

$$F_t := \mathbb{E}^T[g(A_T) | \mathcal{F}_t] \quad (7)$$

This works if we assume the process $X := A/P^T$ is continuous and $F_t = f(t, X_t)$ for some $C^{1,2}$ function $f(t, x)$. The desired deltas (hedge ratios) are then simply given by

$$\delta_t^A := \frac{\partial f}{\partial x}(X_t, t), \quad \delta^P := F - \delta^A X \quad (8)$$

Indeed, $C := P^T F = \delta^A A + \delta^P P^T$ obviously. Moreover, since both X and F are $\mathbb{P}^T$ -martingales, Itô's formula implies $dF = \delta^A dX$. An application of Itô's product rule known as the *numeraire-invariance theorem* cf. [1]), then shows that $dC = \delta^A dA + \delta^P dP^T$.

The above Markovian assumption that $F_t = f(t, X_t)$ for some function $f(t, x)$ is generally satisfied when X is a positive diffusion, specifically when $d[X]_t = X_t^2 \sigma^2(t, X_t) dt$ for some positive continuous bounded function $\sigma(t, x)$. (Here $[X]$ denotes the quadratic variation of X .) This is equivalent to $dX_t = X_t \sigma(t, X_t) dW_t$ for some $\mathbb{P}^T$ -Brownian motion W . In this case, $f(t, x)$ is basically obtained as $\mathbb{E}^T[g(X_T) | X_t = x]$. By Itô's formula, $f(t, x)$ satisfies

$$\frac{\partial f}{\partial t} + \frac{1}{2} x^2 \sigma^2(t, x) \frac{\partial^2 f}{\partial x^2} = 0 \quad (f(x, T) = g(x)) \quad (9)$$

Closed-form Solutions

The classical case assumes as in [7] that the forward price volatility $\sigma(t, X_t)$ is deterministic, that is, independent of X . Then X is a $\mathbb{P}^T$ log-Gaussian martingale, and hence conditioned on time t , $X_T = A_T$ is $\mathbb{P}^T$ -lognormally distributed with mean X_t and log-variance $\int_t^T \sigma^2(s) ds$. As such, for, say, a call option with payoff function $g(x) = \max(x - K, 0)$, equation (7) readily yields

$$C(t) = K P_t^T C_{BS} \left(\frac{A_t}{P_t^T K}, \int_t^T \sigma^2(s) ds \right) \quad (10)$$

where, denoting the standard normal distribution function by $N(\cdot)$,

$$C_{BS}(x, v) := x N \left(\frac{\log(x)}{\sqrt{v}} + \frac{\sqrt{v}}{2} \right) - N \left(\frac{\log(x)}{\sqrt{v}} - \frac{\sqrt{v}}{2} \right) \quad (11)$$

Specific examples are the *Vasicek* or more general *Gaussian interest-rate models* (see **Gaussian Interest-Rate Models**) where the deterministic (forward) zero-coupon bond price volatilities are determined endogenously in terms of mean reversion and other model parameters. For zero-coupon bond options, equation (7) can be computed in the *Cox–Ingersoll–Ross model* (see **Cox–Ingersoll–Ross (CIR) Model**) and the *quadratic Gaussian model* (see **Quadratic Gaussian Models**) in terms of the noncentral chi-squared distribution function. This is derived by showing that the spot interest rate $r_T := f_T^T$ is noncentral chi-squared distributed under the forward measure $\mathbb{P}^T$ (e.g., [4]).

Cap Pricing

A cap is a portfolio of consecutive caplets, and a caplet of maturity T , length ε , and strike rate K is an option with payoff $\varepsilon \max(L_{T-\varepsilon}^{T,\varepsilon} - K, 0)$ at time T . A caplet is actually equivalent to a zero-coupon bond put option, so a bond option model as in the previous section is applicable. However, more directly, by the pricing formula given by equation (4) the caplet price C_t is given by

$$C_t = \varepsilon P_t^T \mathbb{E}^T[\max(L_{T-\varepsilon}^{T,\varepsilon} - K, 0) | \mathcal{F}_t] \quad (12)$$

By the section The Forward Measure, the forward Libor process $L^{T,\varepsilon}$ is a martingale under the forward measure $\mathbb{P}^T$. Hence, if its volatility $\sigma(t)$ is deterministic, it is log-Gaussian and we get, as in, the section Closed-form Solutions,

$$C_t = \varepsilon K P_t^T \text{CBS} \left(\frac{L_t^{T,\varepsilon}}{K}, \int_t^T \sigma^2(t) dt \right) \quad (13)$$

The Forward Measure by Changing the Risk-neutral Measure

Let $r_t := f_t^t$ denote the spot interest rate. One often starts with the “money market” asset $\exp(\int_0^t r_t dt)$ as the numeraire and uses its equivalent martingale measure, often called the *risk-neutral measure* and denoted by $\mathbb{Q}$. Accordingly, $\exp(-\int_0^t r_t dt)C$ is a $\mathbb{Q}$ -martingale for any asset C . One can then change the numeraire to the T -maturity bond P^T and obtain the T -forward measure $\mathbb{P}^T$ by the formula

$$\frac{d\mathbb{P}^T}{d\mathbb{Q}} = \frac{1}{P_0^T} \exp \left(- \int_0^T r_t dt \right) \quad (14)$$

Since the forward rate process f^T is a $\mathbb{P}^T$ -martingale, it follows from the section Numeraire Measures that when P^T is continuous, the $\mathbb{Q}$ -drift of f^T equals $-d[\log P^T, f^T]$.

Libor Market Model SDE in the Forward Measure

Consider a sequence of dates $0 < T_1 \dots < T_{n+1}$, for example, equidistant semiannually. Given “daycount fractions” $\varepsilon_i \approx T_{i+1} - T_i$, the forward Libor rates L_t^i

are defined as in the section The Forward Measure by

$$\varepsilon_i L_t^i = \frac{P_t^{T_i}}{P_t^{T_{i+1}}} - 1 \quad (t \leq T_i, i = 1, \dots, n) \quad (15)$$

Evidently, L^i is a $\mathbb{P}^{T_{i+1}}$ -martingale on $[0, T_i]$.

In some applications such as valuation by Monte Carlo simulation, it is necessary to determine the dynamics of all the forward Libor processes L^i under the same measure. One appropriate measure is the *spot-Libor measure*, a simple-compounding analog of the risk-neutral measure that takes as numeraire a “rolling zero-coupon bond” (cf. [5]). Another convenient measure is the *terminal measure*, that is, the T_{n+1} -forward measure $\mathbb{P}^{T_{n+1}}$. Let $W^1, \dots, W^n$ be $\mathbb{P}^{T_{n+1}}$ -Brownian motions with correlations ρ^{ij} , that is, $d[W^i, W^j]_t = \rho^{ij} dt$. Assume

$$dL_t^i = \mu_t^i dt + \sigma_t^i dW_t^i \quad (16)$$

for some predictable processes μ^i and σ^i . For example, in the deterministic-volatility Libor market model, $\sigma_t^i = \sigma_i(t)L_t^i$ for some deterministic functions $\sigma_i(t)$. Since L^i is a $\mathbb{P}^{T_{i+1}}$ -martingale, it follows from the section Numeraire Measures that $\mu^i dt = -d[L^i, \log F]$, where

$$F := \frac{P^{T_{i+1}}}{P^{T_{n+1}}} = \prod_{j=i+1}^n (1 + \varepsilon_j L^j) \quad (17)$$

Therefore, the drift of the forward Libor rate in the terminal measure is given by

$$\begin{aligned} \mu^i dt &= - \sum_{j=i+1}^n \frac{\varepsilon_j d[L^i, L^j]}{1 + \varepsilon_j L^j} \\ &= - \sum_{j=i+1}^n \frac{\varepsilon_j \sigma^i \sigma^j \rho^{ij}}{1 + \varepsilon_j L^j} dt \end{aligned} \quad (18)$$

The Swap Measure

Let T_i and ε_i be as in the previous section. For each $1 \leq i < j$, the swap measure $\mathbb{P}^{ij}$ is defined on $\mathcal{F}_{T_{i+1}}$ as the equivalent martingale measure associated with the *annuity numeraire*

$$A^{ij} := \varepsilon_i P^{T_{i+1}} + \dots + \varepsilon_{j-1} P^{T_j} \quad (19)$$

The forward swap rate S_t^{ij} with start date T_i and end date T_j is defined for $t \leq T_i$ by

$$S_t^{ij} := \frac{P_t^{T_i} - P_t^{T_j}}{A_t^{ij}} \quad (20)$$

It follows from the section Numeraire Measures that S^{ij} is a martingale under the swap measure $\mathbb{P}^{ij}$.

The main application of the swap measure is to European swaptions, that is, options to enter an interest-rate swap at a fixed strike rate. Specifically, a payer swaption with start date T_i , end date T_j , expiration $T \leq T_j$ and strike rate K has the payoff C_T at time T given by

$$C_T = A_T^{ij} \max(S_T^{ij} - K, 0) \quad (21)$$

(When $j = i + 1$, a payer swaption is just a caplet). Arguments similar to those in the section Option Pricing and Hedging show that the swaption is replicable under general diffusion assumptions, for example, when S^{ij} has deterministic volatility or, more generally, when it is a diffusion process under the swap measure $\mathbb{P}^{ij}$. The swaption price process C is then uniquely characterized by C/A^{ij} being a $\mathbb{P}^{ij}$ martingale, implying by equation (21) that

$$C_t = A_t^{ij} \mathbb{E}^{\mathbb{P}^{ij}} [\max(S_T^{ij} - K, 0) | \mathcal{F}_t] \quad (22)$$

When S^{ij} has a deterministic volatility $\sigma_{ij}(t)$ (i.e., $d[S^{ij}]_t = \sigma_{ij}^2(t)(S_t^{ij})^2 dt$), this yields

$$C_t = K A_t^{ij} \text{C}_{\text{BS}} \left(\frac{S_t^{ij}}{K}, \int_t^T \sigma_{ij}^2(t) dt \right) \quad (23)$$

The market uses this formula to quote swaptions, namely a constant volatility σ_{ij} is quoted from which one computes the swaption price by equation (23). Receiver swaptions are treated similarly.

The valuation of Bermudan options is more complex. Here, the swaption can be exercised at any

time $T_i, \dots, T_{j-1}$. One approach, known as the *coterminous swap market model*, assumes that the forward swap rates $S^{ij}, \dots, S^{j-1,j}$ all have deterministic volatilities. According to equation (23), the model is then automatically calibrated to all the European swaptions with start dates $T_i, \dots, T_{j-1}$ and the same end date T_j , thus ruling out obvious arbitrage opportunities.

Constructs similar to the swap measure have been applied to credit default swaptions.

Term Structure Models

Term structure models describe the behavior of interest rates as a function of time and term (time to maturity). As a function of time, rates behave as stochastic processes (see Figure 1). As a function of term, interest rates on a given date form a *yield curve* (see Figure 2).

Interest rates of different maturities behave as a joint stochastic process. Not all joint processes, however, can describe interest-rate behavior in an efficient market. For instance, suppose that a term structure model postulates that rates of all maturities change in time by equal amounts, that is, that yield curves move by parallel shifts (which, empirically, appears to be a reasonable first-order approximation). It can be shown that in this case a portfolio consisting of a long bond and a short bond would always outperform a medium-term bond with the same Macaulay duration (*see Bond*). In an efficient market, supply and demand would drive the price of the medium maturity bond down and the prices of the long and short bonds up. As this would cause the yield on the medium bond to increase and the yields on the long and short bonds to decrease, the yield curves would not stay parallel. This model therefore cannot describe interest-rate behavior.

In order that riskless arbitrage opportunities are absent, the joint process of interest-rate behavior must satisfy some conditions. Determining these conditions and finding processes that satisfy them is the purpose of term structure models.

The joint stochastic process will be driven by a number of sources of uncertainty. For continuous processes, the sources of uncertainty are often specified as Wiener processes. If the evolution of the yield curve can be represented by Markovian state variables, these variables are called *factors*.

Let $B(t, T)$ be the price at time t of a default-free zero-coupon bond maturing at time T with unit maturity value. *Yield to maturity* $R(t, s)$ at time t with term s is defined as the continuously compounded rate of return on the bond,

$$R(t, s) = -\frac{1}{s} \log B(t, t + s) \quad (1)$$

The instantaneous interest rate will be called the *short rate*,

$$r(t) = \lim_{s \rightarrow 0} R(t, s) \quad (2)$$

An asset accumulating interest at the short rate will be called the *money market account*,

$$\beta(t) = \exp \left(\int_0^t r(\tau) d\tau \right) \quad (3)$$

Forward rates $f(t, T)$ are defined by the equation

$$B(t, T) = \exp \left(- \int_t^T f(t, \tau) d\tau \right) \quad (4)$$

One-factor Models

A general theory of one-factor term structure models was given by Vasicek [9]. He assumed the following:

1. The short rate follows a continuous Markov process.
2. The price $B(t, T)$ of a bond is determined by the assessment at time t of the segment $\{r(\tau), t \leq \tau \leq T\}$ of the short-rate process over the term of the bond.
3. The market is efficient; that is, there are no transaction costs, information is available to all investors simultaneously, and every investor acts rationally (prefers more wealth to less, and uses all available information).

Assumption 3 implies that investors have homogeneous expectations and that no profitable riskless arbitrage is possible.

By assumption 1, the development of the short rate over an interval (t, T) , $t \leq T$, given its values prior to time t , depends only on the current value $r(t)$. Assumption 2 then implies that the price $B(t, T)$ is a function of $r(t)$. Thus, the value of the short rate is the only state variable for the whole term structure.

Let the dynamics of the short rate be given by

$$dr(t) = \zeta(r, t) dt + \varphi(r, t) dW(t) \quad (5)$$

where $W(t)$ is a Wiener process. Denote the mean and variance of the instantaneous rate of return on the bond with price $B(t, T)$ by $\mu(t, T)$ and $\sigma^2(t, T)$, respectively,

$$\frac{dB(t, T)}{B(t, T)} = \mu(t, T) dt - \sigma(t, T) dW(t) \quad (6)$$

Consider an investor who at time t issues an amount w_1 of a bond with maturity date T_1 , and

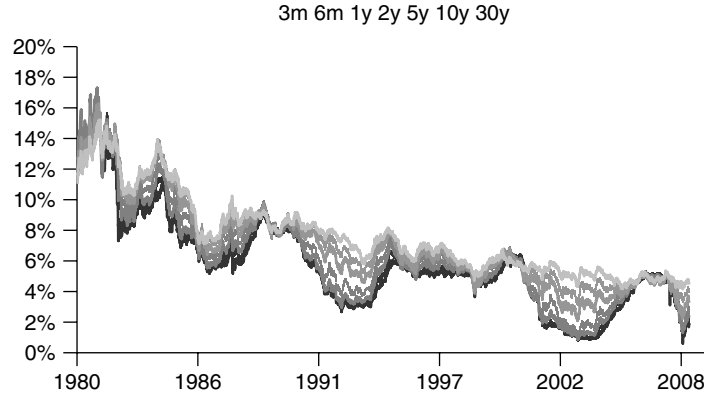

Figure 1 US Treasury Yields

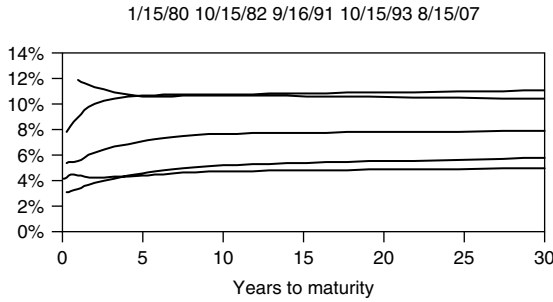

Figure 2 US Treasury Yield Curves

simultaneously buys an amount w_2 of a bond with maturity date T_2 . Suppose the amounts w_1 and w_2 are chosen to be proportional to $\sigma(t, T_2)$ and $\sigma(t, T_1)$, respectively. Then the position is instantaneously riskless, and should realize the short rate of return $r(t)$. It follows that the ratio $(\mu(t, T) - r(t))/\sigma(t, T)$ is independent of T . Its common value $\lambda(t)$ is called the *market price of risk*, as it specifies the increase in the expected rate of return on a bond per an additional unit of risk. We thus have

$$\mu(t, T) = r(t) + \lambda(t)\sigma(t, T) \quad (7)$$

Applying Ito's lemma to the price $B(t, T) = B(t, T, r)$ and comparing with equation (6) yields

$$\frac{\partial B}{\partial t} + (\zeta + \varphi\lambda)\frac{\partial B}{\partial r} + \frac{1}{2}\varphi^2\frac{\partial^2 B}{\partial r^2} - rB = 0 \quad (8)$$

The bond price is subject to the boundary condition $B(T, T) = 1$.

The solution to equation (8) is given by

$$B(t, T) = E_t \exp \left(- \int_t^T r(\tau) d\tau - \frac{1}{2} \int_t^T \lambda^2(\tau) d\tau + \int_t^T \lambda(\tau) dW(\tau) \right) \quad (9)$$

This equation, called the *fundamental bond pricing equation* (the *Vasicek equation*), fully describes the term structure and its behavior.

Model Examples

Various specific cases have been proposed in the literature. Vasicek [9] gives an example of a term structure model in which the short rate follows a mean reverting random walk (the Ornstein–Uhlenbeck process, see **Ornstein–Uhlenbeck Processes**)

$$dr = \alpha(\theta - r) dt + \varphi dW \quad (10)$$

and the market price of risk $\lambda(t, r) = \lambda$ is constant. In that case, the expectation in equation (9) can be evaluated explicitly to give

$$B(t, T) = \exp \left(\frac{1}{\alpha} (1 - e^{-\alpha(T-t)}) (R(\infty) - r) - (T - t)R(\infty) - \frac{\varphi^2}{4\alpha^3} (1 - e^{-\alpha(T-t)})^2 \right) \quad (11)$$

where

$$R(\infty) = \theta + \lambda\varphi/\alpha - \frac{1}{2}\varphi^2/\alpha^2 \quad (12)$$

Interest rates are Gaussian. The advantage of this specification is its tractability. A drawback is that interest rates can become negative.

Cox *et al.* [3] derive a model in which

$$dr = \alpha(\theta - r) dt + \varphi\sqrt{r} dW \quad (13)$$

and the market price of risk $\lambda(t, r) = \eta\sqrt{r}$. In this case, the bond prices can also be explicitly given (*see Cox–Ingersoll–Ross (CIR) Model*). They have the form

$$B(t, T) = A(t, T) \exp(-D(t, T)r(t)) \quad (14)$$

Interest rates are always nonnegative.

Hull and White [8] extended these two models by allowing the parameters in equations (10) and (13), as well as the market price of risk, to be time dependent. This has the advantage that the model can be made consistent with initial data. For instance, by making θ a function of time, the model can be made to exactly fit the initial term structure of interest rates (which is not possible with time-homogeneous models). Similarly, making the volatility φ a function of time allows calibration of the model to the term structure of swaption volatilities. Hull and White give closed-form solutions for bond prices for what they call the *extended Vasicek* and the *extended Cox–Ingersoll–Ross* models. These cases belong to the class of models that Duffie and Kan [4] call the *affine term structure models* (*see Affine Models*), in which bond prices have the form (14).

Black *et al.* [1] and Black and Karasinski [2] give a model with

$$d \log r = \alpha(t)(\log \theta(t) - \log r) dt + \varphi(t) dW \quad (15)$$

In this model, bond prices cannot be given in closed-form formulas, but can be calculated numerically. Interest rates are lognormal. Lognormal models have regularity issues, for example, they produce infinite Eurodollar future prices (*see Eurodollar Futures and Options*).

The term structure theory generalizes easily to multiple factors and multiple sources of uncertainty. In fact, the bond pricing equation (9) is universally valid for any arbitrage-free term structure model. If W, φ, λ are vectors, their products are interpreted as inner products.

Contingent Claim Pricing

One of the main tasks of term structure models in applications is pricing of *interest-rate-contingent claims* (interest-rate derivatives). This could be approached in several ways. For one-factor models it can be shown, by means of an arbitrage argument similar to that above for bonds, that the price $P(t)$ of any interest-rate derivative satisfies the partial differential equation (8). The valuation of the derivative is then accomplished by solving that equation subject to boundary conditions that describe the derivative asset payouts. If a closed-form solution cannot be given, the equation can be solved numerically in a tree or a finite difference lattice. A more general method is to realize that such a solution has the form

$$P(t) = E_t P(s) \exp \left(- \int_t^s r(\tau) d\tau - \frac{1}{2} \int_t^s \lambda^2(\tau) d\tau + \int_t^s \lambda(\tau) dW(\tau) \right) \quad (16)$$

This equation holds even in the cases where there are no Markovian state variables. To calculate the expectation in equation (16), however, is typically more difficult than solving a partial differential equation.

The modern theory of derivative asset pricing (*see Harrison and Kreps [5]*) introduces a change of probability measure as the basic pricing tool. There exists an equivalent probability measure P^* , called the *risk-neutral measure*, such that the value of any asset expressed in units of the money market account $\beta(t)$ follows a martingale under that measure,

$$\frac{P(t)}{\beta(t)} = E_t^* \frac{P(s)}{\beta(s)} \quad (17)$$

The process

$$W^*(t) = W(t) - \int_0^t \lambda(\tau) d\tau \quad (18)$$

is a Wiener process under the risk-neutral probability measure P^* .

If current bond prices are considered given, interest-rate derivatives can be priced without knowing the market price of risk $\lambda(t)$ by writing the dynamics of interest rates directly in terms of the process $W^*(t)$. From equations (6) and (7), bond

prices are subject to

$$\frac{dB(t, T)}{B(t, T)} = r(t) dt - \sigma(t, T) dW^*(t) \quad (19)$$

Integrating equation (19) with respect to t and differentiating with respect to T yields

$$\begin{aligned} f(t, T) - f(0, T) \\ = \int_0^t \varphi(\tau, T) \sigma(\tau, T) d\tau + \int_0^t \varphi(\tau, T) dW^*(\tau) \end{aligned} \quad (20)$$

where $\varphi(t, T)$ is the volatility of the forward rate $f(t, T)$ and

$$\sigma(\tau, T) = \int_{\tau}^T \varphi(\tau, s) ds \quad (21)$$

Thus, knowledge of the initial term structure $f(0, T)$, $T \geq 0$ and of the forward-rate volatilities is sufficient for pricing interest-rate-contingent claims. This was proposed in essence by Ho and Lee [7] and later formalized by Heath *et al.* [6] (see **Heath–Jarrow–Morton Approach**).

OLDRICH ALFONS VASICEK

Cox–Ingersoll–Ross (CIR) Model

The Cox–Ingersoll–Ross (CIR) model, one of the most well-known short-rate models (see **Term Structure Models**), was proposed in 1985 by Cox, Ingersoll, and Ross (see **Ross, Stephen**). In their pioneering work [3], they use an equilibrium approach to derive an explicit formula for the interest rate as a function of the wealth and the state of technology. On the basis of economic arguments, they specify their general framework in [4] and obtain the following dynamics for the short rate (r_t , $t \geq 0$) under the objective probability measure $\mathbb{P}^o$ with a risk premium factor Λ :

$$t \geq 0, dr_t = [\kappa\theta - (\kappa + \Lambda)r_t] dt + \sigma\sqrt{r_t} dW_t^o \quad (1)$$

Here, the process (W_t^o , $t \geq 0$) is a standard Brownian motion, and the real parameters κ , θ , σ satisfy $\kappa\theta \geq 0$ and $\sigma > 0$. To deal with pricing, we, however, consider in the sequel the dynamics under the risk-neutral measure $\mathbb{P}$ (see **Hedging**). The usual assumption is to take a risk premia function equal to $\Lambda\sqrt{r}/\sigma$ (see **Risk Premia**). This choice allows to keep a similar dynamics under $\mathbb{P}$:

$$t \geq 0, dr_t = \kappa(\theta - r_t) dt + \sigma\sqrt{r_t} dW_t \quad (2)$$

$W_t = W_t^o - \int_0^t (\Lambda\sqrt{r_s}/\sigma) ds$ being a Brownian motion under $\mathbb{P}$. Indeed, using $\int_0^t \sqrt{r_s} dW_s^o = [r_t - r_0 - \kappa\theta t + \int_0^t (\kappa + \Lambda)r_s ds]/\sigma$, we can check from equation (3) that $\mathbb{E}^o[\exp[\int_0^t (\Lambda\sqrt{r_s}/\sigma) dW_s^o - \frac{1}{2} \int_0^t (\Lambda/\sigma)^2 r_s ds]] = 1$, so $\mathbb{P}$ is indeed equivalent to $\mathbb{P}^o$. The parameters have a clear interpretation. First, σ determines the volatility of the interest rate. Moreover, for the common practical choice $\kappa, \theta > 0$ that we assume in the following, the short rate has a mean reversion toward θ with a speed driven by κ . It is known that equation (2) has a (pathwise) unique non-negative solution for any starting value $r_0 \geq 0$. Furthermore, the short rate remains positive at any time as long as $r_0 > 0$ and $2\kappa\theta \geq \sigma^2$. Nonnegativity is, of course, a nice feature when modeling interest rates. This is the main qualitative difference between CIR and Vasicek models (see **Term Structure Models**)

that have otherwise similar properties for pricing derivatives.

Analytical Results

Beyond the natural meaning of its parameters, the CIR model strength is to provide analytical formulas for the main financial quantities. It belongs to the class of affine models (see **Affine Models**), which means that the Laplace transform of the joint distribution ($r_t, \int_0^t r_s ds$) is known to be for $\lambda, \mu > 0$,

$$\mathbb{E} \left[e^{-\lambda r_t - \mu \int_0^t r_s ds} \right] = A_{\lambda, \mu}(t) \exp(-r_0 B_{\lambda, \mu}(t)) \quad (3)$$

We have the following formulas (see [10]):

$$A_{\lambda, \mu}(t) = \left[\frac{2\gamma_\mu e^{t \frac{\gamma_\mu + \kappa}{2}}}{\{\sigma^2 \lambda (e^{\gamma_\mu t} - 1) + \gamma_\mu\}} \right]^{\frac{2\kappa\theta}{\sigma^2}},$$

$$B_{\lambda, \mu}(t) = \frac{\lambda[\gamma_\mu + \kappa + e^{\gamma_\mu t}(\gamma_\mu - \kappa)] + 2\mu(e^{\gamma_\mu t} - 1)}{\sigma^2 \lambda (e^{\gamma_\mu t} - 1) + \gamma_\mu - \kappa + e^{\gamma_\mu t}(\gamma_\mu + \kappa)} \quad (4)$$

with $\gamma_\mu = \sqrt{\kappa^2 + 2\sigma^2\mu}$. An analogous formula to equation (3) holds for the Fourier transform, handling complex logarithms with care, and even for a wider range of complex values of λ and μ as long as the left-hand side is well defined. Thanks to equation (3), the law of r_t is known. Defining $c_t = \frac{4\kappa}{\sigma^2(1 - e^{-\kappa t})}$, $c_t r_t$ is distributed as a chi-square distribution with $\nu = \frac{4\kappa\theta}{\sigma^2}$ degrees of freedom and noncentrality parameter $d_t = c_t r_0 e^{-\kappa t}$. More explicitly, this means that r_t has the following density function for $r > 0$,

$$\sum_{i=0}^{\infty} \frac{e^{-\frac{d_t}{2}} \left(\frac{d_t}{2}\right)^i}{i!} \frac{c_t/2}{\Gamma(i + \frac{\nu}{2})} \left(\frac{c_t r}{2}\right)^{i-1+\frac{\nu}{2}} e^{-\frac{c_t r}{2}} \quad (5)$$

In particular, one can see that r_t converges to a steady-state distribution with density $\frac{(c_\infty/2)^{\frac{\nu}{2}}}{\Gamma(\frac{\nu}{2})} r^{\frac{\nu}{2}-1} e^{-\frac{c_\infty}{2} r}$ where $c_\infty = 4\kappa/\sigma^2$ when $t \rightarrow +\infty$. This is a Gamma distribution with mean θ and variance

$\theta\sigma^2/(2\kappa)$. It is the stationary law of the stochastic differential equation (2).

Derivative Pricing

Under a short-rate model, the initial price of a zero-coupon bond with maturity $T > 0$ (see definition in **Bond**) is given by $\mathbb{E}[e^{-\int_0^T r_s ds}]$. It is here analytically known and is equal to $A_{0,1}(T) \exp(-r_0 B_{0,1}(T))$. More generally, the price at time $t > 0$ of a zero-coupon bond with maturity T is given by

$$P(r_t, t, T) = A_{0,1}(T - t) \exp(-r_t B_{0,1}(T - t)) \quad (6)$$

The CIR model also provides closed form formulas for some option prices. For instance, let us consider a call option with strike K and maturity T , written on a zero-coupon bond with maturity $S \geq T$. Its initial price is given by

$$\mathbf{C} = \mathbb{E}[e^{-\int_0^T r_s ds} (P(r_T, T, S) - K)^+] \quad (7)$$

To calculate $\mathbf{C}$, we use another nice feature of the CIR model: the short-rate distribution is known under the forward measure. Let us recall that for a fixed maturity $T > 0$, the T -forward measure is defined by

$$\mathbb{P}^T(A) = \frac{\mathbb{E}\left[e^{-\int_0^T r_s ds} \mathbf{1}_A\right]}{P(r_0, 0, T)} \quad (8)$$

for any event A anterior to time T (see **Forward and Swap Measures**), which amounts to taking the zero-coupon bond as a numeraire. Under $\mathbb{P}^T$, $(r_t, 0 \leq t \leq T)$ solves the following SDE

$$dr_t = [\kappa\theta - (\kappa + \sigma^2 B_{0,1}(T - t))r_t] dt + \sigma\sqrt{r_t} dW_t^T \quad (9)$$

where $(W_t^T, 0 \leq t \leq T)$ is a Brownian motion under $\mathbb{P}^T$. This diffusion is again of the affine type and is tractable. In particular, for $t \in [0, T]$, the law of r_t under $\mathbb{P}^T$ is known: it is distributed as $1/(2\alpha_T(t))$ times a chi-square random variable with ν degrees of freedom and noncentrality parameter $\frac{8r_0\gamma_1^2 e^{\gamma_1 t}}{\sigma^4(e^{\gamma_1 t} - 1)^2 \alpha_T(t)}$, where $\alpha_T(t) = \frac{2\gamma_1}{\sigma^2(e^{\gamma_1 t} - 1)} +$

$\frac{\kappa + \gamma_1}{\sigma^2} + B_{0,1}(T - t)$ (see [2, 4, 8]). Then, from equations (6 and 7), we easily get the call price

$$\begin{aligned} \mathbf{C} &= P(r_0, 0, S) \mathbb{P}^S(r_T \leq r^*) \\ &\quad - K P(r_0, 0, T) \mathbb{P}^T(r_T \leq r^*) \end{aligned} \quad (10)$$

where $r^* = \ln(A_{0,1}(S - T)/K)/B_{0,1}(S - T)$. Obviously, we have a similar formula for put options. Nonetheless, options on zero-coupon bonds are not standard in practice, and products like caps, floors, and swaptions are mostly preferred to get hedge against interest-rate fluctuations (see **Caps and Floors**). A well-known relation is that the price of a floorlet (resp. caplet) between maturities T and S can be written as a simple function of a call (resp. put) option on the zero-coupon bond between T and S (see, e.g., [2]). This way, from equation (10), we derive closed form formulas for cap and floor prices also. Receiver (resp. payer) European swaptions can readily be seen as call (resp. put) option with a unit strike on a bond whose coupon rate corresponds to the swaption strike (see **Bond Options**). Thus, denoting the maturity by T , and with $T < S_1 < \dots < S_n$, the payment grid, its price has the following form $\mathbb{E}[e^{-\int_0^T r_s ds} (\sum_{i=1}^n \alpha_i P(r_T, T, S_i) - 1)^+]$ with $\alpha_i \geq 0$, $\sum_{i=1}^n \alpha_i > 1$. Thanks to the strike decomposition introduced by Jamshidian [7], it turns out to be a combination of call prices on zero-coupon bonds. Indeed, $P(r, T, S)$ being decreasing with respect to r , there is a unique $\rho > 0$ such that $\sum_{i=1}^n \alpha_i P(\rho, T, S_i) = 1$, and we have $(\sum_{i=1}^n \alpha_i [P(r_T, T, S_i) - P(\rho, T, S_i)])^+ = \sum_{i=1}^n \alpha_i (P(r_T, T, S_i) - P(\rho, T, S_i))^+$.

Calibration

Let us turn to the calibration of the CIR model to the market prices. We have analytical formulas for zero-coupon bond, cap, and floor prices. Swaption prices can also be computed very quickly, ρ being obtained, for example, by dichotomy. Therefore, the distance between the market prices and the theoretical ones obtained from the CIR model can be computed quickly and minimized with the use of any optimization algorithm. In this way, we can identify optimal parameters r_0 , κ , θ , and σ . In practice, it is likely to better fit swaption prices than cap and floor prices. Indeed, they do not only

describe the evolution of each single rate for different maturities but also the dependence between them. Unfortunately, these four parameters are anyway not enough in practice, if we want to accurately capture all the market data. For this reason, many works have been done to extend the CIR model. While doing this, the challenge is to preserve the nice analytical tractability of the CIR model. Without being exhaustive, we mention here the extended CIR model [9] where parameters κ , θ and σ are supposed to be time dependent, and the particular case where $\kappa(t)\theta(t)/\sigma^2(t)$ is constant that allow to preserve some closed formulas [8]. Other generalizations have been proposed, like adding a deterministic shift or another independent CIR process (see [2] for some numerical experiments). Most of these extensions are embedded in the general affine framework described in [5] (see **Term Structure Models**).

Monte Carlo Simulation

Finally, it is important to mention the simulation issues concerning square-root diffusions. This topic goes beyond the world of interest derivatives because these diffusions are widespread in finance, such as in the Heston model (see **Heston Model**). First, exact simulation is possible for the CIR model since we know how to simulate a noncentral chi-square distribution [6]. However, in some applications, it may be more convenient to use discretization schemes that often lead to smaller computation times. We face the difficulty that usual schemes such as Euler and Milstein generally fail. This is due to the square root in the CIR dynamics, which is non-Lipschitzian near the origin and is not defined for negative values. Tailored schemes should then be considered as in [1]. More information on the simulation of the CIR process can be found in **Simulation of Square-root Processes**.

Conclusion

The fundamental features of the CIR model—intuitive parameterization, nonnegativity, pricing formulas for main options—explain why it has been widely used for hedging risk on interest-rate derivatives. Nowadays, owing to the complexity of the fixed income market, more sophisticated models are required, such as Libor or Swap Market models (see

LIBOR Market Model and **Swap Market Models**). Nonetheless, the CIR model is often used as a building block for more complex models. Many extensions that rely on the same mathematical properties are widespread for interest-rate modeling (multifactor quadratic Gaussian models (see **Quadratic Gaussian Models**, affine models (see **Affine Models**), the Heston model for equity (see **Heston Model**), or the Duffie–Singleton model on credit derivatives (see **Duffie–Singleton Model**).

Gaussian Interest-Rate Models

A major milestone in interest-rate modeling was the one-factor Gaussian mean-reverting model proposed by Vasicek [6] in 1977 for the short-term interest rate, using a time-homogeneous setup of the Ornstein–Uhlenbeck process (*see Term Structure Models*). Its analytical tractability and feasibility of effective numerical methods made the model popular among practitioners for many years. Multifactor Gaussian interest-rate models were subsequently developed as a natural extension of the Vasicek model and share these properties.

In 1990, Hull and White [3] generalized the Vasicek model to time-dependent parameters to permit fitting term structures of yields and volatilities. The instantaneous short rate $r(t)$ for the Hull–White one-factor (HW1F) model satisfies the evolution

$$dr(t) = (\vartheta(t) - a(t)r(t)) dt + \sigma(t) dW(t) \quad (1)$$

A volatility function $\sigma(t)$ and a mean reversion $a(t)$ are the main parameters of the model. The drift compensator $\vartheta(t)$ serves to fit the initial yield curve. Zero-bond and option pricing, as well as transition probabilities, are available analytically for the HW1F model, which makes it attractive not only for a calibration procedure but also for effective numerical implementations.

One of the main drawbacks of the HW1F model is the fact that yields of all maturities are functions of only one state-variable, $r(t)$, implying that all points on the yield curve are perfectly correlated. For financial contracts sensitive to the joint movements of multiple points on the yield curve, the HW1F model is therefore clearly inadequate. To decorrelate yields of different maturities, Hull and White [4] in 1995 proposed a two-dimensional generalization of the HW1F model, introducing a stochastic mean reversion $u(t)$ in the short rate,

$$dr(t) = (\vartheta(t) + u(t) - a r(t)) dt + \sigma dW(t) \quad (2)$$

$$du(t) = -a_u u(t) dt + \sigma_u dW_u(t) \quad (3)$$

Apart from previously defined short-rate parameters, the stochastic mean reversion $u(t)$ has its own time-independent volatility σ_u and mean reversion

a_u . Nontrivial correlation between the two Brownian motions, $\rho_u = E[dW(t) dW_u(t)]/dt$, and the two mean reversions, $a \neq a_u$, guarantee nontrivial correlations between yields of different maturities.

Duffie and Kan [2] generalized the model (2–3) to an arbitrary dimension as a special case of their affine model. Here, the short-rate process is presented as a sum of correlated Gaussian mean-reverting processes, $x_i(t)$, and an additional deterministic function, $\theta(t)$, used to match the original yield curve,

$$r(t) = \sum_{i=1}^N x_i(t) + \theta(t) \quad (4)$$

Each underlying process $x_i(t)$ obeys the Ornstein–Uhlenbeck equation,

$$dx_i(t) = -a_i(t)x_i(t) dt + \sigma_i(t) dW_i(t) \quad (5)$$

with correlated Brownian motions $E[dW_i(t) dW_j(t)] = C_{ij}(t) dt$. The model's stochastic differential equations (SDEs) are understood to be in the risk-neutral measure associated with the savings account numeraire $N(t) = e^{\int_0^t ds r(s)}$ and the expectation operator $E[\cdot \cdot \cdot]$.

The Hull–White two-factor model (2–3) and the $N = 2$ case of the symmetric form (4–5) are equivalent for $a \neq a_u$ provided that $a = a_1$, $a_u = a_2$, $\sigma^2 = \sigma_1^2 + \sigma_2^2 + 2\rho \sigma_1 \sigma_2$, $\sigma_u = (a_1 - a_2)\sigma_2$, $\rho_u = (\sigma_1 \rho + \sigma_2)/\sigma$, and $\vartheta(t) = a_1 \theta(t) + \theta'(t)$.

Analytical Properties

It is convenient to orthogonalize the Brownian motions in the model (5). For this, introduce vector-valued volatilities $\gamma_i(t)$ with elements $\gamma_{if}(t)$ for $f = 1, \dots, N$. Also consider vector-valued Brownian motion $dZ(t) = \{dZ_1, dZ_2, \dots, dZ_N\}$ with independent elements $E[dZ_f(t) dZ_{f'}(t)] = \delta_{ff'} dt$, where δ_{ij} is the Kronecker symbol. Now the underlying mean-reverting process (5) can be rewritten as

$$dx_i(t) = -a_i(t)x_i(t) dt + \gamma_i(t) \cdot dZ(t) \quad (6)$$

where the dot symbol denotes the dot product $\sum_{f=1}^N \gamma_{if}(t) dZ_f(t) = \gamma_i(t) \cdot dZ(t)$. To restore the initial dynamics (5), one should identify the scalar volatility σ_i with the module $|\gamma_i|$ and the correlation structure $C_{ij}(t) = E[dW_i(t) dW_j(t)]/dt$ with $\gamma_i(t) \cdot$

$\gamma_j(t)/|\gamma_i(t)| |\gamma_j(t)|$. In these notations, the initial Brownian motion can be expressed as $dW_i(t) = \gamma_i(t) \cdot dZ(t)/|\gamma_i(t)|$.

Key Formulas

This mean-reverting Ornstein–Uhlenbeck process (6) has the solution

$$x_i(\tau) = e^{-\int_t^\tau a_i(u) du} \left(x_i(t) + \int_t^\tau e^{\int_t^s a_i(u) du} \gamma_i(s) \cdot dZ(s) \right) \quad (7)$$

provided that its value at time t is fixed. Conditional moments of the x_i are easily shown to be

$$E[x_i(\tau) | x_i(t) = y_i] = e^{-\int_t^\tau a_i(u) du} y_i \quad (8)$$

$$\begin{aligned} \text{Cov}(x_i(\tau), x_j(\tau) | x_i(t) = y_i, x_j(t) = y_j) \\ = \int_t^\tau e^{-\int_t^s (a_i(u) + a_j(u)) du} \\ \times \gamma_i(s) \cdot \gamma_j(s) ds \end{aligned} \quad (9)$$

Let $P(t, T)$ be the time t price of a discount bond maturing at time T , and define instantaneous forward rates by $f(t, T) = -\partial \ln P(t, T)/\partial T$. In the model (4–6),

$$\begin{aligned} P(t, T) = E \left[e^{-\int_t^T r(\tau) d\tau} | F_t \right] = e^{-\int_t^T \theta(\tau) d\tau} \\ \times E \left[e^{-\sum_i \int_t^T x_i(\tau) d\tau} | F_t \right] \end{aligned} \quad (10)$$

which can be evaluated as the processes x_i are Gaussian. Indeed, it is easily established that

$$dP(t, T)/P(t, T) = r(t) dt - \sum_i \alpha_i(t, T) \gamma_i(t) \cdot dZ(t),$$

$$\alpha_i(t, T) \equiv \int_t^T ds e^{-\int_t^s a_i(u) du} \quad (11)$$

where we have used the fact that the drift of $dP(t, T)/P(t, T)$ must be $r(t)$ in the risk-neutral measure. Differentiating the SDE for $\ln P(t, T)$ over T , the forward rate dynamics emerge as

$$df(t, T) = \sum_i e^{-\int_t^T a_i(u) du} \gamma_i(t) \cdot dZ(t) + \mu(t, T) dt \quad (12)$$

where we have defined

$$\mu(t, T) = \sum_{i,j} e^{-\int_t^T a_i(u) du} \alpha_j(t, T) \gamma_i(t) \cdot \gamma_j(t) \quad (13)$$

Integrating the forward rate SDE leads to

$$\begin{aligned} f(t, T) = f(0, T) + \sum_i e^{-\int_t^T a_i(u) du} x_i(t) \\ + \int_0^t \mu(\tau, T) d\tau \end{aligned} \quad (14)$$

so forward rates are clearly Gaussian. For a general approach to the forward rates evolution, *see Heath–Jarrow–Morton Approach*. Integrating equation (14) yields the discount bond reconstitution formula

$$\begin{aligned} P(t, T) \\ = \frac{P(0, T)}{P(0, t)} e^{-\sum_i \alpha_i(t, T) x_i(t) - \frac{1}{2} \int_0^t (v(\tau, T) - v(\tau, t)) d\tau} \end{aligned} \quad (15)$$

where $v(t, T)$ is the instantaneous variance of $dP(t, T)/P(t, T)$, that is, $v(t, T) = \left| \sum_i \alpha_i(t, T) \gamma_i(t) \right|^2$. Note that equation (15) demonstrates that the entire discount curve at time t can be computed from the N Markov state-variables $x_i(t)$, $i = 1, \dots, N$. Also note that, from equation (14),

$$r(t) \equiv f(t, t) = f(0, t) + \sum_i x_i(t) + \int_0^t \mu(\tau, t) d\tau \quad (16)$$

which immediately establishes the drift $\theta(t)$ in formula (4) to be $\theta(t) = f(0, t) + \int_0^t \mu(\tau, t) d\tau$.

Finally, we present the covariance structure for the forward rates,

$$\text{Cov}(df(t, T), df(t, T')) = \frac{E[df(t, T) df(t, T')]}{dt}$$

$$= \sum_{i,j} e^{-\int_t^T a_i(u) du - \int_t^{T'} a_j(u) du} \gamma_i(t) \cdot \gamma_j(t) \quad (17)$$

from which one can obtain two important financial quantities: forward rate variance $V_F(t, T)$ and correlation between two forward rates $C_F(t, T, T')$, or

$$\begin{aligned} V_F(t, T) &= \frac{E[df(t, T) df(t, T)]}{dt} \\ &= \sum_{i,j} e^{-\int_t^T (a_i(u) + a_j(u)) du} \\ &\quad \times \gamma_i(t) \cdot \gamma_j(t) \end{aligned} \quad (18)$$

$$C_F(t, T, T') = \frac{\text{Cov}(df(t, T), df(t, T'))}{\sqrt{V_F(t, T) V_F(t, T')}} \quad (19)$$

European Option Prices

Consider a general European payer swaption with exercise date T_0 and payment dates $T_1, \dots, T_N$. For a fixed rate K , the swaption payoff is

$$\Pi(T_0) = \left(1 - P(T_0, T_N) - K \sum_{n=1}^N \delta_n P(T_0, T_n) \right)^+ \quad (20)$$

where δ_n is a day count fraction for a period starting at T_{n-1} and ending at T_n .

Defining discounted bonds as $R(t, T) = P(t, T)/P(t, T_0)$, the time zero value of the swaption can be written as

$$\begin{aligned} C &= P(0, T_0) E_0 \left[\left(\frac{\Pi(T_0)}{P(t, T_0)} \right)^+ \right] = P(0, T_0) E_0 \\ &\quad \times \left[\left(1 - R(T_0, T_N) - K \sum_{n=1}^N \delta_n R(T_0, T_n) \right)^+ \right] \end{aligned} \quad (21)$$

where $E_0[\dots]$ denotes expectation operator in the T_0 -forward measure, that is, the measure associated with a numeraire of $N_0(t) = P(t, T_0)/P(0, T_0)$ (see **Forward and Swap Measures**). As $R(t, T)$ must be a martingale in the T_0 -forward measure, equation (11) shows that

$$dR(t, T) = -R(t, T) \Sigma(t, T) \cdot dZ_0(t) \quad (22)$$

where $Z_0(t)$ is a Brownian motion in the T_0 -forward measure and $\Sigma(t, T)$ is a vector log-volatility

$$\Sigma(t, T) \equiv \sum_i e^{\int_0^t a_i(u) du} \gamma_i(t) \int_{T_0}^T ds e^{-\int_0^s a_i(u) du} \quad (23)$$

A solution for the discounted bonds can be easily written as

$$R(t, T_n) = \frac{P(0, T_n)}{P(0, T_0)} e^{-Y_n(t) - 1/2 V_n(t)} \quad (24)$$

where we have denoted Gaussian processes $Y_n(t) = \int_0^t \Sigma(\tau, T_n) \cdot dZ_0(\tau)$ and its variance, $V_n(t) = \int_0^t |\Sigma(\tau, T_n)|^2 d\tau$. Note that the processes Y_n can be presented as a linear combination of the driving processes x_i ,

$$\begin{aligned} Y_n(t) &= \sum_i \beta_i(T_n) x_i(t) \text{ for} \\ \beta_i(T_n) &= \int_{T_0}^{T_n} ds e^{-\int_0^s a_i(u) du} \end{aligned} \quad (25)$$

Substituting solution (24) into the price formula (21), we obtain

$$C = P(0, T_0) E_0 \left[\left(1 - \sum_{n=1}^N e^{A_n - Y_n(T_0)} \right)^+ \right] \quad (26)$$

where we have denoted $A_N = \ln((1 + K \delta_N) P(0, T_N)/P(0, T_0)) - 1/2 V_N(T_0)$ and $A_n = \ln(K \delta_n P(0, T_n)/P(0, T_0)) - 1/2 V_n(T_0)$ for $n = 1, \dots, N - 1$.

For the case where $N = 1$, that is when our swaption is really a caplet, equation (26) can be solved in closed form

$$\begin{aligned} C_1 &= P(0, T_0) \Phi \left(-\frac{A_1}{\sqrt{V_1(T_0)}} + \frac{\sqrt{V_1(T_0)}}{2} \right) \\ &\quad - (1 + K \delta_1) P(0, T_1) \\ &\quad \times \Phi \left(-\frac{A_1}{\sqrt{V_1(T_0)}} - \frac{\sqrt{V_1(T_0)}}{2} \right) \end{aligned} \quad (27)$$

where $\Phi(x)$ is the cumulative Gaussian distribution function and $A_1 = \ln((1 + K \delta_1) P(0, T_1)/P(0, T_0)) - 1/2 V_1(T_0)$.

For the case of a regular multiperiod swaption, we can rely on the trick in Jamshidian [5]. It is based on the observation that, for a continuous stochastic variable X taking values on the whole real axis, the following equation

$$\begin{aligned} E \left[\left(1 - \sum_{n=1}^N e^{A_n - B_n X} \right)^+ \right] \\ = E \left[\left(1 - \sum_{n=1}^N e^{A_n - B_n X} \right) 1_{X > x_0} \right] \end{aligned} \quad (28)$$

holds for barrier level x_0 satisfying $1 = \sum_{n=1}^N e^{A_n - B_n x_0}$, provided that coefficients $B_n \geq 0$ and at least one coefficient B is strictly positive. For Gaussian variable V with zero mean and variance v , we have

$$\begin{aligned} E \left[\left(1 - \sum_{n=1}^N e^{A_n - B_n X} \right)^+ \right] = \Phi \left(-\frac{x_0}{\sqrt{v}} \right) \\ - \sum_{n=1}^N e^{A_n + 1/2 B_n^2 v} \Phi \left(-\frac{x_0}{\sqrt{v}} - B_n \sqrt{v} \right) \end{aligned} \quad (29)$$

For the one-factor case, the Jamshidian trick applies directly to equation (26) and leads to a closed-form swaption pricing formula involving a simple root-search for the trigger level x_0 . For two-factor models, where $Y_n(T_0) = \beta_1(T_n) x_1(T_0) + \beta_2(T_n) x_2(T_0)$, defines Gaussian stochastic variables $X_1 = x_1(T_0)$ and $X_2 = x_2(T_0)$ with known covariance matrix by formula (9). To integrate the option price (26) over Gaussian X_1 and X_2 , one can compute analytically the conditional-to- X_1 average

$$E_0 \left[\left(1 - \sum_{n=1}^N e^{A_n - Y_n(T_0)} \right)^+ \middle| X_1 \right] \quad (30)$$

using the Jamshidian lemma, and then do the numerical integration over the Gaussian variable X_1 . The first step is indeed possible since the variable X_2 conditional to X_1 is normally distributed, and the exponents in the option formula (35) depend linearly on the variable X_2 as in expression (29). More details can be found in, for instance, [1].

If the exact option pricing algorithm is slow for concrete applications, or if the number of model factors is more than two, one can come up with a purely

analytical approximation^a in the so-called *swap measure* (see **Forward and Swap Measures**). Namely, introduce a swap level $L(t) = \sum_{n=1}^N \delta_n P(t, T_n)$ of and associate the swap measure with the numeraire $N_S(t) = L(t)/L(0)$ equipped with Brownian motion dZ_S and corresponding expectation operator $E_S[\cdot \cdot \cdot]$. Then, a swap rate,

$$S(t) = \frac{P(t, T_0) - P(t, T_N)}{\sum_{n=1}^N \delta_n P(t, T_n)} = \frac{P(t, T_0) - P(t, T_N)}{L(t)} \quad (31)$$

is a martingale in the swap measure. The option price written in the swap measure reduces to a simple expression, $C(T_0) = L(0) E_S[(S(T_0) - K)^+]$. The swap rate SDE can be easily written,

$$dS(t) = \sum_i \frac{\partial S(t)}{\partial x_i(t)} \gamma_i(t) \cdot dZ_S(t) \quad (32)$$

The partial swap derivatives $d_i(t, x(t)) \equiv \partial S(t) / \partial x_i(t)$ can be calculated using the zero-bond solution (15), $\partial P(t, T) / \partial x_i(t) = -\alpha_i(t, T) P(t, T)$.

Given that the forward rates are here Gaussian, it is natural to assume that the swap rates are as well, approximating derivatives with their value for the underlying rates at the origin, that is $d_i(t, x(t)) \simeq d_i(t, 0)$. This approximation resembles the freezing technique of low-variance processes used for swaption pricing in Libor market models by many authors (see **LIBOR Market Model**).

Define $v = \int_0^{T_0} \left| \sum_i d_i(t, 0) \gamma_i(t) \right|^2 dt$. Then the swaption price for the Gaussian approximation of the swap rate,

$$dS(t) \simeq \sum_i d_i(t, 0) \gamma_i(t) \cdot dZ_S(t) \quad (33)$$

can be easily written

$$\begin{aligned} C = L(0) E_S[(S(T_0) - K)^+] &\simeq L(0) \\ &\times \left((S(0) - K) \Phi \left(\frac{S(0) - K}{\sqrt{v}} \right) \right. \\ &\left. + \sqrt{v} \Phi' \left(\frac{S(0) - K}{\sqrt{v}} \right) \right) \end{aligned} \quad (34)$$

Numerical Methods

Given available transition probabilities for the model, one can apply lattice methods on the basis of the conditional expectation calculus *via* convolution with the Gaussian kernel for the pricing of general payouts. Of course, other lattice techniques—such as finite differences—can be successfully used as well.

When the payout is path-dependent or the dimension of the model is beyond, say, 3 or 4, lattice methods must be replaced by Monte Carlo simulation; path simulation in the Monte Carlo method is straightforward and involves making Gaussian draws with moments computed from the conditional expectations (8–9).

Properties

We cover in detail the two-factor case, $r(t) = x_1(t) + x_2(t) + \theta(t)$ frequently used in the financial industry. In practical applications, the model correlation between the two Brownian motions $\rho(t) = E[dW_1(t)dW_2(t)]/dt$ in the notation (5), or the cosine of the angle between the two volatility vectors $\rho(t) = \gamma_1(t) \cdot \gamma_2(t)/|\gamma_1(t)||\gamma_2(t)|$ in the notations (6), typically takes highly negative values, $\rho(t) \sim -0.9$. The two mean reversions are often radically different $a_1(t) \sim 0.5$ and $a_2(t) \sim 0.05$ with the volatilities $\sigma_1(t) = |\gamma_1(t)| \sim 0.005$ and $\sigma_2(t) = |\gamma_2(t)| \sim 0.01$

Volatility Hump and Correlations

For illustration, we consider in more detail the two-factor model with time-independent parameters. The forward rates variance (18) simplifies to

$$V_F(t, T) = e^{-2a_1(T-t)}\sigma_1^2 + 2e^{-(a_1+a_2)(T-t)} \times \sigma_1\sigma_2\rho + e^{-2a_2(T-t)}\sigma_2^2 \quad (35)$$

For positive correlation ρ , the variance is a monotonous function of $T - t$, although, for negative ρ , it can give the volatility hump observed on the market, see [1] for details.

In our two-dimensional model, the forward rate $f(t, T)$ has instantaneous volatility,

$$\sigma(t, T) = e^{-(T-t)a_1}\gamma_1 + e^{-(T-t)a_2}\gamma_2 \quad (36)$$

obtained from the general formula (12). The correlation between two forward rates $f(t, T)$ and $f(t, T')$ can be computed from equation (19) as

$$C_F(t, T, T') = \frac{\sigma(t, T) \cdot \sigma(t, T')}{|\sigma(t, T)||\sigma(t, T')|} \quad (37)$$

We notice that the correlation is one when $a_1 = a_2$, a result of the fact that the volatilities for $f(t, T)$ and $f(t, T')$ are colinear in this case.

Volatility Smile

Swap rates in the Gaussian model are, as we have seen, nearly Gaussian, irrespective of parameter choice. As such, there is essentially no way to control the volatility skew implied by the model, which is often more steeply downward-sloping than market-observed smiles. Consequently, some care must be taken when applying the model to smile-sensitive instruments (*see Markovian Term Structure Models*).

Calibration

Practitioners typically use two- and three-factor Gaussian models. For four factors and more, pricing of an exotic instrument may become too time consuming.

A standard approach to the two-factor model calibration includes the following steps. First, we fix the time-independent correlation to a highly negative value or calibrate it to average historical correlations between forward rates by inversion of the correlation formula (19). Second, we calibrate the time-dependent volatilities and time-independent mean reversion^b to European options. The calibration options are often taken at-the-money, which reflects the absence of control of the skew and smile. The time-dependent parameters are typically considered as step-wise constant between option exercise dates. One can also use specially parameterized volatility curves, for example, having a hump form. Another popular calibration technique maintains a fixed ratio between the time-dependent volatilities, $\sigma_1(t)/\sigma_2(t) = \text{const}$.

The calibration is typically done using a numerical global optimizer to fit the model option prices to the market prices. The model option prices are calculated analytically, see the section European Option Prices.

For fixed mean reversions, one can also use a bootstrap in option exercise dates for the step wise constant volatilities calibration.

Acknowledgments

The author is indebted to Leif Andersen, Vladimir Piterbarg, and Jesper Andreasen for numerous discussions he had with them and their help with references. He is also grateful to Leo Mizrahi, Maria Belyanina, and his NumeriX colleagues, especially, to Greg Whitten, Serguei Issakov, Nicolas Audet, Meng Lu, Serguei Mechkov, and Patti Harris, for their valuable comments on the article.

End Notes

^aThanks to Leif Andersen and Vladimir Piterbarg for suggesting this approach.

^bTime-dependence in mean reversion is often avoided as it implies nonstationary behavior of the shape of the volatility term structure.

Quadratic Gaussian Models^a

Quadratic Gaussian (QG) models are factor models for the pricing of interest-rate derivatives, where interest rates are quadratic functions of underlying Gaussian factors. The QG model of interest rates was first introduced by Beaglehole and Tenney [3] and by El Karoui *et al.* [11]. Similar models had been introduced in epidemiology [16]. Jamshidian [14], under restrictive hypothesis on the dynamic of the factors, obtained closed formulas for the prices of vanilla options in the QG model. Durand and El Karoui [10] have detailed some properties and statistical analysis of the QG model. One may refer, for example, to [1, 6] for general studies of quadratic term-structure models.

Quadratic Gaussian Model

Uncertainty is represented by an n -dimensional Brownian motion $\hat{W}_t = (\hat{W}_t^1, \hat{W}_t^2, \dots, \hat{W}_t^n)^*$ on the filtered probability space (Ω, F_t, P) , where F_t is the natural augmented filtration of Brownian motion $\hat{W}$ and P the historical probability. We then add two assumptions:

Hypothesis 1 *The asset price processes in all the different markets are regular deterministic functions of n state variables.*

Hypothesis 2 *The state variables have a Gaussian–Markovian distribution with respect to all the risk-neutral probabilities (which includes the forward-neutral probabilities).*

The first hypothesis is common and is used in numerical methods such as finite difference methods to price and hedge options; the second is also natural if we want to have results as explicit as possible. We specify, more precisely, the diffusion of the state variable Z under the risk-neutral probability (*see Ornstein–Uhlenbeck Processes*):

$$dZ_t = (A_t Z_t + \mu_t) dt + \Sigma_t dW_t \quad (1)$$

where (W_t) is a Brownian motion under the domestic risk-neutral probability $\mathcal{Q}$.

Theorem 1 [11]. *Under these assumptions, there exist a family of symmetrical matrices $\hat{\Gamma}(t, T)$, a family of vectors $\hat{b}(t, T)$, and a family of scalars $\hat{a}(t, T)$ such that the zero-coupon price at t of the bond $P(t, T)$ is given by*

$$P(t, T) = \exp [Z_t^* \hat{\Gamma}(t, T) Z_t + \hat{b}^*(t, T) Z_t + \hat{a}(t, T)] \quad (2)$$

In particular, the functional dependence of the short rate r_t on the factors is quadratic affine:

$$\begin{aligned} r_t &= -\partial_T \ln P(t, T)_{t=T} \\ &= [Z_t^* \Gamma(t, T) Z_t + b^*(t, T) Z_t + a(t, T)] \end{aligned} \quad (3)$$

where

$$\begin{cases} \Gamma(t, T) = -\partial_T \hat{\Gamma}(t, T) \\ b(t, T) = -\partial_T \hat{b}(t, T) \\ a(t, T) = -\partial_T \hat{a}(t, T) \end{cases} \quad (4)$$

To describe completely the dynamics of the interest rates, we need to make explicit the computation of the matrices $\hat{\Gamma}(t, T)$, $\hat{b}(t, T)$, and $\hat{a}(t, T)$. Once again, the no-arbitrage assumption will give us the solution.

Theorem 2 [11]. *Given the short rate parameters, $\Gamma(t, t)$, $b(t, t)$, and $a(t, t)$, the matrices $\hat{\Gamma}(t, T)$, $\hat{b}(t, T)$, and $\hat{a}(t, T)$ are the solutions of the backward differential system with respect to the current date t*

$$\begin{cases} \partial_t U_t = -(A_t^* U_t + U_t A_t) + 2U_t^* \Sigma_t \Sigma_t^* U_t - \Gamma(t, t) \\ \partial_t u_t = -A_t^* u_t + 2U_t \Sigma_t^* \Sigma_t u_t - 2U_t \mu_t - b(t, t) \\ \partial_t \alpha_t = -tr[\Sigma_t \Sigma_t^* U_t] - u_t^* \mu_t + \frac{1}{2} u_t^* \Sigma_t \Sigma_t^* u_t - a(t, t) \end{cases} \quad (5)$$

with the initial conditions

$$\begin{cases} U_T = 0 \\ u_T = 0 \\ \alpha_T = 0 \end{cases} \quad (6)$$

These two results, which are direct consequences of the hypothesis, completely describe the diffusion of the interest rates under the risk-neutral probability. In the stationary case, let us denote $\hat{\Gamma}_\infty$ the solution of the algebraic Riccati equation on U :

$$A^* U + U A - 2U^* \Sigma \Sigma^* U + \Gamma = 0 \quad (7)$$

If $A - 2\hat{\Gamma}_\infty \Sigma \Sigma^*$ has only negative eigenvalues, then the equations of Theorem 2 will only have nonexploding solutions. In those cases, one can even obtain

a simple expression for the limit of the zero-coupon interest rate when the maturity increases to infinity; this limit does not depend on the time (see [10]). The QG model admits, for example, the following models as particular cases:

- the Gaussian model of Vasicek [15], its generalization by Hull and White [13], and its multidimensional version by Heath, Jarrow, and Morton (HJM) [12] (see **Gaussian Interest-Rate Models**);
- Cox, Ingersoll, and Ross (CIR) [8], Chen and Scott [7], and Duffie and Kan [9]; also see **Cox–Ingersoll–Ross (CIR) Model**.

Statistical Justification

In addition to the practical and computational justification of the hypothesis that lead to the QG model, this model can also be justified by statistical studies of the interest rates. The most intuitive justification comes from principal component analysis (PCA). For most currencies, using a PCA will lead to keeping two factors to explain the diffusion of the interest yield curves. Then, the residual noise may be explained by a quadratic form of the first two factors of the PCA. For a detailed description of this analysis, we refer to [10].

Option Pricing

In the QG model, the instantaneous volatility of the zero-coupon interest rates $R(t, T)$ is an affine form of the factors Z_t , and when we consider two factors or more, the instantaneous volatility of $R(t, T)$ cannot be written as a deterministic form of $R(t, T)$: in some way, we can therefore consider the QG model as a stochastic volatility model.^c Its main interest will be in interest-rate exotic option pricing and hedging.

Closed Form for Vanilla Option

Quasi-closed form for vanillas options are the consequence of the following result.

Theorem 3 [11]. *Let us denote by $m^T(t, u)$ and $V^T(t, u)$ the conditional mean and the conditional variance of Z_u under the forward-neutral probability of maturity T $\mathbb{Q}_t^T$. The conditional mean $m^T(t, T)$ and*

variance $V^T(t, T)$ of the factors are solutions of the differential system given by equation (8):

$$\begin{cases} \frac{\partial V^T(t, T)}{\partial T} = V^T(t, T)(A_T)^* + A_T V^T(t, T) \\ \quad - 2V^T(t, T)\Gamma(T, T)V^T(t, T) + \Sigma_T \Sigma_T^* \\ \frac{\partial m^T(t, T)}{\partial T} = A_T m^T(t, T) \\ \quad - 2V^T(t, T)\Gamma(T, T)m^T(t, T) \\ \quad + 2V^T(t, T)b(T, T) + \mu_T \\ V^T(t, t) = 0, \quad m^T(t, t) = Z_t \end{cases} \quad (8)$$

and under the risk-neutral probability $\mathbb{Q}_t$, the conditional mean $m(t, T)$ and variance $V(t, T)$ of the factors are solutions of the differential system:

$$\begin{cases} \frac{\partial V(t, T)}{\partial T} = V(t, T)(A_T)^* + A_T V(t, T) + \Sigma_T \Sigma_T^* \\ \frac{\partial m(t, T)}{\partial T} = A_T m(t, T) + \mu_T \\ V(t, t) = 0 \quad m(t, t) = Z_t \end{cases} \quad (9)$$

Assefa [2] has detailed swaption prices in the QG model and has described how approximations may be obtained using Fourier transform. Some analytical approximations of caps, floors, and swaptions are also proposed in [4].

Pricing of Exotic Options

To use the QG model to price and hedge exotic options, one needs to add some constraints to simplify the different equations and to accelerate the different numerical schemes used in the different steps of calibrating the model on plain vanilla option prices and used to price exotic options. Some calibration results of a two-factor QG model on USD Libor caps and swaptions are shown in [2]. Depending on the shape of the smile and on the payoff of the exotic option studied, one uses a one- or two-factor model: empirically, by using a one-factor QG model one will generate increasing or decreasing volatility smiles; with a two-factor QG model, “U-shape” volatility smiles may be generated. The QG model can then be successfully calibrated on vanilla option prices and on interest-rate correlation to price and hedge exotic interest-rate options. We recommend to choose a calibration set for each exotic option and not to try to calibrate simultaneously to the entire volatility cube. We also recommend to specify a correlation structure

on the forward interest rate and not to deduce it implicitly from the market implied volatilities.

Summary

Owing to its capacity to calibrate interest-rate volatility smiles and correlation term structure, the QG is an interesting model to price and hedge exotic interest-rate derivatives, as multicancelable options on interest-rate spreads. Several banks have developed proprietary models based on the QG model, each choosing its own parameterization, mainly as a consequences of choices made on the numerical schemes used.

End Notes

^aThis article reflects the author's point of view and do not necessarily represents the point of view of Banque de France.

^bHere x^* denotes transpose (x).

^cIn fact, as we can deduce the factors Z_t from the interest-rate curve, we can write the instantaneous volatility of $R(t, \theta)$ as a deterministic function of interest rate of different maturities; in a theoretical point of view, the QG model may be not a stochastic volatility model as defined in [5].

PHILIPPE DURAND

Affine Models

Definition

Notation 1 Throughout the article, $\langle \cdot, \cdot \rangle$ denotes the standard scalar product on $\mathbb{R}^N$.

Definition 1 Let r_t be a short-rate model specified as an affine function of an N -dimensional Markov process X_t with state space $D \subseteq \mathbb{R}^N$:

$$r_t = l + \langle \lambda, X_t \rangle \quad (1)$$

for some (nontime-dependent) constants $l \in \mathbb{R}$ and $\lambda \in \mathbb{R}^N$. This is called an affine term structure model (ATSM) if the zero-coupon bond price has exponential-affine form, that is,

$$\begin{aligned} P(t, T) &= \mathbb{E} \left[e^{-\int_t^T r_s ds} \middle| X_t \right] \\ &= e^{G(t, T) + \langle H(t, T), X_t \rangle} \end{aligned} \quad (2)$$

where $\mathbb{E}$ denotes the expectation under a risk neutral probability measure.

Early Examples

Early well-known examples are the Vasiček [14] and the Cox *et al.* [5] (see **Term Structure Models; Cox–Ingersoll–Ross (CIR) Model**) time-homogeneous one-factor short-rate models. In equation (1), both models are characterized by $N = 1$, $l = 0$, and $\lambda = 1$.

Vasiček Model

X_t follows an Ornstein–Uhlenbeck process on $D = \mathbb{R}$,

$$dX_t = (b + \beta X_t) dt + \sigma dW_t, \quad b, \beta \in \mathbb{R}, \quad \sigma \in \mathbb{R}_+ \quad (3)$$

where W_t is a standard Brownian motion. Under these model specifications, bond prices can be explicitly calculated and the corresponding coefficients G and H in equation (2) are given by

$$H(t, T) = \frac{1 - e^{\beta(T-t)}}{\beta}$$

$$\begin{aligned} G(t, T) &= \frac{\sigma^2}{2} \int_t^T H^2(s, T) ds \\ &\quad + b \int_t^T H(s, T) ds \end{aligned} \quad (4)$$

provided that $\beta \neq 0$ (see also **Term Structure Models**).

Cox–Ingersoll–Ross Model

X_t is defined as the solution of the following affine diffusion process on $D = \mathbb{R}_+$, known as *Feller square root process*,

$$\begin{aligned} dX_t &= (b + \beta X_t) dt + \sigma \sqrt{X_t} dW_t \\ b, \sigma &\in \mathbb{R}_+, \quad \beta \in \mathbb{R} \end{aligned} \quad (5)$$

Like in the Vasiček model, there is a closed-form solution for the bond price. If $\sigma \neq 0$, G and H in equation (2) are then of the form:

$$\begin{aligned} G(t, T) &= \frac{2b}{\sigma^2} \ln \left(\frac{2\gamma e^{(\gamma - \beta)(T-t)/2}}{(\gamma - \beta)(e^{\gamma(T-t)} - 1) + 2\gamma} \right) \\ H(t, T) &= \frac{-2(e^{\gamma(T-t)} - 1)}{(\gamma - \beta)(e^{\gamma(T-t)} - 1) + 2\gamma} \end{aligned} \quad (6)$$

where $\gamma := \sqrt{\beta^2 + 2\sigma^2}$ (see also **Cox–Ingersoll–Ross (CIR) Model**).

Since the development of these first one-dimensional term structure models, many multifactor extensions have been considered with the aim to provide more realistic models.

Regular Affine Processes

The generic method to construct ATSMs is to use regular affine processes. A concise mathematical foundation was provided by Duffie *et al.* [8]. Henceforth, we fix the state space $D = \mathbb{R}_+^m \times \mathbb{R}^{N-m}$, for some $0 \leq m \leq N$.

Definition 2 A Markov process X is called *regular affine* if its characteristic function has exponential-affine dependence on the initial state, that is, for

$t \in \mathbb{R}_+$ and $u \in i\mathbb{R}^N$, there exist $\phi(t, u) \in \mathbb{C}$ and $\psi(t, u) \in \mathbb{C}^N$, such that for all $x \in D$

$$\mathbb{E}[e^{\langle u, X_t \rangle} | X_0 = x] = e^{\phi(t, u) + \langle \psi(t, u), x \rangle} \quad (7)$$

Moreover, the functions ϕ and ψ are continuous in t and $\partial_t^+ \phi(t, u)|_{t=0}$ and $\partial_t^+ \psi(t, u)|_{t=0}$ exist and are continuous at $u = 0$.

Regular affine processes have been defined and completely characterized in [8]. The main result is stated below.

Theorem 1 A regular affine process is a Feller semimartingale with infinitesimal generator

$$\begin{aligned} \mathcal{A}f(x) = & \sum_{k,l=1}^N A_{kl}(x) \frac{\partial^2 f(x)}{\partial x_k \partial x_l} \\ & + \langle B(x), \nabla f(x) \rangle - C(x)f(x) \\ & + \int_{D \setminus \{0\}} (f(x + \xi) - f(x) \\ & - \langle \nabla f(x), \chi(\xi) \rangle) M(x, d\xi) \end{aligned} \quad (8)$$

for f in the set of smooth test functions, with

$$A(x) = a + \sum_{i=1}^m x_i \alpha_i, \quad a, \alpha_i \in \mathbb{R}^{N \times N} \quad (9)$$

$$B(x) = b + \sum_{i=1}^N x_i \beta_i, \quad b, \beta_i \in \mathbb{R}^N \quad (10)$$

$$C(x) = c + \sum_{i=1}^m x_i \gamma_i, \quad c, \gamma_i \in \mathbb{R}_+ \quad (11)$$

$$M(x, d\xi) = m(d\xi) + \sum_{i=1}^m x_i \mu_i(d\xi) \quad (12)$$

where m, μ_i are Borel measures on $D \setminus \{0\}$ and $\chi : \mathbb{R}^N \rightarrow \mathbb{R}^N$ some bounded continuous truncation function with $\chi(\xi) = \xi$ in a neighborhood of 0. Furthermore, ϕ and ψ in equation (7) solve the generalized Riccati equations,

$$\partial_t \phi(t, u) = F(\psi(t, u)), \quad \phi(0, u) = 0 \quad (13)$$

$$\partial_t \psi(t, u) = R(\psi(t, u)), \quad \psi(0, u) = u \quad (14)$$

with

$$F(u) = \langle au, u \rangle + \langle b, u \rangle - c$$

$$+ \int_{D \setminus \{0\}} (e^{\langle u, \xi \rangle} - 1 - \langle u, \chi(\xi) \rangle) m(d\xi) \quad (15)$$

$$\begin{aligned} R_i(u) = & \langle \alpha_i u, u \rangle + \langle \beta_i, u \rangle - \gamma_i \\ & + \int_{D \setminus \{0\}} (e^{\langle u, \xi \rangle} - 1 - \langle u, \chi(\xi) \rangle) \mu_i(d\xi) \end{aligned} \quad (16)$$

for $i \in \{1, \dots, m\}$

$$R_i(u) = \langle \beta_i, u \rangle, \quad \text{for } i \in \{m+1, \dots, N\} \quad (17)$$

Conversely, for any choice of admissible parameters $a, \alpha_i, b, \beta_i, c, \gamma_i, m, \mu_i$, there exists a unique regular affine process with generator (8).

Remark 1 It is worth noting that the infinitesimal generator of every Feller process on $\mathbb{R}^N$ has the form of the above integro-differential operator (8) with some functions A, B, C and a kernel M . The specific characteristic of regular affine processes is that these functions are all affine, as described in equations (9–12).

Observe furthermore that by the definition of the infinitesimal generator and the form of F and R , we have

$$\begin{aligned} & \frac{d}{dt} \mathbb{E}[e^{\langle u, X_t \rangle} | X_0 = x] \Big|_{t=0_+} \\ & = (\partial_t^+ \phi(t, u)|_{t=0} + \partial_t^+ \psi(t, u)|_{t=0}) e^{\langle u, x \rangle} \\ & = (F(u) + \langle R(u), x \rangle) e^{\langle u, x \rangle} = \mathcal{A}e^{\langle u, x \rangle} \end{aligned} \quad (18)$$

This gives the link between the form of the operator $\mathcal{A}$ and the functions F and R in the Riccati equations (13) and (14).

Remark 2 The above parameters satisfy certain admissibility conditions guaranteeing the existence of the process in D . These parameter restrictions can be found in Definition 2.6 and equations (2.23)–(2.24) in [8]. We note that admissibility, in particular, means $\alpha_{i,kl} = 0$ for $i, k, l \leq m$ unless $k = l = i$.

Systematic Analysis

Regular Affine Processes and ATSMs

Regular affine processes generically induce ATSMs. This relation is explicitly stated in the subsequent

argument. Under some technical conditions that are specified in [8, Chapter 11], we have for r_t as defined in equation (1),

$$\mathbb{E}\left[e^{-\int_0^t r_s ds} e^{\langle u, X_t \rangle} \middle| X_0 = x\right] = e^{\tilde{\phi}(t, u) + \langle \tilde{\psi}(t, u), x \rangle} \quad (19)$$

where

$$\begin{aligned} \partial_t \tilde{\phi}(t, u) &= \tilde{F}(\tilde{\psi}(t, u)) \\ \partial_t \tilde{\psi}(t, u) &= \tilde{R}(\tilde{\psi}(t, u)) \end{aligned} \quad (20)$$

with $\tilde{F}(u) = F(u) - l$ and $\tilde{R}(u) = R(u) - \lambda$. Setting $u = 0$ in equation (19), one immediately gets equation (2) with $G(t, T) = \tilde{\phi}(T - t, 0)$ and $H(t, T) = \tilde{\psi}(T - t, 0)$.

Diffusion Case

Conversely, for a class of diffusions

$$dX_t = B(X_t) dt + \sigma(X_t) dW_t \quad (21)$$

on D , Duffie and Kan [7] analyzed when equation (2) implies an affine diffusion matrix $A = \frac{\sigma \sigma^T}{2}$ and an affine drift B of form equations (9) and (10), respectively.

One-dimensional Nonnegative Markov Process

For $D = \mathbb{R}_+$, Filipović [9] showed that equation (1) defines an ATSM if and only if X_t is a regular affine process.

Relation to Heath–Jarrow–Morton Framework

Filipović and Teichmann [10] established a relation between the Heath–Jarrow–Morton (HJM) framework (see **Heath–Jarrow–Morton Approach**) and ATSMs: essentially, all generic finite dimensional realizations^a of a HJM term structure model are time-inhomogeneous ATSMs.

Canonical Representation

An ATSM stemming from a regular affine diffusion process X on $\mathbb{R}_+^m \times \mathbb{R}^{N-m}$ can be represented in different ways by applying nonsingular affine transformations to X . Indeed, for every nonsingular $N \times N$ -matrix K and $\kappa \in \mathbb{R}^N$, the transformation

$KX + \kappa$ modifies the particular form of equation (21) and the short-rate process (1), while observable quantities (e.g., the term structure or bond prices) remain unchanged. To group those N -dimensional ATSMs generating identical term structures, Dai and Singleton [6] found $N + 1$ subfamilies $\mathbb{A}_m(N)$, where $0 \leq m \leq N$ is the number of state variables actually appearing in the diffusion matrix (i.e., the dimension of the positive half space). For each class, they specified a canonical representation whose diffusion matrix $\sigma \sigma^T$ is of diagonal form with

$$(\sigma \sigma^T(x))_{kk} = \begin{cases} x_k, & k \leq m \\ 1 + \sum_{i=1}^m \lambda_{k,i} x_i, & k > m \end{cases} \quad (22)$$

where $\lambda_{k,i} \in \mathbb{R}$. For $N \leq 3$ the Dai–Singleton specification comprises all ATSMs generated by regular affine diffusions on $\mathbb{R}_+^m \times \mathbb{R}^{N-m}$. The general situation $N > 3$ was analyzed by Cheridito *et al.* [4].

Empirical Aspects

Pricing

The price of a claim with payoff function $f(X_t)$ is given by the risk neutral expectation formula:

$$\pi(t, x) = \mathbb{E}\left[e^{-\int_0^t r_s ds} f(X_t) \middle| X_0 = x\right] \quad (23)$$

Suppose that f can be expressed by

$$f(x) = \int_{\mathbb{R}^N} e^{\langle C+i\lambda, x \rangle} \tilde{f}(\lambda) d\lambda, \quad \lambda \in \mathbb{R}^N \quad (24)$$

for some integrable function $\tilde{f}$ and some constant $C \in \mathbb{R}^N$. If, moreover,

$$\mathbb{E}\left[e^{-\int_0^t r_s ds} e^{\langle C, X_t \rangle} \middle| X_0 = x\right] < \infty \quad (25)$$

then equation (19) implies

$$\begin{aligned} \pi(t, x) &= \mathbb{E}\left[e^{-\int_0^t r_s ds} \left(\int_{\mathbb{R}^N} e^{\langle C+i\lambda, X_t \rangle} \tilde{f}(\lambda) d\lambda\right) \middle| X_0 = x\right] \\ &= \int_{\mathbb{R}^N} \mathbb{E}\left[e^{-\int_0^t r_s ds} e^{\langle C+i\lambda, X_t \rangle} \middle| X_0 = x\right] \tilde{f}(\lambda) d\lambda \\ &= \int_{\mathbb{R}^N} e^{\tilde{\phi}(t, C+i\lambda) + \langle \tilde{\psi}(t, C+i\lambda), x \rangle} \tilde{f}(\lambda) d\lambda \end{aligned} \quad (26)$$

Hence, the price $\pi(t, x)$ can be computed *via* numerical integration, since the integrands are, in principle, known. For instance, in the case $N = 1$, the payoff function of a European call $(e^x - e^k)^+$, where x corresponds to the log price of the underlying and k to the log strike price, satisfies equation (24). In particular, we have the following integral representation (see [11]):

$$(e^x - e^k)^+ = \frac{1}{2\pi} \int_{\mathbb{R}} e^{(C+i\lambda)x} \frac{e^{k(1-C-i\lambda)}}{(C+i\lambda)(C+i\lambda-1)} d\lambda \quad (27)$$

Therefore, the previous formula to compute the price of the call $\pi(t, x)$ is applicable. An alternative approach leading to the same result can be found in [3].

Estimation

Statistical methods to estimate the parameters of ATSMs have been based on maximum likelihood and generalized method of moments.

Concerning maximum likelihood techniques, the conditional log densities entering into the log likelihood function can, in general, be obtained by inverse Fourier transformation. Since this procedure is computationally costly, several approximations and limited-information estimation strategies have been considered (e.g., [13]). Another possibility is to use closed-form expansions of the log likelihood function, which are available for general diffusions [1] and which have been applied to ATSMs. In the case of Gaussian and Cox–Ingersoll–Ross models, one can forgo such techniques, since the log densities are known in closed form (e.g., [12]).

As conditional moments of the form $\mathbb{E}[X_t^m X_{t-s}^n]$ for $m, n \geq 0$ can be computed from the derivatives of the conditional characteristic function and are, in general, explicitly known up to the solution of the Riccati ordinary differential equations (ODEs) (13) and (14), the generalized method of moments is an alternative to maximum likelihood estimation (e.g., [2]).

Markovian Term Structure Models

An interest rate model is said to be Markovian (*see Markov Processes*) in N state variables if all discount factors at any future date can be written as a function of an N -dimensional Markov process. HJM [7] and Libor market models are generally not Markov in a limited number of state variables—the full yield curve has to be included as a Markov state variable. The separable forward rate volatility structure in the HJM introduced by Babbs [4], Cheyette [5], Jamshidian [8], and Ritchken and Sankarasubramanian [11] avoids this problem. Specifically, if the dimension of the driving Brownian motion is n , then a model with separable volatility will have a Markov representation in $N = n + n(n + 1)/2$ state variables. We discuss the connection to short rate models in general and Gaussian models in particular, calibration techniques, simulation and finite-difference implementation, and the specification of multifactor separable models.

Non-Markovian Nature of HJM Models

Let $P(t, T)$ be the time t price of a zero-coupon bond with maturity T . The continuously compounded forward rates are given by

$$f(t, T) = -\frac{\partial \ln P(t, T)}{\partial T} \quad (1)$$

and the short rate is given by

$$r(t) = f(t, t) \quad (2)$$

Under the assumption of continuous dynamics and one driving Brownian motion, in [3, 7] it is shown that the absence of arbitrage implies that forward rates evolve according to

$$df(t, T) = \sigma(t, T) \left(\int_t^T \sigma(t, s) ds \right) dt + \sigma(t, T) dW(t) \quad (3)$$

where $\{\sigma(t, T)\}_{t \leq T}$ is a family of volatility processes and W is a Brownian motion under the risk-neutral measure, that is, the martingale measure under

which the bank account $B(t) = \exp\left(\int_0^t r(u) du\right)$ is the numeraire.

This shows that all that is required to construct an arbitrage-free interest rate model that automatically fits the initial yield curve is a specification of the forward rate volatility structure $\{\sigma(t, T)\}_{t \leq T}$.

The problem, however, with arbitrary specification of the volatility structure is that the resulting model will generally not be Markov in a limited number of state variables. In general, the whole continuum $\{f(t, T)\}_{t \leq T}$ has to be used as state variables for the model. This is true regardless of the dimension of the driving Brownian motion and it is also the case for deterministic forward rate volatility structures. It should be stressed that the Libor market model exhibits the same problem. Generally, it will require all the modeled discrete forward rates as Markov state variables.

Separable Volatility Structure

Heath–Jarrow–Morton Approach gives the necessary and sufficient conditions on the forward rate volatility structure for the resulting HJM model to be Markov. An important subset of the general class of Markov HJM models is the separable volatility structure models, independently introduced by Babbs [4], Cheyette [5], Jamshidian [8], and Ritchken and Sankarasubramanian [11]. For the one-factor case, the separable form is to assume that the forward rate volatility structure is given by

$$\sigma(t, T) = g(T)h(t) \quad (4)$$

where g is a deterministic function and h is a process.

Under the assumption (4), equation (3) can be rewritten as

$$f(t, T) = f(0, T) + \frac{g(T)}{g(t)}x(t) + y(t) \int_t^T \frac{g(s)}{g(t)} ds \quad (5)$$

where

$$dx(t) = \left(\frac{g'(t)}{g(t)}x(t) + y(t) \right) dt + g(t)h(t) dW(t), \quad x(0) = 0$$

$$\begin{aligned} dy(t) &= (g(t)^2 h(t)^2 + 2 \frac{g'(t)}{g(t)} y(t)) dt, \\ y(0) &= 0 \end{aligned} \quad (6)$$

By defining $\kappa(t) = -g'(t)/g(t)$, $\eta(t) = g(t)h(t)$ and integrating equation (5) we obtain the more convenient model representation

$$\begin{aligned} P(t, T) &= \frac{P(0, T)}{P(0, t)} e^{-G(t, T)x(t) - \frac{1}{2}G(t, T)^2 y(t)} \\ dx(t) &= (-\kappa(t)x(t) + y(t)) dt + \eta(t) dW(t), \\ x(0) &= 0 \\ dy(t) &= (\eta(t)^2 - 2\kappa(t)y(t)) dt, \quad y(0) = 0 \\ G(t, T) &= \int_t^T e^{-\int_t^s \kappa(u) du} ds \end{aligned} \quad (7)$$

So if we assume $\eta = \eta(t, x(t), y(t))$, then we have a Markov representation of the full yield curve in the state variables x, y . Here, we can interpret x as a stochastic yield curve factor that perturbs the yield curve and y as a locally deterministic convexity term that has to be included to keep the model arbitrage-free.

It should be noted here that the bond prices are exponentially affine in the state variables. The separable model thus belongs to the general class of affine models (*see Affine Models*). In this class it is a special member, as the model's second locally deterministic state variable (y) eliminates the need for $\eta(t, x, y)^2$ to be linear in (x, y) , as in the models studied in [6].

From equation (5) we note that $r(t) = f(0, t) + x(t)$ and consequently that the process for the short rate is

$$\begin{aligned} dr(t) &= \left[\frac{\partial f(0, t)}{\partial t} + \kappa(t)(r(t) - f(0, t)) + y(t) \right] \\ &\quad nd \times dt + \eta(t) dW(t) \end{aligned} \quad (8)$$

If we set $\eta = \lambda(t)r(t)^\beta$, we get a model that, except for the state variable y included in the drift term of the short rate, is very similar to the short rate models by Vasicek [12], and others.^a

For $\beta = 0$, or equivalently η deterministic, y becomes deterministic, and the model is equivalent to the Gaussian model, that is, a general time-dependent parameter version of the Vasicek [12] model. For this

case, equation (7) can be seen as a convenient implementation of a time-dependent Vasicek model. The fact that the separable volatility models have a structure that is very close to the Gaussian models led Babbs [4] and Jamshidian [8] to term these models *quasi-Gaussian* and *pseudo-Gaussian*, respectively.

Another feature shared with the Gaussian model is that for fixed κ the distribution of the rates at time t only depends on the volatility up to time t , $\{\eta(u)\}_{0 \leq u \leq t}$. This means that the model can be bootstrap calibrated to swaption prices, by calibrating the model to one swaption expiry at the time. This is not the case for general short rate models because the bond price $P(t, T)$ generally depends on the short rate volatility over the interval $[t, T]$. So short rate models generally have to be calibrated to swaption prices using global routines.

Model Implementation

The forward par swap rate for swapping over the dates $t_0, t_1, \dots, t_n$ is given by

$$\begin{aligned} S(t) &= \frac{P(t, t_0) - P(t, t_n)}{A(t)}, \\ A(t) &= \sum_{i=1}^n \delta_i P(t, t_i), \quad \delta_i = t_i - t_{i-1} \end{aligned} \quad (9)$$

Following **Forward and Swap Measures**, we have that the swap rate is a martingale under the annuity measure, so we can write

$$dS(t) = \frac{\partial S(t)}{\partial x} \eta(t) dW^A(t) \quad (10)$$

where W^A is a Brownian motion under the martingale measure with the annuity A as numeraire. This can be used for deriving approximations for the value of swaptions using the same techniques as in the Libor market model literature. Specifically, we may, for example, approximate the stochastic differential equation (SDE) (10) by

$$dS(t) = \lambda(\beta S(t) + (1 - \beta)S(0)) dW^A(t) \quad (11)$$

Matching the diffusions in equations (10) and (11) in level and derivative with respect to x along the path $x = y = 0$ yields

$$\begin{aligned}\lambda^2 &= t^{-1} S(0)^{-2} \int_0^t [(S_x(u)^2 \eta(u)^2)]_{x=y=0} du \\ \beta &= \frac{\int_0^t [S_x(u) S_{xx}(u) \eta(u)^2 + S_x(u)^2 \eta(u) \eta_x(u)]_{x=y=0} du}{\lambda^2 S(0) \int_0^t [S_x(u)]_{x=y=0} du}\end{aligned}\quad (12)$$

where we have used subscripts for derivatives, so $S_x = \partial S / \partial x$, $\eta_x = \partial \eta / \partial x$.

From this we have that the swaption prices of the model can be approximated by

$$\begin{aligned}E^A[(S(t) - K)^+] &\approx \frac{1}{\beta} [S(0) \Phi(z_+) - \bar{K} \Phi(z_-)] \\ \bar{K} &= \beta K + (1 - \beta) S(0) \\ z_{\pm} &= \frac{\ln(S(0)/\bar{K})}{\beta \lambda \sqrt{t}} \pm \frac{1}{2} \beta \lambda \sqrt{t}\end{aligned}\quad (13)$$

More refined approximations based on the Markovian projection techniques of Piterbarg [10] can be found in [2].

Let $0 = t_0 < t_1 < \dots$ be a simulation time line. Then using equation (5) it can be shown that

$$\begin{aligned}x(t_{i+1}) &= \frac{g(t_{i+1})}{g(t_i)} x(t_i) + \frac{g(t_{i+1})}{g(t_i)} \left(\int_{t_i}^{t_{i+1}} \frac{g(u)}{g(t_i)} du \right) \\ &\quad \times y(t_i) + \int_{t_i}^{t_{i+1}} \frac{g(t_{i+1})}{g(u)} \eta(u) dW^{t_{i+1}}(u) \\ y(t_{i+1}) &= \left(\frac{g(t_{i+1})}{g(t_i)} \right)^2 y(t_i) + \int_{t_i}^{t_{i+1}} \left(\frac{g(t_{i+1})}{g(u)} \right)^2 \\ &\quad \times \eta(u)^2 du\end{aligned}\quad (14)$$

where W^T is a Brownian motion under the martingale measure with $P(\cdot, T)$ as numeraire, that is, the maturity T forward measure.

If we make the approximation $\eta(t) = \eta(t_i)$ for $t \in [t_i, t_{i+1}]$ then equation (14) provides a simulation scheme that produces bias-free pricing of all bonds, in the sense that if we generate discrete paths of $\{x(t_i), y(t_i)\}_{i=0,1,\dots}$ using equation (14) and use these

for producing bond prices, then for all n

$$\begin{aligned}P(0, t_n) &= \hat{E}[B(t_n)], \\ B(t_n) &= \prod_{i=0}^{n-1} P(t_i, t_{i+1}; x(t_i), y(t_i))\end{aligned}\quad (15)$$

where $\hat{E}[\cdot]$ denotes the simulation mean. This is so because over each time step the scheme (14) is the exact simulation of a Gaussian model.

The pricing partial differential equation (PDE) associated with the model is

$$\begin{aligned}0 &= \frac{\partial V}{\partial t} + D_x V + D_y V \\ D_x &= -\frac{r}{2} + (-\kappa x + y) \frac{\partial}{\partial x} + \frac{1}{2} \eta^2 \frac{\partial^2}{\partial x^2} \\ D_y &= -\frac{r}{2} + (\eta^2 - 2\kappa y) \frac{\partial}{\partial y}\end{aligned}\quad (16)$$

The absence of diffusion term in the second dimension can make the finite-difference solution of the PDE quite challenging, and this suggests the use of upwind and fully implicit schemes to prevent “ringing” in the numerical solution which would reduce the accuracy of the solution. Andreasen [1], however, reports good practical results with the $O(\Delta t^2 + \Delta x^2 + \Delta y^4)$ accurate Mitchell scheme [9]

$$\begin{aligned}&\left[\frac{1}{\Delta t} - \frac{1}{2} D_x \right] U(t) \\ &= \left[\frac{1}{\Delta t} + \frac{1}{2} D_x + D_y \right] V(t + \Delta t) \\ &\left[\frac{1}{\Delta t} - \frac{1}{2} D_y \right] V(t) \\ &= \frac{1}{\Delta t} U(t) - \frac{1}{2} D_y V(t + \Delta t)\end{aligned}\quad (17)$$

used with a standard 3-point discretization of D_x and a 5-point discretization of D_y . The 5-point discretization in the second dimension eliminates the need for the use of upwind schemes at a slightly higher computational cost than would be the case for a standard 3-point scheme.

Multiple Factors

The multifactor counterpart to equation (3) is

$$df(t, T) = \sigma(t, T) \cdot \left(\int_t^T \sigma(t, s) ds \right) dt + \sigma(t, T) \cdot dW(t) \quad (18)$$

where $\{\sigma(t, T)\}_{t \leq T}$ is a family of n -dimensional vector processes, W is an n -dimensional vector Brownian motion, and $\cdot$ denotes vector product. In the n factor separable volatility structure model, the forward rate volatility is given by

$$\sigma(t, T) = h(t)g(T) \quad (19)$$

where g is a deterministic vector function on $\mathbb{R}_+^n$ and h is a matrix process on $\mathbb{R}^{n \times n}$. Defining

$$\kappa_i(t) = -\frac{g_i'(t)}{g_i(t)} \quad (20)$$

and

$$\eta_{ij}(t) = g_i(t)h_{ij}(t) \quad (21)$$

the separable volatility model can be written as follows [5]:

So we have a Markov representation involving $n + n(n + 1)/2$ state variables with $x = (x_i)$ being a vector of stochastic yield curve factors and the symmetric matrix $y = (y_{ij})$ being a locally deterministic convexity term that has to be pulled along in simulation of the model to keep the model arbitrage-free.

The number of state variables grows at a quadratic rate and this prevents the use of finite-difference methods for $n > 1$. There are, however, very significant computational savings associated with using this type of model rather than a general HJM (see **Heath–Jarrow–Morton Approach**) or LIBOR market model (see **LIBOR Market Model**) approach even though Monte Carlo simulations have to be used for the numerical solution. For the case of $n = 4$ driving Brownian motions the number of state variables is 14, which should be compared against the 120 state variables of a 30-year quarterly Libor market model.

If we let the mean-reversion parameters, $\kappa_1, \dots, \kappa_n$ be constant, then

$$\sigma_j(t, t + \tau) = \sum_{i=1}^n e^{-\kappa_i \tau} \eta_{ij}(t) \rightarrow \int e^{-\kappa \tau} \eta_{\kappa j}(t) d\kappa \quad (23)$$

for $n \rightarrow \infty$ and an appropriately chosen sequence $\kappa_1, \kappa_2, \dots$. So model (22) can be seen as a representation of the forward rate volatility structure on a (discrete) basis of exponential functions. The function $\kappa \mapsto \eta_{\kappa j}(t)$ can thus be viewed as the inverse Laplace transform of the j th component of the forward rate volatility structure in the tenor dimension: $\tau \mapsto \sigma_j(t, t + \tau)$.

$$P(t, T) = \frac{P(0, T)}{P(0, t)} e^{-\sum_{i=1}^n G_i(t, T)x_i(t) - \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n G_i(t, T)y_{ij}(t)G_j(t, T)}$$

$$dx_i(t) = (-\kappa_i(t)x_i(t) + \sum_{j=1}^n y_{ij}(t)) dt + \sum_{j=1}^n \eta_{ij}(t) dW_j(t)$$

$$dy_{ij}(t) = \left(\sum_{k=1}^n \eta_{ik}(t)\eta_{jk}(t) - (\kappa_i(t) + \kappa_j(t))y_{ij}(t) \right) dt$$

$$G_i(t, T) = \int_t^T e^{-\int_t^s \kappa_i(u) du} ds \quad (22)$$

Still, representation (22) is not particularly concrete in relating the dynamics of the state variables to the dynamics of observable rates. To do so we fix a set of tenors $\tau_1, \dots, \tau_n$ and consider the forward rate vector $F(t) = (f(t, t + \tau_1), \dots, f(t, t + \tau_n))'$. We have

$$dF(t) = \Sigma(t) dW(t) + O(dt)$$

$$\Sigma(t) = \begin{bmatrix} \sigma_1(t, t + \tau_1) & \dots & \sigma_n(t, t + \tau_1) \\ \vdots & \ddots & \vdots \\ \sigma_1(t, t + \tau_n) & \dots & \sigma_n(t, t + \tau_n) \end{bmatrix} \quad (24)$$

In model (22) we have

$$dF(t) = \Gamma(t)\eta(t) dW(t) + O(dt)$$

$$\Gamma(t) = \begin{bmatrix} g_1(t, t + \tau_1) & \dots & g_n(t, t + \tau_1) \\ \vdots & \ddots & \vdots \\ g_1(t, t + \tau_n) & \dots & g_n(t, t + \tau_n) \end{bmatrix}$$

$$g_i(t, T) = e^{-\int_t^T \kappa_i(u) du} \quad (25)$$

If we equate the diffusion terms in equations (24) and (25) we get

$$\eta(t) = \Gamma(t)^{-1} \Sigma(t) \quad (26)$$

So for this choice, models (22) and (24) exactly match on the dynamics of the selected forward rates. Andreasen [2] uses this technique to construct a separable volatility structure model that mimics the dynamics of a Libor market model with rate-dependent and stochastic volatility, and it is shown that a four-factor version of such a model is capable of fitting the full cap and swaption market for all expiries and tenors and strikes within quite narrow tolerances.

End Notes

^aThis volatility specification is suggested in [11]. In [1] it is suggested to model volatility to have dependencies of longer tenor rates.

Swap Market Models

The Black formula [2], (see **Caps and Floors**) is popular among practitioners as a simple tool to price European options on Libor rates, that is, caplets and floorlets (see **Caps and Floors**), and on swap rates (see **LIBOR Rate**), that is, swaptions. More recently, Brace *et al.* [3], Miltersen *et al.* [12], and Jamshidian [11] provided a sound theoretical basis to this practice by introducing a general framework to consistently price interest rate options by no-arbitrage arguments. These works paved the way toward a broader acceptance of the so-called *market models* for interest-rate derivatives by the academic community since they can be recast within the general arbitrage-free framework discussed in [9] (see **Heath–Jarrow–Morton Approach**). These models have the advantage, over those based on the evolution of the spot interest rate, of concentrating on rates that are market observable.

The *Libor market model* [3, 12], (see **LIBOR Market Model**) and the *co-terminal swap market model* [11] are the two major representatives of this class. These models are built by assigning arbitrage-free dynamics on a set of forward Libor rates and of co-terminal forward swap rates, respectively. The advent of new kinds of exotic (over-the-counter) derivatives in fixed income markets has recently inspired the introduction of “hybrid” or “generalized” market models where the underlying variables constitute a mixed set comprising both Libor and swap rates simultaneously. In this context, an extensive study is provided in Galluccio *et al.* [5, 6]. The availability of a general setup to build market models with mixed sets is of interest in applications, for example, to better capture the risk embedded in some complex financial derivatives.

Tenor Structure and Forward Swap Rates

We assume that we are given a prespecified collection of reset/settlement dates $T = \{T_1, \dots, T_M\}$, referred to as the *tenor structure*, with $T_j < T_k, 1 \leq j < k \leq M$, and starting time $T_0 < T_1$. Let us denote the year fraction between any two consecutive dates by $\delta_j = T_j - T_{j-1}$, for $j = 1, \dots, M$. We write $P(t, T_j)$, $j = 1, \dots, M$, to denote the price at time t of a *discount bond* that matures at time $T_j > t$. The

forward swap rate $S(t, T_j, T_k)$, with j and k satisfying $1 \leq j < k \leq M$, is defined through $S(t, T_j, T_k) = (P(t, T_j) - P(t, T_k))/G(t, T_j, T_k)$ for all $t \in [0, T_j]$. Here, $G(t, T_j, T_k)$ is the price of the *annuity* (or level) *numéraire*. Swap market models are based on the continuous time modeling of $S(t, T_j, T_k)$ and, generally, assume that forward swap rates follow a multidimensional diffusion process. In particular, $S(t, T_j, T_k)$ is a P^{T_j, T_k} -martingale so that, under P^{T_j, T_k} ,

$$\frac{dS(t, T_j, T_k)}{S(t, T_j, T_k)} = \lambda(t, T_j, T_k)' dW^{T_j, T_k}(t) \quad \forall t \in [0, T_j] \quad (1)$$

where $\lambda(t, T_j, T_k)$ is a vector valued volatility function. The probability measure P^{T_j, T_k} is equivalent to the historical probability measure P , and is called the *forward swap probability measure* associated with the dates T_j and T_k , or simply the forward swap measure (see **Forward and Swap Measures**). For every $i = 1, \dots, M$, the relative (or “deflated”) bond $P(t, T_i)/G(t, T_i, T_k)$, $\forall t \in [0, \min(T_i, T_{j+1})]$, follows a local martingale process under P^{T_j, T_k} . We denote the corresponding Brownian motion under P^{T_j, T_k} by W^{T_j, T_k} . The *forward Libor rate* $L(t, T_j)$, $j = 1, \dots, M - 1$, defined as

$$L(t, T_j) = \frac{P(t, T_j) - P(t, T_{j+1})}{\delta_{j+1} P(t, T_{j+1})} \quad \forall t \in [0, T_j] \quad (2)$$

is itself a forward swap rate $S(t, T_j, T_k)$ corresponding to $k = j + 1$; its volatility function is denoted by $\lambda(t, T_j)$. Accordingly, we denote by P^{T_j} the corresponding forward probability measure associated to the discount bond price $P(t, T_j)$, and by W^{T_j} a Brownian motion under P^{T_j} . Then, for every $i = 1, \dots, M$, the relative bond price $P(t, T_j)/(\delta_{j+1} P(t, T_{j+1}))$, $\forall t \in [0, \min(T_i, T_{j+1})]$, follows a local martingale under $P^{T_{j+1}}$ (see **Forward and Swap Measures**). We refer to [13] (Chapters 12 and 13) for further material on the theoretical side.

In [5, 6], the authors introduce the so-called *market model approach*, and investigate the weakest condition under which a general specification of a model for observable forward swap rates has a unique specification in all equivalent pricing measures. In this respect, the concept of *admissibility* of a set is introduced, and its theoretical and practical implications are discussed. Interestingly, the properties of these admissible sets can be best understood with

the use of graph theory. This mapping allows to graphically characterize all admissible sets in a simple and intuitive way, so that model selection for a given tenor structure can be performed by visual inspection. Further, it is possible to prove that the class of admissible market models is very large: for a given tenor structure $T = \{T_1, \dots, T_M\}$ comprising M dates, there exist M^{M-2} admissible sets (and models). Admissible models comprise all “standard” market models [3, 11] as special cases. Three major subclasses denominated *co-initial*, *co-sliding*, and *co-terminal* (according to the nature of the family of forward swap rates) can be identified. We hereby briefly discuss their respective features. Remarkably, the Libor market model is the only admissible model of the co-sliding type.

Co-terminal Swap Market Model

The co-terminal swap market model dates back to [11], and is built from an admissible set of forward swap rates with different start dates $\{T_1, \dots, T_{M-1}\}$ and equal maturity date T_M , so that forward swap rates satisfy equation (1). The model is best suited to price *Bermudan swaptions* (and related derivatives; see [5, 6, 15]) where the holder has the right to enter at times $T_1, \dots, T_{M-1}$ into a plain-vanilla swap maturing at T_M . In this case, the only relevant European swaptions from a pricing and hedging perspective are those expiring at $T_1, \dots, T_{M-1}$, and maturing at T_M . Hence, it is natural to introduce a market model where the relevant underlying set coincides with the associated co-terminal forward swap rates. Other derivative securities with similar characteristics include callable cap and reverse floaters, ratchet cap floaters, and Libor knock-in/out swaps; all are good candidates for valuation in a co-terminal framework.

Co-initial Swap Market Model

The co-initial swap market model [5–7] is built from an admissible set of forward swap rates with different end dates $\{T_2, \dots, T_M\}$ and equal start date T_1 , so that forward swap rates satisfy equation (1). The model is best suited to price (complex) European-style derivatives, where the holder owns the right to exercise an option at a single future date T . In this case, the option payoff, no matter how complex, is

measurable with respect to the information available at time T , by definition. Qualitatively speaking, a set of admissible forward swap rates sharing the same initial date T contains all the information needed to evaluate the payoff, the latter being a function of a set of admissible co-initial forward swap rates at that time. Hence, a model market approach based on a set of co-initial forward swap rates provides a powerful tool to price and hedge a large variety of European-style derivatives including forward-start, amortizing, and zero-coupon swaptions.

Co-sliding Swap Market Model

In [5, 6], it is shown that there exists a unique admissible co-sliding swap market model and that it coincides with the Libor market model [3, 12]. The model is built from an admissible set of forward swap rates with start date T_j and end date T_{j+1} ($j = 1, \dots, M-1$), so that forward swap rates satisfy equation (1). They are thus associated to swaps with the same time to maturity. It is easy to see that nonoverlapping forward swap rates of that form are indeed forward Libor rates. The co-sliding model is best suited to price structured constant-maturity swap (CMS)-linked derivatives (with possibly Bermudan features) whose payoff function depends on a set of fixed-maturity instruments (see **Bermudan Swaptions and Callable Libor Exotics**). More precisely, in a CMS (see **Constant Maturity Swap**), the variable coupon that settles at a generic time T_j is linked to the value of a swap rate prevailing at that time (the latter being associated to a swap of a given maturity). In this context, the Libor market model provides an optimal modeling framework since (sliding) CMS rates can be easily described in terms of linear combinations of forward Libor rates.

Numerical Implementation

In the applications, one needs to calibrate a generic swap market model to the available prices of liquid vanilla derivatives to avoid potential arbitrage in the risk-management process. Implied model calibration is a reverse engineering procedure aimed at identifying the relevant model characteristics, such as volatility parameters, from such a set of instruments. In interest-rate derivatives markets, these instruments are plain-vanilla options written on forward swap and

Libor rates, that is, swaptions and caplets, respectively. To achieve a fast and robust model calibration, one should ideally aim at closed or quasi-closed form formulae for plain-vanilla option prices. When these are not available, good analytical approximations are called for. The accuracy of these methods is studied in several papers. They rely on the so-called *freezing approach* [1, 10, 14] or, alternatively, on the *rank-one approximation* method [3]. In turn, the specification of the instantaneous volatility function $\lambda(t, T_j, T_k)$ in equation (1) is sometimes done by introducing flexible functional forms [4, 15] that are meant to reproduce the observed shape of implied swaption and cap/floor volatility term structures through a low-dimensional parameterization. One of the most appreciated features of the instantaneous volatility function among practitioners is *time stationarity*. This is generally imposed to reproduce the analogous temporal evolution of the volatility term structure observed in the market. However, the constraint of perfect model stationarity is generally incompatible with the observed implied volatility market for a generic well-behaved instantaneous volatility function. This market feature forces practitioners to introduce explicit calendar-time dependent functions $\lambda(t, T_j, T_k)$ to mimic a perturbation mode around the time-stationary solution. Efficient simulation algorithms are also available to price exotic interest-rate derivatives by Monte Carlo methods [8] (see **LIBOR Market Models: Simulation**).

Markov Functional Models

Market models (see **LIBOR Market Model**) are formulated directly in terms of market observable rates, such as *LIBORs* (see **LIBOR Rate**), their volatilities, and correlations. They were the first models that could calibrate exactly to Black's formula for pricing liquid instruments for all strikes. Though the models provide an excellent framework for selecting and understanding a model, and have become a benchmark in the market place, they do have one significant drawback. An accurate implementation of a market model can only be done by simulation because of the high dimensionality of the model. This is true even when there is only one stochastic driver.

In this article, we describe models that can fit the observed prices of liquid instruments in a similar fashion to the market models, but which also have the advantage that derivative prices can be calculated just as efficiently as in the most tractable *short-rate model* (see **Term Structure Models**). To achieve this, we consider the general class of Markov-functional interest-rate models [4, 8], which, as we shall discuss, can be specified using the numeraire approach restricted to a finite time horizon. The defining characteristic of Markov-functional models is that pure discount bonds prices are at any time a function of some low-dimensional process that is Markovian in some martingale measure. This ensures that the implementation is efficient since it is only necessary to track the driving process, something that is particularly important for Bermudan-style products. Market models do not possess this property for some low-dimensional Markov process and this is the obstacle to their efficient implementation.

Nnumeraire Approach to Specifying Interest-rate Models

Let $\{\Omega, \mathcal{F}, \{\mathcal{F}_t\}, \mathbb{P}\}$ be a filtered probability space. Denote by D_{tT} the value at t of a pure discount bond with maturity T , an asset that pays a unit amount on its maturity date. There are several ways to model the complete term structure of pure discount bonds, $\{D_{tT} : 0 \leq t \leq T \leq \infty\}$ and it is not necessary to specify the model under the "real-world" measure $\mathbb{P}$. The

numeraire approach follows from the definition of a numeraire pair. Let $\mathbb{N}$ be an *equivalent martingale measure* (see **Equivalent Martingale Measures**) corresponding to a numeraire N (see **Change of Numeraire**). Then any numeraire-rebased asset is a martingale under the measure $\mathbb{N}$.

Noting that $D_{TT} = 1$, we see that

$$D_{tT} = \mathbb{N}_t \mathbb{E}_{\mathbb{N}} [N_T^{-1} | \mathcal{F}_t] \quad (1)$$

Thus, once we have specified the numeraire pair $(N, \mathbb{N})$ and the filtration $\{\mathcal{F}_t\}$, we have defined a term structure model under the equivalent martingale measure $\mathbb{N}$.

For practical applications, it is usual to restrict attention to a finite time horizon, $0 \leq t \leq T$. Here, to specify a model using the numeraire approach, in addition to knowledge of the numeraire, we need to know its joint distribution under $\mathbb{N}$ with the pure discount bonds on some boundary curve. In applications that we have encountered, it is sufficient to take these bonds to be D_{tS} , for $S \in [T, T']$ for some fixed $T' \geq T$. Then we can again use the martingale property of numeraire-rebased assets to recover the pure discount bonds at earlier times for maturities up to T' .

Markov-functional Models

We now give a formal definition of a Markov-functional model. We restrict attention to a finite time horizon and so the definition includes the boundary curve mentioned above. This definition is very general and, if we allow the process driving the model to be of high dimension, the definition will encompass nearly all models of practical interest (including market models). The real spirit of Markov-functional modeling is explained in the next section when we discuss how to recover the prices of calibrating liquid instruments *via* a functional sweep.

Definition 1 *An interest-rate model is said to be Markov-functional if there exists some numeraire pair $(N, \mathbb{N})$ and some process x such that*

1. *the process x is a (time-inhomogeneous) Markov process under the measure $\mathbb{N}$;*
2. *the pure discount bonds are of the form*

$$D_{tS} = D_{tS}(x_t), \quad 0 \leq t \leq \min\{S, T\} \quad (2)$$

From our discussion of the numeraire approach, we see that to completely specify a general Markov-functional model, it is sufficient to specify the joint law of the numeraire N and the process x under $\mathbb{N}$, and the functional form of the discount factors on the boundary. This observation forms the basis for setting up a Markov-functional model in practice.

Recap of the Standard Markov-functional Approach

The formal definition above tells us the general properties of the model we wish to develop, but nothing about the practicalities of how to set up a model for a particular pricing problem. Here, we summarize the standard case in which the driving process, denoted by x , is chosen to be of low dimension and Gaussian. This ensures that the model is efficient to implement. We comment on the choice of covariance structure for x below. Assuming x has been chosen, the practical problem we now seek to address is that of setting up a model that is arbitrage-free and calibrates well to a set of vanilla instruments appropriate for the product we wish to price. In this article, we restrict our discussion to a special case—the LIBOR Markov-functional model in the terminal measure. For further details on practical aspects of this model, see [4, 6, 8] and [10].

As in a *LIBOR market model* (see **LIBOR Market Model**), we assume we have a set of contiguous forward LIBORs denoted by L^i for $i = 1, \dots, n$ corresponding to tenor structure $T_1, \dots, T_{n+1}$. We write $S_i := T_{i+1}$ for $i = 1, \dots, n$ and so L^i is the LIBOR corresponding to the period $[T_i, S_i]$.

In this section, we use $\mathbb{N}$ to denote the terminal measure corresponding to taking the bond $D_{\cdot, S_n}$ as numeraire and $\mathbb{E}$ to denote expectations in this measure.

Consider the problem of how to choose the functional forms so that the resulting model calibrates accurately to the prices of the set of caplets (equivalently digital caplets) corresponding to the forward LIBORs $L^1, \dots, L^n$. The model is actually only specified on a grid. That is, we specify the functional forms $D_{T_i T_j}(x_{T_i})$ for $1 \leq i < j \leq n+1$, since this is all that is (typically) needed in practice. Note that here all we need to recover these discount factors are the functional forms of the numeraire for times $T_1, \dots, T_n$. The functional forms are derived numerically from market prices and the martingale properties necessary to make the model arbitrage-free.

The algorithm for finding the functional forms works back iteratively from the terminal time T_n . Suppose we have reached T_i , having already found the functional forms $D_{T_k S_n}(x_{T_k})$, $k = i+1, \dots, n+1$. Trivially, this is true when $i = n$ as there is nothing to know since $D_{T_{n+1} S_n}(x_{T_{n+1}}) = 1$. Then from the martingale property of numeraire-rebased assets we can find

$$\begin{aligned} \hat{D}_{T_i T_{i+1}}(x_{T_i}) &:= \frac{D_{T_i T_{i+1}}(x_{T_i})}{D_{T_i S_n}(x_{T_i})} \\ &= \mathbb{E} \left[\frac{1}{D_{T_{i+1} S_n}}(x_{T_{i+1}}) \mid x_{T_i} \right] \end{aligned} \quad (3)$$

Noting, by definition, that

$$L_{T_i}^i = \frac{1 - D_{T_i T_{i+1}}}{\alpha_i D_{T_i T_{i+1}}} \quad (4)$$

where α_i is the accrual factor for the interval $[T_i, S_i]$, it follows that

$$D_{T_i S_n}(x_{T_i}) = \frac{1}{\hat{D}_{T_i T_{i+1}}(x_{T_i})(1 + \alpha_i L_{T_i}^i(x_{T_i}))} \quad (5)$$

Thus we see that to determine the functional form for the numeraire at time T_i , $D_{T_i S_n}(x_{T_i})$, it is sufficient to find the functional form for $L_{T_i}^i(x_{T_i})$. Equivalently, it is sufficient to find the off-diagonal discount factor $D_{T_i T_{i+1}}(x_{T_i})$.

We begin with the case in which the process x is one dimensional. Here, we view the process x as capturing the overall level of interest rates.

One-dimensional Case. In setting up our model, we make the assumption that the i th forward LIBOR at time T_i , $L_{T_i}^i$, is a monotonic increasing function of the variable x_{T_i} , that is, we assume that $L_{T_i}^i = f^i(x_{T_i})$, for some monotonic increasing function f^i . The functional forms are found using market prices of digital caplets. This is equivalent to calibrating to caplets as we can recover the price of a caplet with strike K , $C^i(K)$, from the prices of digital caplets:

$$C^i(K) = \int_K^\infty V^i(\hat{K}) d\hat{K} \quad (6)$$

where $V^i(K)$ denotes the market value of the digital caplet with strike K (setting at T_i , paying at S_i). In an arbitrage-free model, we must have

$$V^i(K) = D_{0, S_n} \mathbb{E} \left[\frac{D_{T_i S_i}}{D_{T_i S_n}} \mathbf{1}_{\{L_{T_i}^i > K\}} \right] \quad (7)$$

Choose a grid of values x^* and for each x^* calculate

$$\begin{aligned} J_0^i(x^*) &:= D_{0S_n} \mathbb{E} \left[\frac{D_{T_i S_i}}{D_{T_i S_n}}(x_{T_i}) \mathbf{1}\{x_{T_i} > x^*\} \right] \\ &:= D_{0S_n} \mathbb{E} \left[\mathbb{E} \left[\frac{D_{T_{i+1} S_i}}{D_{T_{i+1} S_n}}(x_{T_{i+1}}) | x_{T_i} \right] \mathbf{1}\{x_{T_i} > x^*\} \right] \end{aligned} \quad (8)$$

We can do this (numerically) from what we already know, having calibrated the model at all $T_j, j > i$. Now find the value $K(x^*)$ such that $V^i(K(x^*)) = J_0^i(x^*)$. Equating equations (7) and (9) we find that

$$\begin{aligned} D_{0S_n} \mathbb{E} \left[\frac{D_{T_i S_i}}{D_{T_i S_n}}(x_{T_i}) \mathbf{1}\{L_{T_i}^i(x_{T_i}) > K(x^*)\} \right] \\ &= V^i(K(x^*)) \\ &= J_0^i(x^*) \\ &= D_{0S_n} \mathbb{E} \left[\frac{D_{T_i S_i}}{D_{T_i S_n}}(x_{T_i}) \mathbf{1}\{x_{T_i} > x^*\} \right] \\ &= D_{0S_n} \mathbb{E} \left[\frac{D_{T_i S_i}}{D_{T_i S_n}}(x_{T_i}) \mathbf{1}\{L_{T_i}^i(x_{T_i}) > L_{T_i}^i(x^*)\} \right] \end{aligned} \quad (9)$$

Under the assumption that $L_{T_i}^i(x)$ is increasing in x , we can now conclude that $L_{T_i}^i(x^*) = K(x^*)$, thus, repeating this on a grid of values x^* , we have derived the required functional form.

Multidimensional Case. This is a straightforward generalization of the one-dimensional case. The key to this extension is to ensure in the generalization that we

1. retain the univariate and monotonicity properties that were required to make the functional fitting efficient;
2. capture the desired correlation/covariance structure.

To do this, we introduce the idea of a *prior model*. The prior model expresses each LIBOR as a function of the driving Markov process x , which is now of dimension $k > 1$. This prior model is chosen to capture the basic dynamics of the market, but may admit arbitrage. We discuss the choice of a prior model based on a market model below. Once the prior

model is chosen, the approach now is to regard the Markov-functional sweep as a (small) perturbation of this prior model, which removes the arbitrage.

In particular, we assume that the functional dependence of $L_{T_i}^i$ on the multidimensional x_{T_i} is only via the prior model LIBOR $\tilde{L}_{T_i}^i$. Thus

$$L_{T_i}^i(x_{T_i}) = f_i \left(\tilde{L}_{T_i}^i(x_{T_i}) \right) \quad (11)$$

for some monotonic function f_i . It is this specialization that enables us to achieve the univariate and monotonicity properties in this higher dimensional setting. The last step is the derivation of the functional forms f_i . This is almost identical to the one-factor case. For details, the reader is referred to [6].

Covariance Structure of x -process and Comparison with Market Models. Typically, x is taken to be a k -dimensional Gaussian process with i th component of the form

$$x_t^i = \int_0^t \sigma_s^i dW_s^i \quad (12)$$

where the W^i s are Brownian motions under the measure $\mathbb{N}$, with instantaneous correlations $dW_t^i dW_t^j = \rho_{ij}^i dt$. With x of this form, we have explicit knowledge of all marginal and conditional transition densities and all the required conditional expectations can be computed efficiently.

As in any interest-rate model, care must be taken in the choice of the instantaneous volatilities so that the resulting model has the appropriate qualitative behavior. For example, many authors illustrate the features of a model by using a simple exponential form of the instantaneous volatilities. However, use of this, in practice, would lead to a model having unrealistic hedges as the resulting correlation structure does not change in an appropriate way when the implied volatilities change. One appropriate choice based on a Hull–White short-rate model is given in [1].

Recall that in a k -dimensional Markov-functional model, the prior model is chosen with some desired correlation structure in mind. If the instantaneous volatilities $\sigma^i, i = 1, \dots, n$ are taken to be separable in that for each i , σ_t^i can be written as a vector product of constants depending on i and a common volatility function σ_t , then it is very easy to form a prior model from the corresponding k -factor LIBOR

market model with the same instantaneous volatilities. A first-order approximation to this model could, for example, be obtained by taking the usual SDE and replacing the time-dependent drift with its time-zero value. This would result in a model with something very close to the desired correlation structure, for which all LIBORs are lognormally distributed, but for which there is significant arbitrage. This makes the approximation too poor for use as a model in practice, but it remains adequate as a starting point for an arbitrage-free Markov-functional model. In fact, it is shown in [1] that in the one-dimensional case, Markov-functional and separable LMM models are very similar across a broad range of parameter values.

Generalizations. The discussion above focused on a LIBOR Markov-functional model specified in the terminal measure. For a version of this model that uses the discrete savings account as numeraire and forward induction, see [2]. The Markov-functional method is not restricted to calibrating to the market implied distributions of LIBORs. For a given tenor structure, one can formulate a model that calibrates to any swap rate or LIBOR at each time slice. In addition, the boundary can be extended so that more than one discount factor can be modeled on the final time slice. The details for a swap model can be found in [4, 8]. This is an appropriate choice for pricing *Bermudan swaptions* (see **Bermudan Swaptions and Callable Libor Exotics**) as the resulting model can be calibrated to vanilla swaption prices.

A multicurrency Markov-functional model first presented in [5] is described in [3].

If one is willing to employ Monte Carlo methods, the Markov-functional approach can be extended to formulate a high-dimensional model comparable

with a full-rank market model. See [9] for details. For further developments in the high-dimensional setting, see [7].

JOANNE KENNEDY

Hedging of Interest Rate Derivatives

Cash and the Zero Curve

The simplest contract is a unit notional, zero-coupon bond to be paid at time T (the *maturity*). The value of such a bond is denoted by $P(T)$.^a

The function P thus describes the evolution through time of interest rate expectations.

The instantaneous *forward rate* f is defined by $f(T) \equiv -P'(T)/P(T)$. Thus, the *forward curve* f provides a local view of the market forecast for future interest rates. While knowledge of P and f are in principle equivalent, the latter provides a superior framework for practical analysis.

FRAs, Swaps, and Bond Equivalence

A forward rate agreement, *FRA*, is a contract to lend at a previously agreed rate over some time interval—thus it is equivalent to a calendar spread of zero-coupon bonds. A swap is very similar to a succession of FRAs, so its price can nearly be determined from the zero curve. The slight differences between Libor swaps and coupon-paying bonds stem from the differences between the Libor end date and the period payment date, and also (in most currencies) the difference between fixed and floating payment frequencies. For a more detailed description, see **LIBOR Rate**.

Libor Futures

A Libor futures contract (see **Eurodollar Futures and Options**) pays, at its settlement, a proportion of the Libor rate fixed on the futures expiry date. However, since an FRA makes its payment only at its maturity date, its par rate in a risk-neutral world is equal to the expectation under the discount-adjusted measure to that maturity date. The daily updating of posted margins for Libor futures means that profit or loss from rate fluctuations is realized immediately; thus the par futures price reflects the risk-neutral expectation in an undiscounted measure.

Because the resulting “futures convexity adjustment” does not closely track other measures of

volatility, it is traded actively only by a few specialists. For most purposes, we can think of a future as being equivalent to an FRA plus an exogenously specified spread.

Yield Curve Construction

Since the function $P(T)$, or equivalently $f(T)$, practically determines the value of these Libor-based instruments, we price less-liquid instruments by fitting a *yield curve*—any object from which P and f can be computed—to the observed values of the most liquid *build instruments*. Since there will not be above a few dozen such instruments, this fitting problem is severely underconstrained.

One common method is *bootstrapping of zero yields*: we specify that the yield curve will be defined by linear interpolation on the zero-coupon bond yield $y(T) \equiv -\ln P(T)/T$. This restricts the curve's degrees of freedom to one per interpolation point. If we place one interpolation point at the last maturity date (the latest payment or rate end date) of each build instrument, we can solve for each corresponding value of y with a succession of one-dimensional root searches.

Since $f(T) = y(T) + Ty'(T)$, the forward curve thus constructed is gratuitously discontinuous and contains large-scale interpolation artifacts. We do not wish to recommend this construction method or to disparage others, but only wish to note its frequent use and to show a concrete example. For a more complete discussion, see **Yield Curve Construction**.

Hedging on the Yield Curve

Once a yield curve is built, it can be used to price similar trades that are not among the build instruments, such as forward-starting or nonstandard swaps. Such pricing depends on two implicit assumptions: that the yield curve is the underlying of these trades as well as of its build instruments, and that its interpolation methods (or other nonmarket constraints) are sufficiently accurate. In practice, the former is widely accepted for Libor-based products, while the latter is a major arena of competition among market makers.

Any trade priced on the yield curve will have a *forward rate risk*, which we denote by $\delta_f(T)$, so that its change in value for a small curve fluctuation Δ_f is

equal to the change in $\delta_f \Delta f \equiv \int_0^\infty \delta_f(u) \Delta f(u) du$. Formally, we write

$$\delta_f(t) \equiv \lim_{h \rightarrow 0, \epsilon \rightarrow 0} \frac{U(f + h\eta_{t,\epsilon}) - U(f)}{h\epsilon} \quad (1)$$

where

- $U(f)$ is the trade's value for a given yield curve described by the forward rates f ;
- $\eta(z)$ is a C^∞ test function with support in $[0, 1]$ and $\int_0^1 \eta = 1$; and
- $\eta_{t,\epsilon}(z) \equiv \eta((z - t)/\epsilon)$.

For the *linear* trades, that we have so far discussed, δ_f will change very little as f changes. A portfolio of trades with no net δ_f has, at least for that moment, no interest rate risk.

Figure 1 shows the forward rate risk for a swap. The large-scale behavior is unsurprising; the forward rate risk steadily decreases as coupons are paid. The small-scale spikes are caused by overlapping, or in one case underlapping, of the start and end dates for the Libor rates on the floating side. The vertical scale is, of course, proportional to the swap notional amount, and is not shown here.

In practice, especially when trades cannot be exactly represented by equivalent cash flows, we will not know δ_f exactly but we will have rather a numerically computed (e.g., piecewise constant) approximation thereto; but since we can control the

buckets, that is, the intervals over which δ_f is kept constant, this is not a major difficulty.

Response Functions

However, we cannot execute a hedge of the forward rate risk directly; instead, we must choose a set of *hedge instruments* that will allow us to offset it. Often, these hedge instruments are exactly the build instruments. Each hedge instrument will also, of course, have a forward rate sensitivity. In practice, we generally consider the sensitivity, not of the instrument value, but of the *implied par rate* (or just *implied rate*): The implied FRA rate for futures, par coupon for swaps, or yield for bonds implied by the yield curve.

In this case, we can compute a hedge by slightly bumping each instrument's implied rate r_i , rebuilding the curve, repricing the trade being hedged, and measuring its price change. This method has the advantage of enabling very precise p/l explanation, at the cost of requiring repeated yield curve builds.

The resulting *instrument sensitivity* is closely related to the forward rate risk. To be precise, let the *response function* $\beta_i(T) \equiv dF(T)/dr_i$. Then, the instrument sensitivity is exactly $\beta_i \delta_f$. Thus, response functions provide an ideal tool for examining curve build methods.

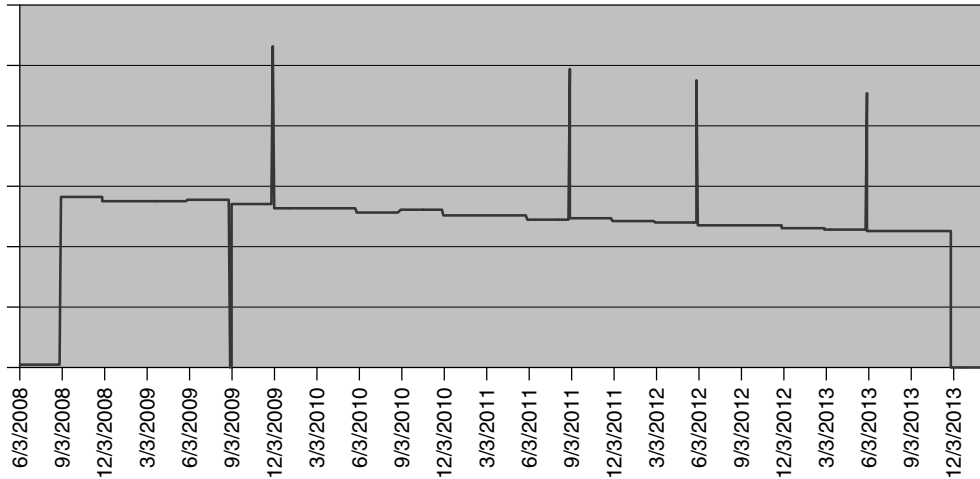

Figure 1 Forward rate risk for a (Payer) swap

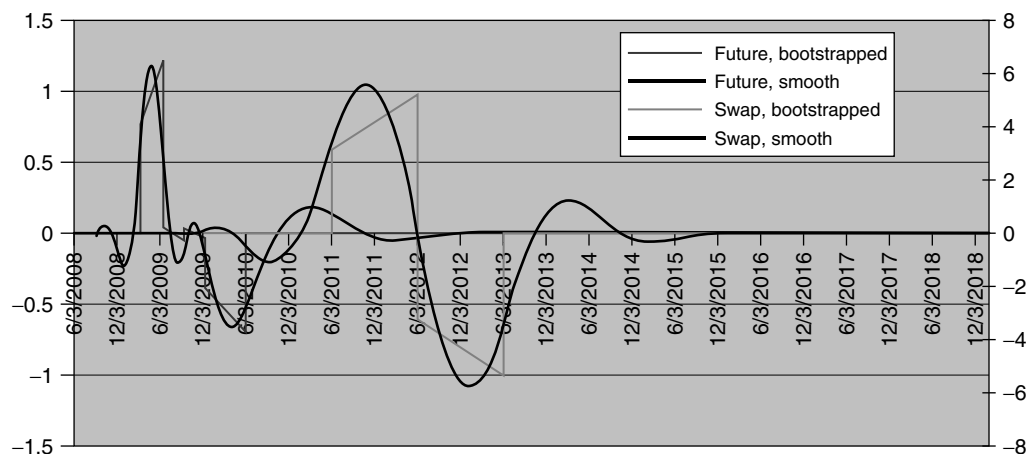

Figure 2 Response of F to fourth future and to 4-year swap

The response functions for two typical build instruments are displayed in Figure 2, for two different curve build methods. The response to a futures rate, shown against the left-hand scale, changes the forwards within the futures period and decreases them in the interval from the last future to the first swap (so that all other build instruments will have unchanged rates); naturally, within the futures period, $dF(T)/dt_i \simeq 1$. The response to a swap rate, which is substantially larger, is shown against the right-hand scale. In both cases, the bootstrapped curve shows the “sawteeth” characteristic of linear interpolation on y , while the smooth curve shows the inevitable loss of locality. This tension between smoothness and locality arises because a smooth curve, by its very nature, must alter values far from the source of a change in order to preserve smoothness; for details see **Yield Curve Construction**.

Bucket Delta Methods

Another common hedge method is to set the bucket end dates to the maturities of the curve build instruments, and then compute the *bucket deltas*: sensitivities $\bar{\delta}_k$ to the forward rate in the k th bucket, computed by applying a parallel shift to those forward rates. We can also define a Jacobian matrix J such that J_{ik} is the sensitivity of the i th instrument’s implied rate to the forward rate in the k th bucket; then the instrument sensitivities are given by $J^{-1}\bar{\delta}$. This is known as the *inverse method*.

A hedge can also be constructed from $\bar{\delta}$ by minimizing the p/l variance of the hedge trade plus a portfolio of hedging instruments; for this we need an estimate of the covariance $\Sigma(T_k, T_m)$ between the forward rates $f(T_k)$ and $f(T_m)$. The variance is then a quadratic form in the hedge instrument notionals, which can easily be minimized. Any other quadratic form, such as a penalty function based on the hedge notionals, can be included without difficulty.

Nonlinear Products

For any product, the sensitivity δ_f is defined in each yield curve state; however, it need not be independent of that state. This nonlinearity is most pronounced for options, especially when they are short-dated and nearly at-the-money. In this case, to lock in an option value by hedging we must dynamically rebalance the hedging instruments, subject to the well-known limitations of payoff replication strategies.

One issue of particular importance is that the local hedge, based on δ_t in the current state of the yield curve, can differ greatly from the variance-minimizing hedge if the rebalancing frequency is finite or if jumps are present. This occurs when the distribution of possible curve shifts is strongly asymmetric, or more frequently when the second derivative of the payoff is highly state-dependent.

These issues are not unique to interest rates, but they can become more pronounced for some payoffs owing to the tendency of short rates to move in

discrete increments (e.g., in response to a central bank action). Nonlinearity is also important to the pricing and hedging of very long-dated swaps and bonds.

Projected Gamma

The second-order “gamma” risk is formally described by an extension of the first-order forward rate risk that we have just discussed; in fact, there is a power series

$$U(f) = U(f_0) + \delta_f \Delta_f + \frac{1}{2} \int \int \gamma_f(u, v) \Delta(u) \Delta(v) du dv + \dots \quad (2)$$

where $\Delta_f(t) \equiv f(t) - f_0(t)$ and δ_f , γ_f , and so on, are computed at $f = f_0$. However, extracting this γ_f in all its detail is prohibitively time-consuming. Instead, we compute the f -dependence of δ_f , which is the same to this order (and is, in fact, the more relevant measure), by computing the delta hedge in various interest rate scenarios.

These scenarios are generally constructed by parallel shifts to the market yield curve. There are several reasons for this:

- Only parallel-shift gamma can realistically be hedged (by trading short-dated options).
- Large unexpected moves in rates, necessitating delta rehedging, tend to be roughly parallel.
- The parallel shift is uniquely easy to define and to explain.

The industry standard is to create a progression of scenarios using parallel shifts, which are multiples of 10 basis points, for example, from -50 to $+50$ in steps of 10. This aids visualization of higher-order contributions to the hedge, which can sometimes be traced to their source; for example, a sudden change in delta indicates an upcoming option expiry or barrier test in that interval.

Vega Hedging

The volatility sensitivity, or “vega”, of an interest rate derivative is characterized by both the time during which its optionality is active, and the time

covered by the underlying rate. In other words, nonlinear interest rate derivatives are sensitive to the Heath–Jarrow–Morton (HJM)^b *forward volatility* $\sigma(t, T)$, the volatility at time t of $f(T)$. This does not mean that we must use an HJM model: any interest rate model defines an expected forward volatility.

A given trade, then, has a “forward volatility footprint” $v(t, T)$ so that its change in value, to first order in volatility, equals the change in $\int \int v(t, T) \sigma(t, T) dt dT$. In more sophisticated models, this change is computed with other parameters (e.g., correlations, elasticity of rates, or volatility of volatility) held fixed. Thus, $v(t, T)$ is precisely analogous to the forward rate sensitivity $\delta_f(T)$.

In addition, any mechanistic calibration technique has a response function

$$B_j(t, T) \equiv \frac{\partial \sigma(t, T)}{\partial \sigma_j} \quad (3)$$

where σ_j is the quoted volatility of the j th calibration instrument and partial derivatives are taken with other calibration instruments fixed. The inner product $\int \int v(t, T) B_j(t, T) dt dT$ is thus the *calibration instrument vega*, which will be computed by bumping, recalibrating, and repricing (“bump-and-grind”). It is worth noting that examination of response functions is by far the best test of the quality of a calibration technique.

Models with few state variables harshly restrict the form of $\sigma(t, T)$; for example, in one-state-variable models we have $\sigma(t, T) = g(t)H(T)$.^c This impacts vega hedging in two main ways. First, the forward vol footprint simply cannot be measured using such a model, since it is the sensitivity to a perturbation which the model cannot reproduce. Second, the response functions must reflect the constraints on $\sigma(t, T)$; thus, they are inevitably nonlocal and often highly unnatural. Such models can be used for vega hedging in restricted environments, such as when the maturity of the hedging instruments is already known; but, in general, they are incapable of “finding” the vega hedge, owing to their intrinsic inability to localize perturbations.

Cost of Funding Complications

So far, we have assumed that the market Libor rate reflects our own cost of funds; this assumption is necessary for a single zero curve to exist. In

practice, many market participants consistently fund their operations above or below Libor; thus they must maintain a zero curve Z_c for their own cashflows, and a different curve Z_r for rate forecasts. To a very good approximation, this effect can be encapsulated by specifying the *funding adjustment* $Z_c(T)/Z_r(T)$.

This is most important in markets where the demand for currencies is highly asymmetric, particularly in Japanese Yen (*JPY*). The steady demand of *JPY*-based issuers for dollars means that foreign dealers can fund their *JPY* debts more cheaply, effectively increasing their own Z_c —this effect drives the currency basis swaps market.

The presence of funding adjustments causes different dealers, observing the same market swap rates, to deduce different forward curves. The effect is always to create an incentive for the party with the higher cost of funds to take the side with initial positive cash flows, thus borrowing a fraction of the swap notional. To minimize this effect, most market quotes are for mutually collateralized swaps.

Cost of Tenor Complications

The frequency of Libor fixings also influences the par rate for a swap; the curve Z_r , which forecasts 3-month Libor will not forecast 1-month or 6-month Libor. In practice, the forward rates are higher for longer-tenor Libor rates; this is generally attributed to credit issues, since a longer tenor entails a greater risk of a downgrade during the loan period.

This can be addressed by constructing separate curves for each tenor, or by adjusting Libor rate forecasts by some *ad hoc* tenor-dependent correction. The floating-for-floating swaps at mismatched tenors, in which these corrections can be traded, are also called *basis swaps*.

Collateral and Repo Complications

For some markets, notably US Treasury bonds, the value of a bond is not fully captured by the value of its cashflows. The complex repo market for these bonds makes some *special* bonds valuable as collateral, giving them a positive convenience yield

and raising their price above that predicted from the zero curve. Such markets are usually treated by building a *general collateral* curve based on bonds with no such added value, and then relating the premium in some bond's price to its expected repo rates. A derivative whose underlying is a special bond is thus exposed to both general collateral rates and the bond's forecast repo rates. For short-expiry trades, this combination of exposures is accurately expressed as an exposure to the special bond's price, but long-dated trades require separate consideration of the two curves.

End Notes

^aEven this simple contract is fraught with credit and collateral issues, which our notation conceals. Most of these are beyond the scope of this discussion.

^bFor details of the HJM approach, see Bjork **Heath–Jarrow–Morton Approach**.

^cHere $\sigma(t, T)$ need not be the normal HJM volatility; in Black–Karasinski models, for example, it is the volatility of the log forward rate in the risk-neutral measure which is separable.

Inflation Derivatives

The market for financial inflation products started with public sector bonds linked to some measure for inflation of prices of (mainly) goods and services. This dates back to as early as the first half of the eighteenth century when the state of Massachusetts issued bonds linked to the price of silver on the London Exchange [4]. Over time, and particularly, in the last 20 years or so, the dominant index used for inflation-linked bonds has become the consumer price index (CPI). A notable exception is the UK inflation-indexed gilt market, which is linked to the retail price index (RPI).^a The actual cash-flow structure of inflation-indexed bonds varies from issue to issue, including capital-indexed bonds (CIBs), *interest-indexed bonds*, *current pay bonds*, *indexed annuity bonds*, *indexed zero-coupon bonds*, and others. By far the most common cash-flow structure is the CIB, on which we shall focus in the remainder of this article.

Bonds, Asset Swaps, and the Breakeven Curve

Inflation-indexed bonds (of CIB type) are defined by

- N —a notional;
- I —the inflation index;
- L —a lag (often three months);
- $T_i : \{1 \leq i \leq n\}$ —coupon dates;
- $c_i : \{1 \leq i \leq n\}$ —coupon at date T_i (usually, all c_i are equal); and
- $I(T_0 - L)$ —the bond's base index value.

The bond pays the regular coupon payments

$$N c_i \frac{I(T_i - L)}{I(T_0 - L)} \quad (1)$$

plus the inflation-adjusted final redemption, which often contains a capital guarantee according to

$$N \max \left(\frac{I(T_n - L)}{I(T_0 - L)}, 1 \right) \quad (2)$$

Asset swap packages swapping the inflation bond for a floating leg are liquid in some markets such as for bonds linked to the CPTFEMU (also known as the *HICP*) index. Since the present value of an inflation-linked bond can be decomposed into the value of each coupon

$$P_{T_i}(T_0) N c_i \frac{1}{I(T_0 - L)} \mathbb{E}_0^{\mathcal{M}(P_{T_i})} [I(T_i - L)] \quad (3)$$

wherein $\mathbb{E}_\tau^{\mathcal{M}(X)}[\cdot]$ denotes expectation in filtration $\mathcal{F}_\tau$ under the measure induced by choosing X as numéraire, and the value of the final redemption

$$P_{T_n}(T_0) N \frac{1}{I(T_0 - L)} \times \mathbb{E}_0^{\mathcal{M}(P_{T_n})} [\max(I(T_n - L), I(T_0 - L))] \quad (4)$$

these products give us a mechanism to calibrate the *forward curve* $F(t, T)$, where

$$\begin{aligned} F(t, T - L) &:= \text{The index forward for (payment)} \\ &\quad \text{time } T \text{ seen at time } t \\ &:= \mathbb{E}_t^{\mathcal{M}(P_T)} [I(T - L)] \end{aligned} \quad (5)$$

The forward curve is often also referred to as the *breakeven curve*. The realized inflation index fixing level is thus naturally $I(T) = F(T, T)$. Note that while equation (4), strictly speaking, requires a stochastic model for consistent evaluation due to the convexity of the $\max(\cdot, 1)$ function, in practice, the $\max(\cdot, 1)$ part is usually ignored, since its influence on valuation is below the level of price resolution.^b

If there were a multitude of inflation-linked bonds, or associated asset swaps, with well-dispersed coupon dates liquidly available for any given inflation index, then the above argument would be all that is needed for the construction of a forward index curve, that is, breakeven inflation curve. In reality, though, for many inflation markets, there is only a small number of reasonably liquid bonds or asset swaps available. This makes it necessary to use interpolation techniques for forward inflation levels or rates between the attainable index-linked bond's maturity dates. In some cases, this may mean that for the construction of a 10-year (or longer) inflation curve, only three bonds are available, and extreme care must be taken for the choice of interpolation. However, even when a sufficiently large number of bonds is traded, to have a forward inflation rate for each year determined by the bond market, sophisticated interpolation methods are still needed. This is because of inflation's *seasonal* nature. For instance, consumer prices tend to go up significantly more than the annual average just before Christmas and tend to drop (or rise less than the annual average) just after.

The most common approach to incorporate seasonality into the breakeven curve is to analyze the statistical deviation of the month-on-month inflation

rate from the annual average with the aid of historical data, and to overlay a seasonality adjustment on top of an annual inflation average curve in a manner such that, by construction, the annual inflation index growth is preserved. In addition, some authors used to suggest that one may want to add a long-term attenuation function (such as $e^{-\lambda t}$) for the magnitude of seasonality. This was supposed to represent the view that, since we have very little knowledge about long-term inflation seasonality, one may not wish to forecast any seasonality structure. This idea has gone out of fashion though, probably partly based on the realization that, historically, the seasonality of inflation became *more* pronounced over time, not exponentially *less*.

Inflation Derivatives

Daily Inflation Reference

Ultimately, all inflation fixings are based on the publication of a respective index level by a government or cross-government funded organization such as Eurostat for the HICP index series in Europe, or the Bureau of Labor Statistics for the CPI-U in the United States. This publication tends to be monthly, and usually on the same day of the month with a small amount of variability in the publication date. In most inflation bond markets, index-linked bonds are written on the publication of these published index levels in a straightforward manner such as $I(T_i)/I(T_0)$ times a fixed number as discussed in the previous section, with T_i indicating that a certain month's publication level is to be used. For some inflation bonds, however, the inflation reference level is not a single month's published fixing, but instead, an average over the two nearest fixings. In this manner, the fact that a bond's coupon is possibly paid between two index publication dates, and thus should really benefit from a value between the two levels, can be catered for. French OAT i and OAT ϵi bonds, for instance, use this concept of the daily inflation reference (DIR) defined as follows:

$$\begin{aligned} \text{DIR}(T) = & I(T_{m(T)-3}) + \frac{n_{\text{day}}(T) - 1}{n_{\text{days}}(m(T))} \\ & \times [I(T_{m(T)-2}) - I(T_{m(T)-3})] \end{aligned} \quad (6)$$

with $m(T)$ indicating the month in which the reference date T lies, T_i the publication date of month

i , $n_{\text{day}}(T)$ the number of the day of date T in its month, and $n_{\text{days}}(m(T))$ the number of days in the month in which T lies. For example, the DIR applicable to June 21st is $\frac{10}{30}$ times the HICP for March plus $\frac{20}{30}$ times the HICP for April. While the DIR is in itself not an inflation derivative, it is a common building block for derivatives in any market that uses the DIR in any bond coupon definitions. The DIR clause complicates the use of any model that renders inflation index levels as lognormal or similar, since any payoff depending on the DIR thus depends on the weighted sum of two index fixings.

Futures

Futures on the Eurozone HICP and the US CPI have been traded on the Chicago Mercantile Exchange since February 2004. Eurex launched Euro inflation futures based on the Eurozone HICP in January 2008. Both exchanges show, to date, very little actual trading activity in these contracts. An inflation futures contract settles at maturity at

$$M \left(1 - \frac{1}{\Omega} \left(\frac{I(T-L)}{I(T-L-\Omega)} - 1 \right) \right) \quad (7)$$

with M being a contract size multiplier and Ω an additional time offset. The lag L is usually one month. The offset Ω is three months for CPI-U (also known as CPURNSA) on the CME, that is, $\Omega = 1/4$ above. For the HICP (also known as CPT-FEMU) on both Eurex and CME, $\Omega = 1$, that is, one year. Exactly why the inflation trading community has paid little attention to these futures is not entirely clear, though, one explanation may be the difference in inflation linkage between bonds and futures. Both HICP-linked bonds and US Treasury-Inflation Protected Securities (TIPS) pay coupons on an inflation-adjusted notional, that is, they are CIBs. In contrast, both CPI and HICP futures pay period-on-period inflation rates. As a consequence, a futures-based inflation hedge of a single CIB coupon would require a whole sequence of futures positions and would leave the position still exposed to realized period-on-period covariance.

Zero-coupon Swaps

This simple inflation derivative is as straightforward as the simplest derivative in other asset classes: two

counterparties promise to exchange cash at an agreed date in the future. One counterparty pays a previously fixed lump sum, and the other counterparty pays an amount that is given by the published fixing of an agreed official inflation index (times an agreed fixed number). In the world of equity derivatives, this would be called a *forward contract* on the index. Since inflation trading is, by nature and origin, leaning on fixed income markets, this contract is referred to as a *swap*, which is the fixed income market equivalent of a forward contract. Conventionally, swaps are defined by repeated exchange of fixed for floating coupons. Since the inflation index forward contract has no cashflows during the life of the contract, and only at maturity money is exchanged, in analogy to the concept of a *zero-coupon bond*, the inflation index forward contract is commonly known as the *inflation index-linked zero-coupon swap*, or just *zero-coupon swap*^c for short. More precisely speaking, zero-coupon swaps have two legs. The two legs of the swap pay

$$\begin{aligned} \text{inflation leg: } & N \frac{I(T-L)}{I(T_0-L)} \\ \text{fixed leg: } & N(1+K)^{T-T_0} \end{aligned} \quad (8)$$

where N is the notional, T_0 is the start date of the swap, T the maturity, and K the quote. These swaps appear in the market comparatively liquidly as hedges for the inflation bond exposure to the final redemption payment—they act as a mirror. However, this should not mask the fact that the true source of the liquidity is the underlying asset swap/inflation bond.

The Vanilla Option Market

In the inflation option market, the most liquid instruments are as follows.

- **Zero-coupon caps and floors:**

At maturity T , they pay

$$\left[\phi \left(\frac{I(T-L)}{I(T-L-\Omega)} - (1+K)^\tau \right) \right]_+ \quad (9)$$

where Ω is the index offset, L is the index lag, K the annualized strike, τ the year fraction between $(T-L-\Omega)$ and $(T-L)$, and ϕ is +1 for a cap and -1 for a floor. For most of those options, the index in the denominator is actually known (i.e., $\Omega = T$), and

the option premium depends only on the volatility of the index $I(T-L)$.

- **Year-on-year caps and floors:**

The option is a string of year-on-year caplets or floorlets individually paying according to equation (9) with $\Omega = \tau = 1$ at increasing dates spaced by one year. Apart from the front period, these caplets and/or floorlets thus depend on one index forward in their payoff's numerator, and on a second one in their payoff's denominator, whence some authors refer to these products being subject to *convexity*, though this is not to be confused with the usual concept of convexity induced by correlation with interest rates (there is more on this in the section Two Types of Convexity). An alternative view of a year-on-year caplet/floorlet's volatility dependence is to consider *volatility of the year-on-year ratio* as the fundamental driver of uncertainty. In this framework, no convexity considerations are required. The payoff of an inflation caplet/floorlet resembles the payoff of a vanilla option on the return of a money market account if one replaces inflation rates with interest rates.

The Swap Market

A close cousin of inflation caps and floors is the inflation swap. The swap consists of a series of short-tenored *forward starting zero-coupon swaps* each of which pays

$$\frac{I(T-L)}{I(T-L-\Omega)} - (1+K)^\tau \quad (10)$$

at the end of its respective period. Just like an interest rate swap can be seen as a string of *forward interest rate agreements*, an inflation swap can be seen as a string of *forward inflation rate agreements*. Unlike vanilla interest rate swaps, though, the period an inflation swap's individual forward inflation rate agreement is linked to does not have to be equal to the period the associated coupon is nominally associated with. An example for this is an asset swap on an Australian (inflation-linked) government bond whose coupons are typically paid quarterly and are “indexed to the average percentage change in the CPI over the two quarters ending in the quarter that is two quarters prior to that in which the next interest payment falls” [4]. In other words, Ω is six months, $\tau = 1/2$, and L is in the range of one to three months for quarterly coupons.

Total Return Inflation Swaps

These structures pay out a fixed sum linked to an inflation measure over time. With growing inflation concerns in mid-2008, these, together with inflation caps, became increasingly popular with private as well as institutional investors.

The Limited Price Index

A limited price index (LPI) is an instrument that is used in the market to provide a hedge to inflation, but with limited upside and/or downside exposure. When period-on-period inflation is within an agreed range, the LPI grows at the same rate as its underlying official publication index. When period-on-period inflation is outside this range, the LPI grows at the, respectively, capped or floored rate. Given an underlying inflation index I , the LPI $\tilde{I}$ is constructed using I , a base date T_b , a fixing time tenor (i.e., frequency period) τ , an inflation capping level $l_{\max} \in (0, \infty]$, and an inflation flooring level $l_{\min} \in [0, \infty)$. Using T_b and τ , we create a publication sequence for $\tilde{I}$:

$$\tilde{I}_{\text{publication sequence}} = \{T_b, T_b + \tau, T_b + 2\tau, T_b + 3\tau, \dots\} \quad (11)$$

The LPI $\tilde{I}$ can be defined recursively, starting with $\tilde{I}(T_b) = 1$, and continuing with

$$\tilde{I}(T_b + (i+1)\tau) = \tilde{I}(T_b + i\tau) \begin{cases} 1 + l_{\min} & \text{if } \frac{I(T_b + (i+1)\tau)}{I(T_b + i\tau)} \leq 1 + l_{\min} \\ \frac{I(T_b + (i+1)\tau)}{I(T_b + i\tau)} & \text{if } 1 + l_{\min} \leq \frac{I(T_b + (i+1)\tau)}{I(T_b + i\tau)} \leq 1 + l_{\max} \\ 1 + l_{\max} & \text{if } 1 + l_{\max} \leq \frac{I(T_b + (i+1)\tau)}{I(T_b + i\tau)} \end{cases} \quad (12)$$

Given the definition of the LPI, derivatives such as zero-coupon swaps and options on the LPI can be built. LPI-linked products are most common in the UK market. A common comparison made by trading and structuring practitioners is to view an LPI, especially if it is only one sided, as very similar to an inflation cap or floor. It is worth noting that the two structures do have different sensitivities to inflation curve autocorrelation assumptions

whence an exact static replication argument based on inflation caps and floors is not attainable. As a consequence, LPIs require a fully fledged (stochastic) model for relative value comparison with inflation bonds, zero-coupon swaps, and inflation caps and floors.

The Inflation Swaption

This product is in its optionality very similar to a conventional interest rate swaption. However, the underlying swap can have a variety of special features. The start date of the swap T_{start} is on or after the expiry of the option. The swap has one inflation-rate-linked leg, and one (nominal) interest-rate-linked leg. For instance, the underlying swap could be agreed to be given by the following.

- The inflation leg is a sum of n annual forward inflation rate agreements, paid at dates $T_1, T_2, \dots, T_{n-1}, T_n$ with T_n representing the final maturity of the underlying swap. Each inflation leg coupon pays $k^{\text{DIR}(T_i)} / I_{\text{Base}}$, with $\text{DIR}(T_i)$ being the daily inflation reference for date T_i . The leg also pays a final notional redemption floored at 0, which can of course be seen as an enlarged coupon plus a zero-coupon floor struck at 0.
- The Libor leg is a sequence of quarterly forward (nominal) interest rate agreements. A variation

of this is for the interest rate leg to pay Libor plus a fixed margin, or Libor minus a fixed margin floored at zero, which makes this leg alone already effectively a nominal interest rate cap.

There are many variations of inflation-linked swaptions, such as *swaptions on the real rate* (the real rate is explained further on), but most of them are only traded over-the-counter and in moderate size.

Inflation Modeling

For vanilla products such as inflation zero-coupon caps and floors, and year-on-year caplets and floorlets, practitioners tend to use terminologies and conventions relating to the Black and Bachelier models. For instance, to translate the price of an option that pays $(I_T - K)_+$, that is, simply at some point in the future the level of the index minus a previously agreed fixed number, or zero, whichever is greater, practitioners tend to use the concept of implied volatility for the index as if the index evolved in a Black–Scholes modeling framework. For options that pay a year-on-year rate, either Black implied log-normal volatilities or, alternatively, Bachelier, that is, absolute normal volatilities may be used. The latter are also sometimes referred to as *basis points volatilities* to indicate the fact that these are expressed in absolute, rather than relative terms (as Black volatilities would).

Jarrow–Yildirim

Most articles on inflation modeling start out with what is referred to as *the Fisher equation*. This is the definition that *real returns* are given by the relative increase in *buying power* on an investment, not by nominal returns [5]. In other words, the Fisher equation is the *definition*

$$r_{\text{real}} = r - y \quad (13)$$

or

$$r = r_{\text{real}} + y \quad (14)$$

with r being the continuously compounded nominal rate, y the continuously compounded inflation rate, and r_{real} represents a thus defined *real rate*. While this definition is, in practice, of no further consequence to any derivatives modeling, the terminology and concepts are useful to know since they pervade the inflation modeling literature.

One of the earliest publications suggesting a comprehensive set of dynamics for the evolution of inflation (rates) in relation to nominal interest rates is the Jarrow–Yildirim model [8]. The original article discusses the generic setting of a *real economy*, a *nominal economy*, and a translation index between the two, employing the mathematical no-arbitrage HJM apparatus [6]. This results in a framework that is completely analogous to a foreign exchange rate

model with foreign (the *real economy's*) interest rate dynamics, domestic (the *nominal economy's*) interest rate dynamics, and an exchange rate that represents the inflation index. A confusing aspect for people not used to inflation financials is the nomenclature to refer to observable real-world interest rates as *nominal* rates, and to nonobservable (derived) inflation-adjusted return rates (i.e., to nominal interest rates minus inflation rates) as *real* rates. In practice, this model tends to be implemented with both individual economies' interest rate dynamics being given by an extended Vasicek [12] ([7], but also see **Term Structure Models** and **Gaussian Interest-Rate Models**) model, with locally geometric Brownian motion for the real/nominal FX rate, that is, the inflation index. In short, in the nominal money market measure, the dynamics of nominal zero-coupon bonds $P_T(t)$, real zero-coupon bonds $P_{\text{real},T}(t)$, and the inflation index $X(t)$ are governed by the stochastic differential equations:

$$\frac{dP_T(t)}{P_T(t)} = r(t) dt + \sigma_P(t, T) dW_P(t) \quad (15)$$

$$\begin{aligned} \frac{dP_{\text{real},T}(t)}{P_{\text{real},T}(t)} = & (r_{\text{real}}(t) - \rho_{P_{\text{real}},X} \sigma_X(t) \sigma_{P_{\text{real}}}(t, T)) dt \\ & + \sigma_{P_{\text{real}}}(t, T) dW_{P_{\text{real}}}(t) \end{aligned} \quad (16)$$

$$\frac{dX(t)}{X(t)} = (r(t) - r_{\text{real}}(t)) dt + \sigma_X(t) dW_X(t) \quad (17)$$

with

$$\sigma_P(t, T) = \int_t^T \zeta(s) e^{-\int_t^s \kappa(u) du} ds \quad (18)$$

$$\sigma_{P_{\text{real}}}(t, T) = \int_t^T \zeta_{\text{real}}(s) e^{-\int_t^s \kappa_{\text{real}}(u) du} ds \quad (19)$$

The Jarrow–Yildirim model, initially, gained significant popularity with quantitative analysts, though, arguably, primarily because this model could be deployed for inflation derivatives comparatively rapidly since it was already available as a cross-currency Hull–White model in the respective practitioners' group's analytics library. Its main drawbacks are that calibration and operation of the model requires specification of a set of correlation numbers between inflation index and (nominal) interest rates,

inflation index and real rates, and (nominal) interest rates and real rates, of which only the first one is directly observable. Also, this model requires volatility specifications for nonobservable (and nontradable) real rates.

Inflation Forward “Market” Modeling

In an alternative model suggested by Belgrade *et al.* [2], inflation index forward levels $F(t, T_i)$ for a discrete set of maturities $\{T_i\}$ are permitted to evolve according to

$$\frac{dF(t, T_i)}{F(t, T_i)} = \mu(t, T_i) dt + \sigma(t, T_i) dW_i(t) \quad (20)$$

The drift terms $\mu(t, T_i)$ are determined as usual by no-arbitrage conditions, but the volatility functions $\sigma(t, T_i)$ can be chosen freely, as can the correlations between all the Wiener processes W_i . The authors discuss a variety of different possible choices. When interest rates are deterministic, or assumed to be uncorrelated with forward inflation index levels, all drift terms vanish and the model reduces to a set of forward levels that evolve as a multivariate geometric Brownian motion. The main drawback of this model is that it permits highly undesirable forward inflation rate dynamics, specifically with respect to the breakeven curve’s autocorrelation structure, unless complicated modifications of the instantaneous correlation and volatility functions are added. The model also introduces many free parameters that have to be calibrated, which is not ideal in a market that is as illiquid as the inflation option market.

The Exponential Mean-reverting Period-on-period Model

When a model’s purpose is predominantly for the pricing and hedging of contracts that only depend on year-on-year returns of the inflation index, a useful model is to consider the year-on-year ratio process:

$$Y(t) = F_Y(t) e^{-\frac{1}{2} V_0[x(t)] + x(t)} \quad (21)$$

$$dx(t) = -\kappa x(t) dt + \alpha(t) dW(t) \quad (22)$$

with $V_0[x(t)]$ representing the variance of the inflation driver process x from time 0 to time t , and the deterministic function $F_Y(t)$ is implicitly defined by

the choice of measure, that is, it is calibrated such that the model reproduces the breakeven curve (and thus all inflation-linked bonds) correctly. This model is known as the *exponential mean-reverting year-on-year* model. Note that even though the year-on-year ratio process is formulated as a continuous process, it is really only monitored at annual intervals when relevant fixings become available, that is,

$$Y(T_i) = \frac{I(T_i)}{I(T_i - \Omega)} \quad (23)$$

The advantage of this model is its comparative simplicity and its reasonable inflation curve autocorrelation characteristics. This model can also be combined with simple interest rate dynamics (such as given by the Hull–White model). A further benefit is that it promotes the view of a future inflation index level fixing being the result of year-on-year return factors:

$$I(T_n) = I(T_0) \prod_{i=1}^n Y(T_i) \quad (24)$$

The sequence of $Y(T_i)$ fixings are a set of strongly positively correlated lognormal variables (even when interest rates are stochastic in a Hull–White setting) in analogy to the correlation structure of a set of forward starting zero coupon bonds in a standard Hull–White model. As such, they lend themselves very well to an approximation of independence conditional on one or two common factors [1, 3]. Conditional independence permits easy evaluation of the LPI [11]. For other inflation products, the model can also be written on shorter period-on-period returns and can be equipped with more than one inflation driver: $x(t) \rightarrow x_1(t) + x_2(t)$, and so on.

The Multifactor Instantaneous Inflation Model with Stochastic Interest Rates

For more complex products depending on more than just the period-on-period autocorrelation structure, the exponential period-on-period model with Hull–White interest rate dynamics can be taken to the limit of infinitesimal return periods, which makes it structurally similar to the Jarrow–Yildirim model, with the main difference being that we model inflation rates directly, rather than real rates. Dropping all lag-induced convexity considerations for clarity (i.e.,

assuming $L = 0$ and no settlement delay), this gives us, for m inflation and one interest rate factor, in the T -forward measure,

data into unobservable “real rate” volatilities and autocorrelations.

$$I(t) = F(0, t) e^{-B_a(t, T) \text{Cov}_0 \left[\sum_{i=1}^m X_i(t), z(t) \right] - \frac{1}{2} \text{V}_0 \left[\sum_{i=1}^m X_i(t) \right] + \sum_{i=1}^m X_i(t)} \quad (25)$$

$$P_T(t) = \frac{P_T(0)}{P_i(0)} e^{-B_a(t, T) \left(z(t) - \frac{1}{2} B_a(t, T) \text{V}_0[z(t)] \right)} \quad (26)$$

$$z(t) = \int_0^t e^{-a(t-u)} \sigma(u) dW^z(u) \quad (27)$$

$$x_i(t) = \int_0^t e^{-\kappa_i(t-u)} \alpha_i(u) dW^i(u) \quad (28)$$

$$X_i(t) = \int_0^t x_i(s) ds = \int_0^t B_{\kappa_i}(u, T) \alpha_i(u) dW^i(u) \quad (29)$$

$$B_\mu(t_1, t_2) = \int_0^{t_2-t_1} e^{-\mu s} ds \quad (30)$$

wherein all x_i and z are standard Ornstein–Uhlenbeck processes under the T -forward measure, of numéraire P_T , the zero-coupon bond paying in T , and we assume flat mean reversion a and κ_i . It is naturally straightforward to translate these dynamics to other measures (see, e.g., **Forward and Swap Measures**).

A suitable choice of the different drivers’ correlation, volatility, and mean reversion strength permits highly flexible calibration to the inflation curve’s desired autocorrelation structure, which is another major advantage over the Jarrow–Yildirim model. For the specific case when there are two inflation factors, and the mean reversion strength of one of the factors, say x_1 , is taken to the limit $\kappa_1 \rightarrow \infty$ while at the same time keeping α_1^2/κ_1 constant, the cumulative process X_1 becomes a Brownian motion.^d In this case, inflation has one geometric Brownian motion factor, and one mean-reverting inflation rate factor, in complete analogy to the Jarrow–Yildirim model. In this sense, the multifactor instantaneous inflation model with stochastic interest rates encompasses the Jarrow–Yildirim model’s autocorrelation structure as a special case, but, in general, allows for more flexible calibration, while, at the same time, it avoids the need to translate market observable

Common Inflation Modeling Considerations

Two Types of Convexity. In the inflation market, when practitioners talk about *convexity* effects, confusingly, and differently from the derivatives market of most other asset classes, they might be referring to one of the two possible effects whose origins are rather distinct.

The first of the two convexity effects arises in the context of period-on-period inflation rate related products such as year-on-year caps and floors (and obviously also inflation futures). In this context, *convexity* is generated only if the fundamental observable of the underlying inflation market is considered to be the *inflation index* since period-on-period payouts are always governed by the return factor

$$Y(T - L) = \frac{I(T - L)}{I(T - K - \Omega)} \quad (31)$$

which is *hyperbolic*, and thus convex, in the first of the two index fixings entering the return ratio $Y(T - L)$. For inflation derivatives practitioners whose background is firmly in the area of exotic interest rate derivatives, and who prefer to view period-on-period rates, that is, $(Y(T - L) - 1)/\Omega$ or similar, as the fundamental underlying, this convexity, quite naturally, does not exist, and is merely an artifact of

choice of fundamental variables. Given the fact that ultimately all inflation fixing data result in the publication of an index figure, that is, $I(T)$, and the impact this setting has on the mind-set of inflation investors, this *hyperbolicity* effect is worth bearing in mind.

The second of the two convexity effects is the same as can be observed in other asset classes due to correlation with interest rates. It arises from a *timing discrepancy* between the fixing (observation) time of a financial observable and the time at which a payoff based on it is actually paid out. For instance, if an inflation zero-coupon swap payment is to be made with a certain delay, any nonzero correlation with interest rates gives rise to a risk-neutral valuation difference. Intuitively, one can understand this without the use of any model by considering that, in any scenario of high inflation, assuming positive correlation with interest rates, a delay of the payment is likely to incur a higher-than-average discount factor attenuation since, in that scenario, interest rates are also likely to be high. As a consequence, *ab initio*, one would tend to value a delayed inflation payment lower than its nondelayed counterpart (if we assume positive correlation between inflation and interest rates).

Both the hyperbolicity effect's and the interest rate correlation induced convexity effect's valuation formulae depend of course on the specific model used but are, typically, in any tractable model, straightforward to derive.

Fixing Lag Effects. An inconvenient feature of the inflation market is that the prices of tradables, even in the simplest of all possible cases, do not, in general, converge to the level at which they finally settle when the last piece of relevant market information becomes available. Take, for instance, a forward contract on the one month return of a money market account with daily interest rate accrual at the overnight rate. Clearly, the amount of uncertainty in the settlement level of this forward contract decreases at least linearly as we approach the last day of the one month period. On the day before the final overnight rate becomes known, at worst, 1/30 (say) of the uncertainty is left as to where this contract will fix. In contrast, for a similar inflation rate contract, such as a month-on-month caplet or floorlet, the amount of uncertainty in the beginning of the one month period and at its end is very

similar. This is because only limited extra information as to where the inflation index will fix becomes available during the month. As a consequence, it is common practice to consider for all volatility and variance related calculations, the reference date, that is, the point in time assumed to be $t = 0$, to be the *last index publication date*. Arguably, this may or may not be seen as an inconsistency between the framework assumed within any used model and its application, but, in practice, this appears to be a usable compromise.

Another point worth noting for the implementation of models, which is rarely spoken about in publications on the subject, is that all fixing timing tends to be subject to lags, offsets, and so on. This seemingly innocuous feature can, in practice, turn out to require intricate attention to detail. Unfortunately, since inflation structures can have very long final maturities of up to one hundred years, these small differences, if systematically erroneous, can build up to major valuation differences and can thus not be ignored. A specific mistake that is exceptionally easy to make is to assume that a breakeven curve, traded and quoted as zero-coupon swap rates, relates to future inflation index fixing levels in their own T -forward measure, with T being the publication date of the respective index level. This is insidiously wrong since actual zero-coupon swaps pay at a date that is a given tenor after the day of inception, and this could be any day in the month. For instance, if we enter into a five-year zero-coupon swap on the first of a month, ignoring weekends, this will typically settle in five years on the third of the month, and pay the index level published (say) at the beginning of the month three months before the settlement month. If we enter into the same swap on the 26th of the month, it will settle on the 28th five years later, and pay the same index fixing level as the previous example. For an arbitrary zero-coupon swap with lag L , depending on the day of the month at which it is entered into, this means it may settle with an effective lag of L months, or almost $L + 1$ months, or anything in between. Any associated interest rate convexity considerations thus depend not only on time to expiry and nominal lag but also on the day of the month. This may not sound much for a short-maturity zero-coupon swap such as one or two years, but for a 50-year zero-coupon swap, the interest rate convexity incurred makes a prohibitively expensive difference!

Backward Induction for Interest Rate/Inflation Products. It is not uncommon for inflation products to contain elements of a more traditional interest rate derivatives nature as, for example, was mentioned for the comparatively benign inflation swaptions discussed in the section The Inflation Swaption. When more exotic products allow for easy valuation in a strictly forward looking manner, one can of course employ Monte Carlo simulation techniques. However, if a product such as an inflation swaption is equipped with a Bermudan callable feature, as a quantitative analyst, one faces the problem that interest rates are by their nature forward looking, whereas inflation rates are by their nature backward looking. What we mean is that, typically, a natural floating interest rate coupon's absolute value is known *at the beginning* of the period for which it is paid. In contrast, floating inflation coupons are always paid after their associated period has elapsed. In a conventional backwards induction implementation on any type of lattice (e.g., explicit finite differencing solver or tree), this poses the problem that, as one has rolled the valuation back to the beginning of an interest rate period, one has to compare the value of the so induced filtration specific spot Libor rate, in some kind of pay-off formula, with the contemporaneous inflation rate, which is due to the inflation driver's evolution *in the past*, and thus *unknown* on the backwards induction lattice. The problem is ultimately very similar to the valuation of, say, a forward starting equity option. The paradox is that one needs to have simultaneous access to the effect of the interest rate driver's evolution over a future interval *and* to the inflation rate driver's evolution in the past, on any valuation node in the lattice. A practical solution to this dilemma is in fact very similar to the way in which the valuation of a hindsight, or, even simpler, Asian, option in an FX or equity setting can be implemented on a lattice [13]. By enlarging the state space by one dimension, which represents a suitably chosen extra state variable, one can indeed roll back future interest rates in tandem with past inflation rates. In practice, this is in effect nothing other than a parallel roll-back of *delayed equations*. The fact that this may become necessary for what appears to be otherwise relatively vanilla products is a unique feature of the inflation market.

The Inflation Smile. Similar to other asset classes, volatilities implied from inflation options, when

visible in the market, tend to display what is known as "smile" and "skew", and several authors have suggested the pricing of inflation options with models that incorporate a smile, for example, see [9, 10]. Unlike many other asset classes, though, the liquidity in options for different strikes, at the time of this study, is extremely thin. It is therefore arguable whether a sophisticated model that reflects a full smile is really warranted for the management of exotic inflation derivatives structures, or whether a simpler, yet more robust, model, that only permits control over the skew, or possibly even only over the level of volatility, if managed prudently (i.e., conservatively), is perhaps preferable. As and when the inflation options market becomes more liquid, the value differences between management of a trading book with a smiling model and a mere skew model may be attainable by hedging strategies, and then the use of fully fledged smile model for inflation is definitely justified. Since the liquidity in options has not significantly increased in the last few years, it is not clear whether this day of sufficient option liquidity to warrant, for instance, stochastic volatility models for inflation, will come.

End Notes

^aThe main difference between CPI and RPI is that the latter includes a number of extra items mainly related to housing, such as council tax and a range of owner-occupier housing costs, for example, mortgage interest payments, house depreciation, buildings insurance, and estate agents' and conveyancing fees.

^bNote that for the $\max(\cdot, 1)$ function to become active, *the average inflation over the life of the bond must be negative*. While inflation does, in practice, become negative for moderate periods of time, the market tends to assign no measurable value to the risk of inflation being negative on average for decades (the typical maturity of inflation bonds). Also note that inflation bond prices tend to be quoted with a four or five digit round-off rule, and that inflation indices themselves are published rounded (typically) to one digit after the decimal point, for example, the UK RPI for June 2008 was published as 216.8 (based on 1987 at 100).

^cThis can be confusing to newcomers to the inflation market who come from a fixed income background since a zero-coupon swap, by definition as used in the interest rate market, is a contract to never exchange any money whatsoever.

^dThis is a consequence of the fact that an Ornstein–Uhlenbeck process, in the limit $\kappa \rightarrow \infty$ with α^2/κ kept constant converges to the *white noise* process, which, in

turn, is in law equal to the temporal derivative of standard Brownian motion.

Swaps

A *swap* is an over-the-counter (OTC) derivative where two parties exchange regular interest rate payments over the life of the contract based on a principal. The most liquid market for swaps is for maturities between 2 and 10 years. However, in some markets, 30- or 40-year swaps are traded as well, and there exist even longer term deals. Swap legs may be denominated in single currency, as in *interest rate swaps* (IRS), or in different currencies, as in *currency swaps*. We cover the most common contracts of both types that use LIBOR (see **LIBOR Rate**) to fix the interest payments. An extensive discussion of how swaps are priced and risk-managed can be found in [2].

Plain Vanilla Swaps

The simplest IRS product is the *fixed/float swap* (sometimes also called *plain vanilla swap*). It is a contract where the payer pays a fixed rate and the receiver pays a floating rate fixed periodically against some rate index, for example, LIBOR; see Figure 1. The plain vanilla swap contract does not involve the principal exchange; only the interest is paid by the parties.

The purpose of such a transaction is to hedge against variations in the interest rates. In such capacity, vanilla swaps are used as basic hedges for all interest-rate-linked products (see **Hedging of Interest Rate Derivatives**). Another common use of vanilla swaps is to translate the fixed rate liabilities into floating rate ones on the back of bond issuance (see **Bond**). Since both forward rate agreement (FRA) and vanilla swap markets are fairly liquid, both of those instruments are used for yield curve construction (see **Yield Curve Construction**).

Most of the swap contracts are agreed on the terms of International Swaps and Derivatives Association

Figure 1 Fixed/float swap. The payer pays a fixed rate and receives a floating rate

(ISDA). For information about ISDA, conventions that specify swap agreements, see [1]. A swap can be viewed as a set of contiguous FRAs. Unlike in the FRAs, however, the frequencies of payments on the floating and the fixed legs of the swap may not be the same. Another difference is that each leg of a swap is normally making payments at the end of each accrual period. The latter fact allows to treat vanilla swaps as “linear” instruments. There exist other types of swaps for which the linear property does not hold (see **Constant Maturity Swap**).

Each payment amount in a plain vanilla swap equals the corresponding interest rate multiplied by the time fraction of the accrual period and by the notional amount. Such simple payout allows us to write down the present value (PV) formula of the plain vanilla swap for one unit of notional as

$$PV(0) = \sum_{k=1}^N L(0, t_{k-1}, t_k) \cdot \tau_k \cdot P(0, t_k) - R_0 \sum_{j=1}^M \tau_j \cdot P(0, t_j) \quad (1)$$

where the first sum runs over the floating leg payments, the second sum runs over the fixed leg payments, τ_k is the time fraction of accrual period (t_{k-1}, t_k) , R_0 is the swap’s fixed rate, $P(T, S)$ is the value of discount bond at T , and $L(t, T, S)$ is the forward reference rate at t .

The valuation formula in equation (1) demonstrates that a plain vanilla swap, effectively being a linear combination of FRAs, can be valued off a forward curve and a discount function. At the inception of the swap transaction, the fixed rate is chosen such that PV is equal to zero. Such a rate is called *break-even swap rate*.

In addition to the plain vanilla swaps there exist other types of swaps based on LIBOR rates, for example, basis swaps and cross-currency basis swaps.

Basis Swaps

In a *basis swap* the parties exchange floating payments fixed against different rate indices. Very often both legs are LIBOR-based. For example, one leg pays 3M LIBOR plus quoted spread, and the other leg pays 6M LIBOR. The economic rationale behind

the existence of the basis spread between different LIBOR rates in single currency can be explained by the credit and the liquidity considerations. A bank would rather provide an unsecured credit for 3 months, then assess the market situation, and provide credit for another 3 months rather than lend money for 6 months from the very beginning.

Cross-currency Basis Swaps

These contracts are designed to provide funding in one currency through borrowing of funds in another currency. In a *cross-currency basis swap*, the two legs of the swap are each denominated in a different currency. Usually, one floating leg is USD floating rate. In this type of a swap contract, the parties exchange both the principals and the interest payments in the two currencies, based on the foreign exchange rate at the time of the trade. The interest payments are normally fixed against the corresponding currencies' 3M LIBOR rates. The principal exchange, typically occurring at both the start and the end of the contract, is an important aspect of this transaction. Without the principal exchange, the associated swap would not

achieve the goal of transforming liability from one currency into another.

Finite Difference Methods for Barrier Options

Barrier options, options that cease to exist (knock-out barrier options) or that only come into existence (knock-in barrier options) when some observable market parameter crosses a designated level (the barrier), have become ubiquitous in financial contracts for virtually all asset classes, including equities, foreign exchange, fixed income, and commodities.

Pricing of continuously monitored barrier options using partial differential equations (PDEs) enables the use of coordinate transformations to obtain smooth, rapid convergence, highly desirable properties that are difficult to obtain using traditional lattice methods. The finite difference method is perhaps the most straight forward and intuitive approach to the numerical solution of PDEs. Yet even in this seemingly simple approach, there exist subtleties that can be exploited for tremendous gains in accuracy and/or computational efficiency [7]. We explore several ways in which finite difference pricing models for barrier options may be designed for increased accuracy and performance.

Pricing models in which the monitoring of the barrier knockout or knock-in condition is approximated as being continuous have been popular principally because they may yield analytic solutions, at least for simple underlying processes (e.g., Black–Scholes.) Even for underlying process for which numerical PDE solution methods are required (e.g., stochastic volatility models with correlation of the underlying level and its instantaneous variance), the continuously monitored barrier condition is often easier to treat with simple numerical methods.

However, in the vast majority of barrier option contracts, the barrier conditions are monitored at discrete times or dates. For the volatilities observed in most markets, even barrier monitoring as frequently as daily yields barrier option prices surprisingly far from those yielded by a continuous monitoring approximation. Broadie *et al.* [2] derive a formula for shifting a discrete barrier so that pricing with continuously monitored barrier yields the discretely monitored barrier price to lowest order in the monitoring interval for a lognormal process. In many cases of interest, however, direct numerical solution of the discretely monitored barrier pricing

problem is required. Therefore, in this article, the continuously monitored barrier case is discussed fairly briefly, while the majority of space is devoted to the discretely monitored barrier case.

For simplicity of notation, we focus on a simple Black–Scholes [1] pricing PDE but none of the methods discussed require that PDE coefficients be constant, so the methods are directly applicable to local volatility models. When methods of conforming finite difference grids to barrier and/or strike positions are discussed, they apply only to the coordinate representing the financial factor subject to a barrier. Other coordinate grids, for example, the instantaneous volatility in a stochastic volatility model [5], or a second or third asset in a basket model are unaffected. Therefore, the methods presented are applicable to these problems as well.

The case of jump-diffusion models requires further analysis and is discussed in [3] (*see Partial Integro-differential Equations (PIDEs)*).

Continuous Monitoring

The simplest pricing partial differential equations (PDEs) typically encountered is the Black–Scholes equation [1], written in the form

$$\frac{\partial V}{\partial t} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + (r - q)S \frac{\partial V}{\partial S} - rV = 0 \quad (1)$$

where V is the option value, S is the underlying asset price, r and q are the forward rate and continuous dividend yield, respectively, and σ is the volatility.

A simple up-out call option is used for illustration. In this case, the payoff condition at option expiration $t = T$ is

$$V(S, T) = \max(S - K, 0) : \quad S < B \quad (2)$$

$$V(S, T) = R : \quad S \geq B \quad (3)$$

where B is the up-out barrier, K is the option strike, and R is a rebate paid immediately upon knockout. The upper grid boundary can be placed at $S = B$ with boundary condition $V(B, t) = R$, while that for the lower boundary $S_{\min}$ is not well defined unless $S_{\min} = 0$. Terminating the grid at $S_{\min} = 0$ may be a quite inefficient use of finite difference grid points, since the option value may be very small over most

of the grid. Rather, one may choose a simple rule of thumb such as

$$S_{\text{Min}} = S_0 e^{-N\sigma\sqrt{T}} \quad (4)$$

which places the lower boundary N standard deviations below the initial asset price S_0 , so that for $N \geq 4$ there is only a minuscule chance of the asset price reaching the strike price before expiration to yield a positive payoff. Then $V(S_{\text{Min}}, t) = 0$ becomes an accurate boundary condition.

The commonly used coordinate transformation $x = \log(S)$ is avoided here for three reasons: (i) since the volatility may have a dependence on S (local volatility), it does not necessarily yield a PDE with constant coefficients. (ii) In a fully numerical PDE solution, constant coefficients are of marginal benefit. (iii) It is far more useful to employ other, more general coordinate transformations.

In particular, the transformation used here is a slight warping of an otherwise uniform grid. The grid is warped so that the strike K is “pinned” midway between two grid points independent of S_{Min} or the number of grid points, while keeping the grid spacing as uniform as possible. The benefit of doing so is that smooth monotonic convergence—superior to that typical of lattice methods—is obtained as demonstrated by Tavella and Randall [7]. In the transformed coordinates, the PDE becomes

$$\begin{aligned} \frac{\partial V}{\partial t} + \frac{1}{2}\sigma^2 \frac{S^2(x)}{J(x)} \frac{\partial}{\partial x} \left(\frac{1}{J(x)} \frac{\partial V}{\partial x} \right) \\ + (r - q) \frac{S(x)}{J(x)} \frac{\partial V}{\partial x} - rV = 0 \end{aligned} \quad (5)$$

where $J(x) = \partial S(x)/\partial x$ is the Jacobian of the transformation. The new coordinate x is by convention equally spaced on a grid, $x_0 \leq x_i \leq x_I$, where $0 \leq i \leq I$ and subject to the boundary conditions, $S(x_0) = S_{\text{Min}}$, $S(x_I) = B$, and the “pinning condition” $K = (S_p + S_{p+1})/2$, where p is the index of the grid point just below K .

A method for numerically computing a smoothly varying coordinate transformation $S(x)$ so as to place particular “pinning” points (e.g., K) either exactly on grid points or exactly midway between grid points through the use of spline interpolation, is also discussed in detail in [7].

Table 1 shows the convergence of the numerical results *versus* the number of grid points I for an

at-the-money up-out call option. The option and market parameters are given in the caption. The column labeled $V(S_0)$ is the present value, that labeled *Error* is the finite difference result minus the converged result, and that column labeled *Ratio* is the ratio of *Errors* for grid I and grid $I/2$. The numerical solution converges smoothly and monotonically because the option strike (where the payoff has a discontinuity of slope) always has a fixed relationship to the grid, namely it is always midway between two grid points. The convergence is almost exactly quadratic, that is, *Ratio* is very close to 4 when I is doubled. In order to make time discretization error negligible so that the spatial grid discretization effects of interest could be examined in isolation, 50 000 time steps have been used with a Rannacher [4] time discretization scheme. Time discretization effects with practical numbers of time steps are discussed later.

(One of the benefits of full or partially implicit PDE methods like Crank–Nicolson or Rannacher is that the number of spatial grid points and time steps are independent, whereas in lattice methods they are closely coupled.)

Discrete Monitoring

In modeling continuously monitored barrier options, as in the previous section, it is sufficient to place the barrier(s) on the grid boundaries and enforce a boundary condition $V(B, t) = R$. It is of no consequence that gradient of option value $V(S)$ (the option Δ) is discontinuous at the barriers because the pricing PDE (which includes second derivative terms that become singular) is not solved at the barriers. Boundary conditions are enforced instead.

When modeling discretely sampled barriers, however, the barriers appear inside the solution region,

allowing the option value $V(S)$ to “diffuse” across the barriers between monitoring times. The knockout conditions are enforced only at the monitoring times. Consequently, the pricing PDE is solved at the barrier position, and the grid must resolve the very strong gradients that are periodically created there by the discrete monitoring. To do this efficiently, it is convenient to use a coordinate transformation that results in a concentration of grid points near a specified set of points, for example, the strike K and barrier B .

A transformation useful for this purpose can be obtained as the solution of the ordinary differential equation (ODE)

$$\frac{dS}{dx} = \frac{A}{\left[\sum_i \frac{\alpha^2 + (S - P_i)^2}{\alpha^2 \beta^2 + (S - P_i)^2} \right]^{1/2}} \quad (6)$$

where A is a constant to be determined through the boundary conditions $S(x_{\text{Min}}) = S_{\text{Min}}$ and $S(x_{\text{Max}}) = S_{\text{Max}}$, and the summation is over the set of specified points P_i , $0 \leq i \leq n_p$. The properties of the transformation are easiest to see in the special case of a single specified point, where the ODE simplifies to

$$\frac{dS}{dx} = A \left[\frac{\alpha^2 \beta^2 + (S - P)^2}{\alpha^2 + (S - P)^2} \right]^{1/2} \quad (7)$$

Thus, far from the specified point, $|S - P| > \alpha$, $dS/dx = A$ is a constant. If x is uniformly spaced, then far from the specified point P , S is uniformly spaced as well. In the neighborhood of the specified point $S = P$, $dS/dx = \beta A$ is minimized ($\beta < 1$), and the S grid is finer by the ratio β .

To compute that transformation in equation (6), a uniform grid is first created in the underlying coordinate x and an initial guess for the constant A is made. After enforcing the left boundary condition $S(x_{\text{Min}}) = S_{\text{Min}}$, a simple ODE solver such as Runge–Kutta can be used to step through the x grid, computing $S(x)$. If, at the right end of the grid, the boundary condition $S(x_{\text{Max}}) = S_{\text{Max}}$ is not satisfied to a given precision, then the constant A is adjusted *via* a Newton’s method and the ODE solution repeated until the right boundary condition is satisfied. Convergence is typically rapid. Finally, a secondary transformation is applied, slightly warping the computed S grid so as to place the set of specified points either exactly at grid points or at grid midpoints as described in [7].

Table 2 Finite difference results for a discretely monitored up-out barrier call. Parameters: $T = 1$, $K = 100$, $B = 110$, $R = 0.5$, $r = 0.05$, $q = 0.03$, $\sigma = 0.1$, $S_0 = 100$, 250 monitoring dates, 50 000 time steps, $\alpha = 20$, $\beta = 0.1$

Table 2 shows the convergence of option value with the number of grid points I for an at-the-money up-out call option, discretely monitored 250 times per year. The option and market parameters are given in the caption. The column labeled $V(S_0)$ is the present value, that labeled *Error* is the finite difference result minus the analytic result, and that column labeled *Ratio* is the ratio of *Errors* for grid I and grid $I/2$. Even in this case of frequent discrete monitoring of the barrier, in which discontinuities of option value V are created periodically throughout the integration of the PDE, the numerical solution converges smoothly and monotonically. This is possible because the option strike and the barrier both always have a fixed relationship to the grid, namely, they are always midway between two grid points. The convergence is again almost exactly quadratic, that is, *Ratio* is very close to 4 when the number of grid points is doubled. Again, a very large number of time steps (50 000) have been used in order to isolate spatial grid discretization effects.

Smooth convergence according to a known scaling law also allows fairly robust extrapolation to the continuum result from several computationally inexpensive sparse grid computations.

$$V(I \rightarrow \infty) \approx \frac{4V(2I) - V(I)}{3} \quad (8)$$

For example, using $I = 100$ in equation (8), the estimated continuum result is 0.919187, which is very close to the presumed converged result 0.919204. Thus, one extrapolates to very near the converged value from two very cheap and fast sparse grid computations. Robust extrapolation from lattice computations of barrier option value is typically not possible.

The converged values of the continuously monitored and daily monitored options differ by over 8%

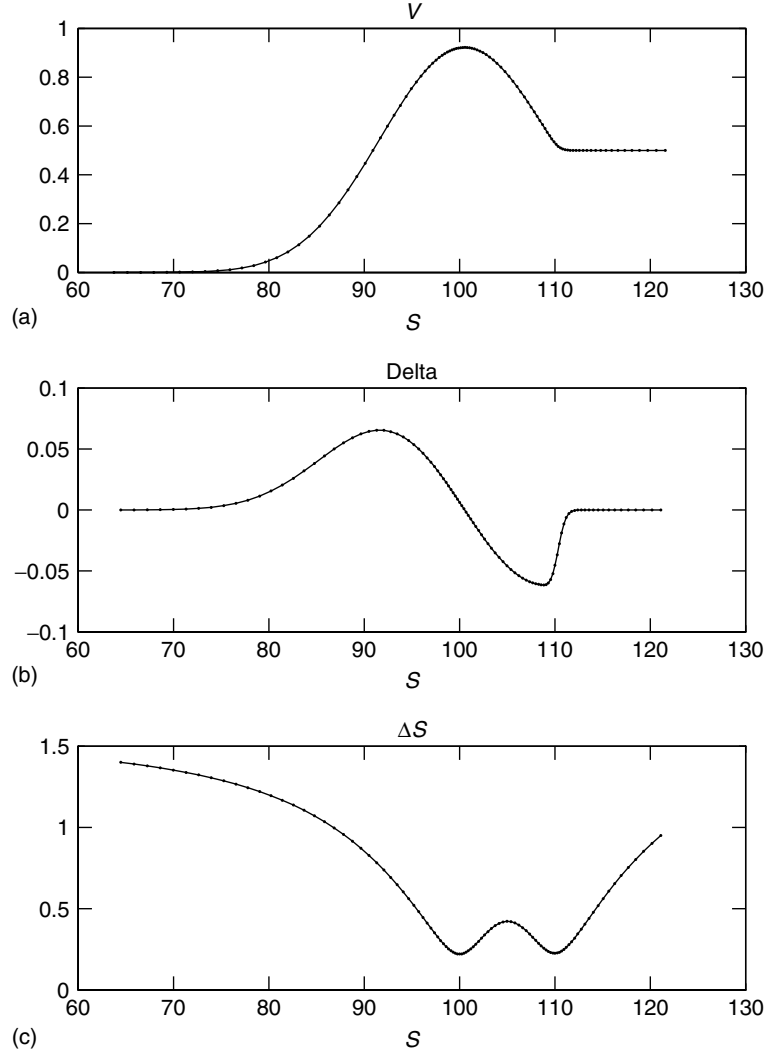

Figure 1 Option value (a), option Δ (b), and grid spacing (c) for a discretely monitored up-out barrier call. Parameters: $T = 1$, $K = 100$, $B = 110$, $R = 0.5$, $r = 0.05$, $q = 0.03$, $\sigma = 0.1$, $S_0 = 100$, 250 monitoring dates, 50 000 time steps, $\alpha = 20$, $\beta = 0.1$, $I = 100$ grid points

even for this relatively low volatility case. The continuity correction formula in [2] yields an option value of 0.9217721, which is much closer to the converged value of the daily monitored option, but still too large by approximately 0.3%. Since the formula is basically an expansion in $\sigma\sqrt{\Delta t_B}$, where Δt_B is the monitoring interval, the accuracy of the correction will degrade for larger volatilities and/or less frequent monitoring. The accuracy of the formula also depends on the proximity of S_0 and B .

The grids used in the computations of Table 2 were concentrated about the option strike and barrier, with coordinate transformation parameters $\alpha = 20$, $\beta = 0.1$. Figure 1 displays the present ($t = 0$) option value $V(S)$, option delta $= \partial V(S)/\partial S$, and the grid spacing $\Delta S(S) = J(S)\Delta x$ when $I = 100$. With the next barrier monitoring date one day hence, the option has significantly larger value at the barrier $S = B = 110$ than the discounted rebate value of approximately $R = 0.5$. The option Δ changes rapidly in

the neighborhood of the barrier, but remains continuous. The grid spacing ΔS is minimized near the two designated points $K = 100$ and $B = 110$ yielding a ratio of largest to smallest spacing on the grid of about a factor of 7. Even with just $I = 100$ grid points, the small grid spacing near the barrier resolves the rapid change of Δ through the region. Similarly, the small spacing near the strike helps resolve the rapid variation of Δ in the region close to option expiration.

Table 3 compares the accuracy of the solution for an up-out call option for three finite difference grids. Grid A is equally spaced ($\beta = 1$) with the barrier exactly on a grid point. (The strike remains at a grid midpoint.) Grid B is also equally spaced, but with the barrier at a midpoint. Finally, Grid C is the nonuniform grid of Table 2, whose data is simply reproduced for comparison.

In the case of Grid A, the fixed relationship of the strike and barrier to the grid yields smooth monotonic

convergence, but it is only linear (*Ratio* is close to 2 when I is doubled) and the observed error is 1–3 orders of magnitude larger than that of Grid C.

In the case of Grid B, the barrier is at a grid midpoint and quadratic convergence (*Ratio* ~ 4) is restored, but because the grid is still uniform, the spacing near the barrier is roughly three times larger than it is for Grid C. As a result, the observed error, while far superior to that of Grid A, is about an order of magnitude larger than that of the nonuniform Grid C. Clearly, use of a nonuniform grid, while taking care to place a discretely sampled barrier at a grid midpoint yields superior convergence. The computational effort involved in computing such a grid is generally negligible compared to the PDE solution itself and obviously worth the effort.

Continuously monitored barriers are optimally priced when the barrier(s) coincide with grid points, while the foregoing numerical results seem to establish that a discretely sampled barrier option is optimally priced when the barrier is midway between two grid points. Of course, as the monitoring frequency is increased, a discretely monitored barrier becomes a continuously monitored one. Therefore, a dimensionless parameter is needed, one that, given a monitoring frequency, determines the optimal grid style to be used. An obvious choice is the ratio of characteristic grid diffusion time near the barrier to the monitoring interval:

$$R_{\Delta t} = \frac{\Delta t_{\text{Grid}}}{\Delta t_B}$$

$$\Delta t_{\text{Grid}} = \frac{(\Delta S/B)^2}{\sigma^2/2}$$

$$\Delta t_B = \frac{T}{n_B} \quad (9)$$

where T is option expiration and n_B is the number of monitoring dates. One expects that for $R_{\Delta t} > 1$, the discretely monitored barrier is effectively continuously monitored to the resolution of the grid, and the barrier should be placed at a grid point. Conversely, when $R_{\Delta t} < 1$ then the barrier should be midway between grid points for optimal accuracy.

This criterion, which is easy to verify numerically, can be used to choose where to place a discretely sampled barrier for optimal accuracy. However, it is easy to see that for almost any discretely sampled barrier option with typical parameters, the barrier(s)

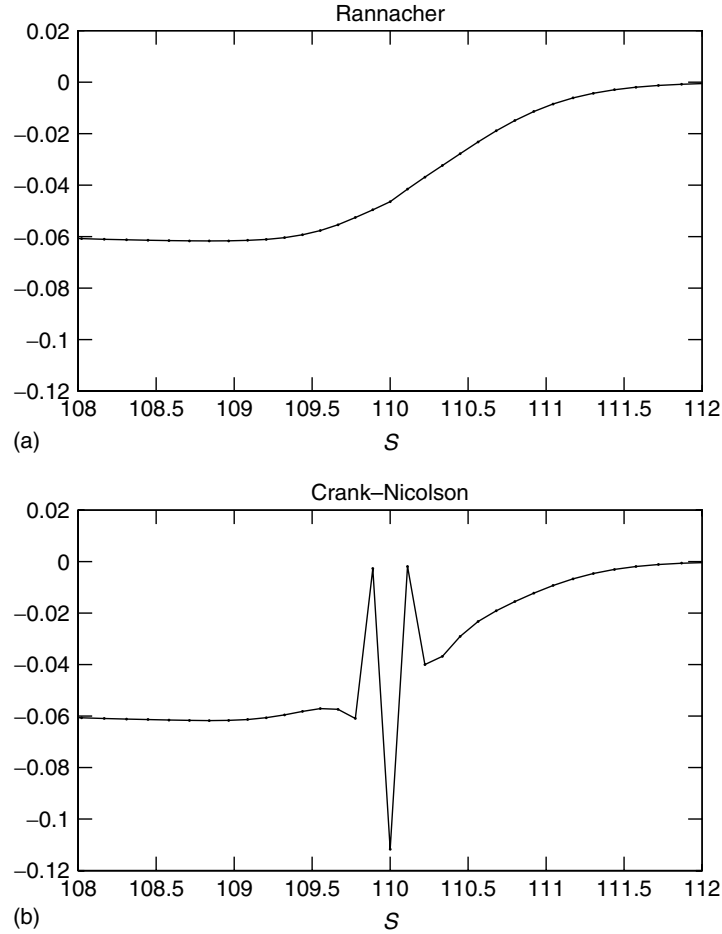

Figure 2 Option Δ in the neighborhood of the barrier for two time discretizations for a discretely monitored up-out barrier call: Rannacher (a), and Crank–Nicolson (b). Parameters: $T = 1$, $K = 100$, $B = 110$, $R = 0.5$, $r = 0.05$, $q = 0.03$, $\sigma = 0.1$, $S_0 = 100$, 250 monitoring dates, 1000 time steps, $\alpha = 20$, $\beta = 0.1$, $I = 100$ grid points

are optimally at grid midpoints. For example, choosing the nonuniform grid with $I = 100$ in Figure 1, one computes $\Delta t_{\text{Grid}} \approx 0.00066$. Since the approximate daily sampling interval is $\Delta t_B \approx 0.004$, the ratio is $R_{\Delta t} \approx 0.16$ and best results are achieved with the barrier midway between grid points. For finer grids, the ratio $R_{\Delta t}$ is even smaller. Thus, for fairly typical parameters, the monitoring interval for which placing barriers on grid points becomes optimal is so small that simply modeling the option as continuously monitored to begin with is probably sufficiently accurate. It is surely much more efficient, because the time steps can be much larger than Δt_{Grid} when semi-implicit time-stepping

methods like Crank–Nicolson or Rannacher [4] are used.

Time Discretization

In the examples thus far, very large numbers of time steps have been used (far in excess of what is practical or desirable), to eliminate time discretization error and isolate spatial discretization error. Considering for the moment the simple heat equation (written in reverse time as it might be in the context of finance),

$$\frac{\partial V}{\partial t} + \kappa \frac{\partial^2 V}{\partial x^2} = 0 \quad (10)$$

the following partially implicit time discretization can be proposed:

$$\frac{V^{n+1} - V^n}{\Delta t} + \theta \kappa \frac{\partial^2 V^{n+1}}{\partial x^2} + (1 - \theta) \kappa \frac{\partial^2 V^n}{\partial x^2} = 0 \quad (11)$$

to advance the solution from t^{n+1} to t^n , where θ is the “implicitness” parameter.

The Crank–Nicolson method, which is often recommended because its truncation error is $O(\Delta t^2)$, corresponds to $\theta = 0.5$. As is well known [5, 6], a Fourier analysis of equation (11) shows that the Crank–Nicolson method is also unconditionally stable. No individual Fourier mode grows exponentially as $n \rightarrow \infty$ no matter the size of Δt relative to the characteristic diffusion time of the grid. However, the Nyquist modes, which change sign at alternate grid points, while stable for large time steps, do not diffuse away, but simply alternate sign on succeeding time steps. On the other hand, a fully implicit method $\theta = 1$ has truncation error $O(\Delta t)$, but the Nyquist modes decay rapidly when Δt is large relative to the diffusion time of the grid.

In pricing discretely sampled barrier options, one enforces the knockout or knock-in conditions by simply changing the option value $V(S)$ appropriately on monitoring dates. Doing so creates discontinuities that add energy to the Nyquist portion of the Fourier spectrum. Thus, while the Nyquist modes formally remain stable under Crank–Nicolson differencing, their amplitude can still grow with each periodic monitoring. The result can be oscillatory solutions near the barrier. And because the Nyquist modes are highly oscillatory, they have a much larger polluting effect on the Greeks Δ and γ than on the value itself [6].

In the Rannacher [4] method, several fully implicit time steps are taken after each barrier monitoring date (or more generally after any event that can result in value or Δ becoming discontinuous), followed by Crank–Nicolson steps. If the number of implicit steps remains constant as the total number of time steps is increased, then the method is $O(\Delta t^2)$. However, it has superior performance when applied to solutions with discontinuities such as digital options or discretely monitored barrier options, since the fully implicit steps in Rannacher drastically reduce the Nyquist modes. An alternative three-level time discretization that likewise has truncation error

of $O(\Delta t^2)$ while eliminating Nyquist modes can also be formulated for the parabolic PDEs common in computation finance. See [7] for a detailed discussion of the three-level scheme for pricing discretely monitored barrier options. Here, the Rannacher scheme is used because of its simplicity.

Figure 2 displays the present ($t = 0$) option delta $= \partial V(S)/\partial S$ in the immediate neighborhood of the barrier for Grid C of Table 3 when $I = 200$, for both Rannacher discretization and Crank–Nicolson. However, the number of time steps is a more practical 1000. The accumulation of Nyquist mode energy near the barrier is evident for Crank–Nicolson differencing, but absent for Rannacher in which two fully implicit time steps were used after each monitoring date. With 250 monitoring dates and 1000 time steps, fully one half of the time steps were implicit. Hence, time discretization error is fairly large despite the stability. However, as the number of time steps is increased, the fraction of fully implicit steps decreases and convergence is quadratic in Δt as shown in Table 4.

Comparing the results of Table 2 ($N = 50\,000$ time steps) to those of Table 4, (N varies with I) it is apparent that most of the error in Table 4 can be ascribed to time discretization, even with a scheme that is clearly quadratically convergent. This is expected for a barrier option with high frequency (approximately daily) monitoring. The monitoring periodically creates discontinuous option values $V(S)$ in the neighborhood of the barrier, and sufficient time steps are required to resolve the evolution of the strong gradients (large Δ s and γ s) created.

Finite Difference Methods for Early Exercise Options

Analytical formulas for the price are not available for options with early exercise possibility. Numerical methods are needed for pricing them. A common way is to derive a partial differential equation (PDE) for the price of the corresponding European-type option (without early exercise possibility) and then modify the equation to allow early exercise. With this approach, most often the underlying partial differential operator is discretized using a finite difference method that we consider in the following. Finite difference methods can be seen as a special (but simpler) case of the finite element method (*see Finite Element Methods*).

An American-type option can be exercised any time during its life (*see American Options*) while a Bermudan-type option can be exercised at specified discrete times during its life. Most typical examples are American put and call options, but American and Bermudan exercise features can be added virtually to any option. In the following, we use an American put option under the Black–Scholes model as an example. Many of the considered methods can be used in a straightforward manner for other types of models and options, as discussed below.

PDE Formulation

We denote the price of an option by V , which is a function of the value of the underlying asset S and time t . As it is more common to consider problems forward in time instead of backward, we use the inverted time variable $\tau = T - t$ instead of t in the following. The payoff function g gives the value of the option at the expiry date T , and also if it is exercised early. For example, for a put option, it is $g(S, \tau) = \max\{K - S, 0\}$, where K is the strike price.

The price V of a European option is given by a parabolic PDE

$$V_\tau + LV = 0 \quad (1)$$

with the initial condition $V = g$ at $\tau = 0$ together with boundary conditions, where L is linear partial

differential operator. Under the Black–Scholes model [6], the operator L is defined by

$$LV = -\frac{1}{2}\sigma^2 S^2 V_{SS} - rSV_S + rV \quad (2)$$

for $S > 0$, where σ is the volatility and r is the interest rate (*see Black–Scholes Formula*).

At the moment when the owner of an American or Bermudan-type option exercises it, she/he will receive a payment defined by the payoff function g . Hence the value V of such an option cannot be less than g , otherwise there would be an arbitrage opportunity. This leads to an early exercise constraint

$$V \geq g \quad (3)$$

which holds whenever the option can be exercised. As this inequality constrains the price V , it does not satisfy the PDE (1) everywhere; instead, it satisfies an inequality

$$V_\tau + LV \geq 0 \quad (4)$$

whenever equation (3) holds. Furthermore, either equation (3) or equation (4) has to hold with the equality at each point. Combining these conditions for an American-type option leads to a linear complementarity problem (LCP)

$$\begin{aligned} V_\tau + LV &\geq 0, \quad V \geq g, \\ (V_\tau + LV)(V - g) &= 0 \end{aligned} \quad (5)$$

For a Bermudan option, the LCP (5) holds when the option can be exercised, and at other times, the PDE (1) holds. Another possibility is to formulate a variational inequality for the price V ; see [1, 18, 27], for example.

At time τ , the space can be divided into two parts: an early exercise (stopping) region $E(\tau)$ and a hold (continuation) region $H(\tau)$. In the early exercise region, it is optimal to exercise the option, whereas in the hold region, it is optimal not to exercise it. For example, under the Black–Scholes model, these regions can be defined as

$$\begin{aligned} E(\tau) &= \{S > 0 : V(S, \tau) = g(S)\}, \\ H(\tau) &= \{S > 0 : V(S, \tau) > g(S)\} \end{aligned} \quad (6)$$

The boundary between these regions is called the *early exercise boundary* $S_f(\tau)$. This is a time-dependent free boundary whose location is not known before solving the LCP (5) or some equivalent problem.

Alternatively, the price V can be computed as the solution of a free boundary problem in which the function $S_f(\tau)$ is also unknown. When the smooth pasting principle holds, the first derivative of V is continuous across the boundary $S_f(\tau)$, and this gives an additional boundary condition on $S_f(\tau)$ that can be used to locate the free boundary. We remark that the smooth pasting principle does not hold, for example, when the model has $\sigma = 0$ like the variance gamma model (see **Variance-gamma Model**). Under the Black–Scholes model, we can formulate the problem for a put option:

$$\begin{aligned} V_\tau + LV &= 0 \quad \text{for } S > S_f(\tau), \\ V(S_f(\tau), \tau) &= g(S_f(\tau)) = S_f(\tau) - K, \\ V_S(S_f(\tau), \tau) &= g_S(S_f(\tau)) = -1 \end{aligned} \quad (7)$$

with the initial condition $V(S, 0) = g(S)$. One advantage of this formulation is that it can give a good approximation for the free boundary $S_f(\tau)$. The domain $(S_f(\tau), \infty)$ in which the PDE needs to be satisfied is time varying. This makes the use of a finite difference method more complicated. An approach used in [32, 43] is to use a time-dependent change of variable in such a way that the computational domain is independent of time. The free boundary problem (7) is nonlinear, and devising a simpler and efficient solution procedure can be also a challenging task. We do not consider this formulation in the following.

A semilinear formulation for American put and call options under the Black–Scholes model was described in [4, 28]. For a put option, it leads to a semilinear PDE

$$V_\tau - LV = q \quad (8)$$

for $S > 0$, where

$$q(S, \tau) = \begin{cases} 0 & \text{if } V(S, \tau) > g(S) \\ rK & \text{if } V(S, \tau) \leq g(S) \end{cases} \quad (9)$$

This PDE has a simple form, and it is posed in the fixed domain $(0, \infty)$. The discontinuous q can make the numerical solution of this problem difficult. The

PDE (8) with a regularized q was solved using an explicit finite difference method in [5].

Finite Difference Scheme

Here, we consider the finite difference discretization of the LCP formulation (5) for an American option. Furthermore, we use the Black–Scholes operator L in equation (2) as an example. For discussion on finite difference discretizations, see [1, 15, 36, 37].

First, the domain $(0, \infty)$ is truncated into a sufficiently large interval $(0, S_{\max})$ and an artificial boundary condition is introduced at $S_{\max}$. For a put option, one possibility is $V(S_{\max}, \tau) = 0$. Next, we define a grid S_i , $i = 0, \dots, p$, such that $0 = S_0 < S_1 < \dots < S_p = S_{\max}$. We allow the grid to be nonuniform, that is, the grid steps $\Delta S_{i+1} = S_{i+1} - S_i$ can vary. An alternative approach would be to use a coordinate transformation together with a uniform grid (see **Finite Difference Methods for Barrier Options**). In the finite difference discretization, we seek the value of V at the grid points S_i . For better accuracy, it is desirable to have finer grid where V changes more rapidly such as near the strike price K for a put and call option, and near where the option price is desired. For example, we can construct a finer grid near the strike price K using a formula

$$S_i = \left(1 + \frac{\sinh(\mu(i/p - \xi))}{\sinh(\mu\xi)}\right) K \quad (10)$$

where the constant μ is solved numerically from the equation $S_p = S_{\max}$. By choosing ξ , we control the amount of grid refinement.

The adopted space finite difference discretization leads to an approximation

$$\begin{aligned} (LV)(S_i) &\approx -\alpha_i V_{i-1} \\ &\quad + (\alpha_i + \beta_i + r)V_i - \beta_i V_{i+1} \end{aligned} \quad (11)$$

at the internal grid points S_i , $i = 1, \dots, p-1$, where the grid point values of V are denoted by $V_i = V(S_i)$. The coefficients α_i and β_i are defined by

$$\begin{aligned} \alpha_i &= \frac{\sigma^2 S_i^2}{\Delta S_i (\Delta S_{i+1} + \Delta S_i)} \\ &\quad - \frac{r S_i}{\Delta S_{i+1} + \Delta S_i}, \end{aligned}$$

$$\beta_i = \frac{\sigma^2 S_i^2}{\Delta S_{i+1}(\Delta S_{i+1} + \Delta S_i)} + \frac{r S_i}{\Delta S_{i+1} + \Delta S_i} \quad (12)$$

if $\Delta S_i \leq \sigma^2 S_i / r$, and otherwise by

$$\alpha_i = \frac{\sigma^2 S_i^2}{\Delta S_i(\Delta S_{i+1} + \Delta S_i)},$$

$$\beta_i = \frac{\sigma^2 S_i^2}{\Delta S_{i+1}(\Delta S_{i+1} + \Delta S_i)} + \frac{r S_i}{\Delta S_{i+1}} \quad (13)$$

The reason to switch over to the latter formulas based on a one-sided difference for V_S when the above condition does not hold is to always have positive coefficients α_i (and β_i). The latter formulas are less accurate. Usually, it is necessary to use them only for a few grid points near $S = 0$, and this has minor (or no) influence on accuracy. We form a vector

$$\mathbf{V} = \begin{pmatrix} V_0 \\ V_1 \\ \vdots \\ V_p \end{pmatrix} \in \mathbb{R}^{p+1} \quad (14)$$

and a $p+1 \times p+1$ tridiagonal matrix $\mathbf{A}$ with $A_{i+1,i} = -\alpha_i$, $A_{i+1,i+1} = \alpha_{i+1} + \beta_{i+1} + r$, and $A_{i+1,i+2} = -\beta_{i+1}$ for $i = 1, \dots, p-1$. The first and last row of $\mathbf{A}$ depends on the boundary conditions. For example, for a put option, we choose them to be zero rows. The matrix vector multiplication $\mathbf{A}\mathbf{V}$ results in a vector that contains the approximations of LV at the grid points.

The space finite difference discretization leads to a semidiscrete LCP for the vector function $\mathbf{V}(\tau)$ given by

$$\mathbf{V}_\tau - \mathbf{A}\mathbf{V} \geq \mathbf{0}, \quad \mathbf{V} \geq \mathbf{g},$$

$$(\mathbf{V}_\tau - \mathbf{A}\mathbf{V})^T (\mathbf{V} - \mathbf{g}) = 0 \quad (15)$$

for $\tau \in (0, T]$. The initial value $\mathbf{V}(0)$ and the vector $\mathbf{g}$ contain the grid point values of the payoff function g . In the above and following, the inequalities hold componentwise.

The finite difference discretization of the LCP gives the value of V only at the grid points. Thus, any simple approximation of the early exercise region $E(\tau)$ and the free boundary $S_f(\tau)$ can have only the same accuracy as the grid step size.

The time discretization approximates the vector function $\mathbf{V}$ at times τ^n such that $0 = \tau^0 < \tau^1 < \dots < \tau^m = T$. In the following, $\mathbf{V}$ at the approximation time τ^n is denoted by $\mathbf{V}^n = \mathbf{V}(\tau^n)$ and the time step between τ^n and τ^{n+1} is denoted by $\Delta\tau^{n+1} = \tau^{n+1} - \tau^n$. The popular θ time stepping scheme leads to a sequence of discrete LCPs

$$\mathbf{B}\mathbf{V}^{n+1} \geq \mathbf{b}^{n+1} \quad \mathbf{V}^{n+1} \geq \mathbf{g},$$

$$(\mathbf{B}\mathbf{V}^{n+1} - \mathbf{b}^{n+1})^T (\mathbf{V}^{n+1} - \mathbf{g}) = 0 \quad (16)$$

for $n = 0, 1, \dots, m-1$ with the initial vector $\mathbf{V}^0 = \mathbf{g}$, where we have used the notations

$$\mathbf{B} = \mathbf{I} + \theta^{n+1} \Delta\tau^{n+1} \mathbf{A},$$

$$\mathbf{b}^{n+1} = [\mathbf{I} + (1 - \theta^{n+1}) \Delta\tau^{n+1} \mathbf{A}] \mathbf{V}^n \quad (17)$$

Different choices of θ^{n+1} lead to the following commonly used method: the explicit Euler method $\theta^{n+1} = 0$, the Crank–Nicolson method $\theta^{n+1} = 1/2$, and the implicit Euler method $\theta^{n+1} = 1$. The Rannacher scheme is obtained by taking a few (say, four) first time steps with the implicit Euler method ($\theta_n = 1$, $n = 1, 2, 3, 4$) and then using the Crank–Nicolson method ($\theta_n = 1/2$, $n = 5, \dots, m$) (see **Crank–Nicolson Scheme**).

Usually, the exercise boundary $S_f(\tau)$ moves rapidly near the expiry and more slowly away from it. For example, for a put option under the Black–Scholes model the boundary behaves like

$$S_f(\tau) \approx K \left(1 - \sigma \sqrt{-\tau \log \tau} \right) \quad (18)$$

near the expiry $\tau = 0$ [29]. Because of this, with uniform time steps, time discretization errors are likely to be much larger during the first time steps than during the later steps. This suggests that it is beneficial to use variable time steps. By gradually increasing the length of time steps, the errors can be made more equidistributed. This way, better accuracy can be obtained with a given number of time steps. Thus, we can reduce the computational effort to reach a desired accuracy.

One possible way to choose the time steps is so that the exercise boundary moves approximately the same amount at each time step. For the Rannacher scheme, by neglecting the logarithm term in the exercise boundary estimate given by equation (18), this approach leads to the approximation

times

$$\begin{aligned}\tau^n &= \left(\frac{n}{2m-4}\right)^2 T, \quad n = 1, 2, 3, 4, \\ \tau^n &= \left(\frac{n-2}{m-2}\right)^2 T, \quad n = 5, \dots, m\end{aligned}\quad (19)$$

where the lengths of the four implicit Euler steps are further reduced by the factor $\frac{1}{2}$.

Another approach is to use adaptive time step selector that uses already computed time steps to predict a good length for the next time step. In [17], the time step $\Delta\tau^{n+1}$ was suggested to be selected according to

$$\Delta\tau^{n+1} = C \left(\min_i \left[\frac{\max\{|V_i^{n-1}|, |V_i^n|, D\}}{|V_i^n - V_i^{n-1}|} \right] \right) \Delta\tau^n \quad (20)$$

where C is a target relative change over the time step and D is a scale of value of the option (for example, we could have $D = 1$ if the value of the option is of the order of one monetary unit).

In the following sections, we describe common ways to solve the discrete LCPs (16), or approximate them and then solve resulting problems.

Solution Methods for LCPs

In the following, we consider the solution of the model LCP

$$\begin{aligned}\mathbf{BV} &\geq \mathbf{b}, \quad \mathbf{V} \geq \mathbf{g}, \\ (\mathbf{BV} - \mathbf{b})^T (\mathbf{V} - \mathbf{g}) &= 0\end{aligned}\quad (21)$$

arising at each time step.

A commonly used iterative method for LCPs is the projected successive over relaxation (PSOR) method [11, 12, 22]. It reduces to the projected Gauss–Seidel method when the relaxation parameter denoted by ω is 1. The basic idea of the projected Gauss–Seidel method is to solve components V_i successively, using the i th row of the system $\mathbf{BV} = \mathbf{b}$ and then project V_i to be g_i if it is below it. The PSOR method over corrects each component by the factor ω before the projection. The following pseudocode performs one iteration with the PSOR method for the LCP (21). The vector $\mathbf{V}$ contains the initial guess for the solution,

which is usually the value from the previous time step or the vector $\mathbf{V}$ returned by the previous iteration.

Algorithm PSOR($\mathbf{B}$, $\mathbf{V}$, $\mathbf{b}$, $\mathbf{g}$)

For $i = 1, p + 1$

$$r_i = b_i - \sum_j B_{i,j} V_j$$

$$V_i = \max\{V_i + \omega r_i / B_{i,i}, g_i\}$$

End For

The PSOR method is guaranteed to converge when the matrix $\mathbf{B}$ is strictly diagonal dominant with positive diagonal entries ($\sum_{j \neq i} |B_{i,j}| < B_{i,i}$ for all i) and the relaxation parameter ω has value in $(0, 1]$. For more precise and general convergence results, we refer to [11, 22]. The convergence rate reduces as the number of grid points grows. On the other hand, smaller time steps make the matrix $\mathbf{B}$ more diagonally dominant and convergence improves. Overall, the convergence slows down somewhat when both space and time steps are reduced at the same rate. The relaxation parameter ω has a big influence on the convergence. Usually, on coarse grids, the optimal value of ω is closer to 1 and on finer grids, it approaches 2. There is no formula for the optimal value; however, it is possible to form a reasonable estimate for it. Even then, quite often, ω is chosen by hand tuning it for a given grid.

A grid-independent convergence rate can be obtained using multigrid methods (see **Multigrid Methods**). For LCPs, suitable projected multigrid methods have been considered in [7, 33, 34], for example. The basic idea is to use a sequence of coarser grids to get better corrections with a small computational effort. These methods are more involved and thus it takes more effort to implement them. Nevertheless, for higher dimensional models, it may be necessary to use these methods to keep computation times feasible.

The LCP (21) can be equivalently formulated as a linear programming (LP) problem [14] when $\mathbf{B}$ is a Z-matrix (offdiagonal entries are nonpositive, that is, $B_{i,j} \leq 0$ for all $i \neq j$) and it is strictly diagonal dominant with positive diagonal entries. The solution $\mathbf{V}$ of equation (21) is given by the LP

$$\min_{\mathbf{V} \in F} \mathbf{c}^T \mathbf{V}, \quad F = \{\mathbf{V} \in \mathbb{R}^{p+1} : \mathbf{V} \geq \mathbf{g}, \mathbf{BV} \geq \mathbf{b}\} \quad (22)$$

for any fixed $\mathbf{c} > 0$ in $\mathbb{R}^{p+1}$. The LP problems can be solved using the (direct) simplex method or an

(iterative) interior point method. For discussion on this approach see [14].

When the matrix $\mathbf{B}$ is symmetric ($\mathbf{B}^T = \mathbf{B}$) and strictly diagonal dominant with positive diagonal entries, the LCP (21) can be equivalently formulated as a quadratic programming (QP) problem, which reads

$$\min_{\mathbf{V} \geq \mathbf{g}} \frac{1}{2} \mathbf{V}^T \mathbf{B} \mathbf{V} - \mathbf{b}^T \mathbf{V} \quad (23)$$

There exists a host of methods to solve such QP problems. Our example of discretization above does not lead to a symmetric matrix $\mathbf{B}$. However, it is often possible to symmetrize the problem by performing a coordinate transformation for the underlying operator or by applying a diagonal similarity transform to LCP. Particularly, these two approaches are applicable for the Black–Scholes operator. For example, we could employ a common transformation to the heat equation to symmetrize $\mathbf{B}$.

The Brennan–Schwartz algorithm [8] is a direct method to solve the LCP (21) with a tridiagonal matrix $\mathbf{B}$. In [27], it has been shown that the algorithm gives the solution of the LCP when $\mathbf{B}$ is a strictly diagonal dominant matrix with positive diagonal entries and there exists k such that $V_i = g_i$ for all $i \leq k$ and $V_i > g_i$ for all $i > k$. The latter condition means that the early exercise region is $(0, S_k)$. This is the case with a put option. A similar direct method has been considered in [16].

Effectively, the algorithm forms an $\mathbf{UL}$ decomposition for $\mathbf{B}$ such that $\mathbf{L}$ is a bidiagonal lower-triangular matrix and $\mathbf{U}$ is a bidiagonal upper-triangular matrix with ones on the diagonal. Then it performs the steps of solving the system $\mathbf{ULV} = \mathbf{b}$ with the modification that in the backsubstitution step employing $\mathbf{L}$, the components of $\mathbf{V}$ are projected to be feasible ($V_i = \max\{V_i, g_i\}$) as soon as they are computed. The following pseudocode solves the LCP (21) using the Brennan–Schwartz algorithm.

Algorithm BS($\mathbf{B}, \mathbf{V}, \mathbf{b}, \mathbf{g}$)

$w_{p+1} = B_{p+1,p+1}$

For $i = p, 1, -1$

$w_i = B_{i,i} - B_{i,i+1}B_{i+1,i}/w_{i+1}$

$V_i = V_i - B_{i,i+1}V_{i+1}/w_{i+1}$

End For

$V_1 = \max\{V_1/w_1, g_1\}$

For $i = 2, p + 1$

$V_i = \max\{(V_i - B_{i,i-1}V_{i-1})/w_i, g_i\}$

End For

When the continuous early exercise region is $(S_k, S_{\max})$ for some k , there are two possible ways to use a Brennan–Schwartz-type algorithm. This is the case with a call option. The first one is to use the above code with the reverse index numbering for the vectors and matrices. Alternatively, the algorithm can be changed to use an $\mathbf{LU}$ decomposition instead of the $\mathbf{UL}$ decomposition.

The Brennan–Schwartz algorithm is usually the fastest way to solve LCPs when it is applicable. Direct methods for LCP with tridiagonal matrices can also be developed for more general exercise regions [13]. These methods are more complicated to implement and they are computationally more expensive.

The LCP (21) can be equivalently formulated using a Lagrange multiplier λ as

$$\begin{aligned} \mathbf{B}\mathbf{V} - \lambda &= \mathbf{b}, \\ \lambda &\geq \mathbf{0}, \quad \mathbf{V} \geq \mathbf{g} \\ \lambda^T (\mathbf{V} - \mathbf{g}) &= 0 \end{aligned} \quad (24)$$

or, alternatively, [21] as

$$\begin{aligned} \mathbf{B}\mathbf{V} - \lambda &= \mathbf{b}, \\ \lambda - \max\{\lambda + \eta(\mathbf{g} - \mathbf{V}), \mathbf{0}\} &= \mathbf{0} \end{aligned} \quad (25)$$

for any $\eta > 0$. For these formulations, several active set solution strategies have been developed; see [1, 21, 42] and references therein.

Penalty Methods

The penalty methods enforce the early exercise constraint by penalizing its violations. For the model LCP (21) a typical power penalty approximation is given by

$$\mathbf{B}\mathbf{V} = \mathbf{b} + \frac{1}{\epsilon} [\max\{\mathbf{g} - \mathbf{V}, \mathbf{0}\}]^k \quad (26)$$

where the maximum and the power function are applied componentwise, and $\epsilon > 0$ is a small penalty parameter. The linear penalty $k = 1$ and the quadratic penalty $k = 2$ are the most common ones. For example, the linear penalty was considered for the Black–Scholes model in [17], and both linear and quadratic penalties were considered for the Heston stochastic volatility model in [45]. The penalty

parameter ϵ controls the quality of the approximation. A small value for ϵ enforces the constraint more strictly. The following pseudocode performs one (semismooth) Newton iteration for the system of nonlinear equations (26). The vector $\mathbf{V}$ contains the initial guess for the solution or the vector $\mathbf{V}$ returned by the previous iteration.

Algorithm Penalty($\mathbf{B}$, $\mathbf{V}$, $\mathbf{b}$, $\mathbf{g}$)

$\mathbf{J} = \mathbf{B}$

For $i = 1, p + 1$

$r_i = b_i - \sum_j B_{i,j} V_j$

If $V_i < g_i$ Then

$r_i = r_i + \frac{1}{\epsilon}(g_i - V_i)^k$

$J_{i,i} = J_{i,i} + \frac{1}{\epsilon}k(g_i - V_i)^{k-1}$

End If

End For

Solve $\mathbf{Jd} = \mathbf{r}$

$\mathbf{V} = \mathbf{V} + \mathbf{d}$

For our example of discretization, the Jacobian matrix $\mathbf{J}$ is tridiagonal and the system $\mathbf{Jd} = \mathbf{r}$ can be solved efficiently using an **LU** decomposition (or the **UL** decomposition used by Algorithm BS), for example. With higher dimensional models, it is probably necessary to solve these problems iteratively to obtain reasonable computational times. Under the Heston model, the BiCGSTAB method with an incomplete **LU** preconditioner was used in [45] and a multigrid method was used in [25].

The penalty approximation (26) leads to $\mathbf{V}$ that violates the early exercise constraint $V \geq g$ by a small amount in the early exercise region. The size of the violation depends on the penalty parameter ϵ and the violation vanishes when ϵ approaches zero. The use of very small values for ϵ can lead to numerical difficulties. A modified penalty approximation in [26],

$$\mathbf{BV} = \mathbf{b} + \max\{\bar{\lambda} + (\mathbf{g} - \mathbf{V})/\epsilon, \mathbf{0}\} \quad (27)$$

with $\bar{\lambda} = \max\{\mathbf{B}\mathbf{g} - \mathbf{b}, \mathbf{0}\}$ can be shown to lead always to $\mathbf{V}$ satisfying the constraint $\mathbf{V} \geq \mathbf{g}$. For example, the above (semismooth) Newton method can be modified to solve the system (27). Another penalty function enforcing the constraint strictly was considered in [32].

Other Approximations for LCP

The simplest way to enforce the early exercise constraint $V \geq g$ is to treat it explicitly. In this so-called explicit payoff method, one first solves the system of linear equations

$$\mathbf{B}\tilde{\mathbf{V}} = \mathbf{b} \quad (28)$$

and then the intermediate solution $\tilde{\mathbf{V}}$ is projected to be feasible by setting

$$\mathbf{V} = \max\{\tilde{\mathbf{V}}, \mathbf{g}\} \quad (29)$$

Typically, this approach leads the order of accuracy to be only $\Delta\tau$. With the explicit Euler method, the LCP (21) reduces to the steps in equations (28) and (29) with $\mathbf{B}$ being the $p + 1 \times p + 1$ identity matrix. Owing to the stability restriction of the explicit Euler method, the time step $\Delta\tau$ has to be of order $(\Delta S)^2$. Thus with the explicit Euler method, the order of accuracy usually is $\Delta\tau \sim (\Delta S)^2$.

Another approach to approximate the LCP with a system of linear equations and a correction enforcing the constraint is to employ an operator splitting method [23, 25]. This method is based on the Lagrange multiplier formulation (24). The basic idea is to use the Lagrange multiplier λ from the previous time step to form a linear system, and then update the solution and Lagrange multiplier to satisfy the constraints pointwise. In the first step, the system of linear equations reads

$$\mathbf{B}\mathbf{V}^{n+1} = \mathbf{b}^n + \lambda^n \quad (30)$$

and the correction in the second step is

$$\begin{aligned} \mathbf{V}^{n+1} - \tilde{\mathbf{V}}^{n+1} &= \lambda^{n+1} - \lambda^n, \\ \lambda^{n+1} &\geq \mathbf{0}, \quad \mathbf{V}^{n+1} \geq \mathbf{g}, \\ (\lambda^{n+1})^T (\mathbf{V}^{n+1} - \mathbf{g}) &= 0 \end{aligned} \quad (31)$$

For higher dimensional models like the Heston model or options on several assets, the LCPs are much more challenging to solve than those with one-dimensional models. One approach is to approximate the resulting problems with a sequence of problems corresponding to a one-dimensional model as in alternating direction implicit (ADI) schemes (see **Alternating Direction Implicit (ADI) Method**). With early exercise possibility, this approach usually leads to solving LCPs with Black–Scholes-type

one-dimensional models. When the solutions have suitable form, these LCPs can be solved efficiently using the Brennan–Schwartz algorithm. Such methods have been considered for American options in [24, 25, 39].

Example

As an example, we consider pricing an American put option with the parameters: $S = K = 100$, $r = 0.1$, $T = 0.25$ years, and $\sigma = 0.2$. The same option was also priced in [17]. For discretization, we truncate the semi-infinite interval at $S_{\max} = 400$, and we construct nonuniform time–space grids that are refined near the expiry date $\tau = 0$ and the strike price K . The space grid is constructed using the formula (10) with $\xi = 0.4$. We choose the time steps explicitly for the Rannacher time stepping according to the formulas (19).

We compute the option price using the Brennan–Schwartz algorithm, the linear penalty method

with $\epsilon = (\Delta\tau^m)^2$, and the PSOR method. For a comparison, we also use the explicit payoff method. Table 1 reports the results. The errors with the explicit and implicit treatments of the constraint are given for a sequence of grids. All implicit methods give essentially the same accuracy. The total iteration counts are reported for the penalty method and the PSOR method. We have optimized the relaxation parameter ω for each grid. CPU times show that it is possible to price hundreds of options with a good precision in one second under the Black–Scholes model.

We have plotted a very coarse grid and an approximation of the early exercise boundary $S_f(\tau)$ in Figure 1. It shows a typical jagged boundary obtained using the LCP formulation. Though the approximation of $S_f(\tau)$ can be only ΔS Accurate, the order of accuracy for the price appears to be $(\Delta S)^2$ and $(\Delta\tau)^2$ with the implicit treatment of the early exercise constraint. This behavior is studied in [17], which concludes that with suitably chosen time steps a quadratic convergence rate is attainable.

Table 1 Numerical results with different methods for an American put option. The parameters are $S = K = 100$, $r = 0.1$, $T = 0.25$ years, and $\sigma = 0.2$. The reference price is 3.0701067. The number of time steps is m and the number of space grid points is $p + 1$. Ratio is the ratio of successive errors. Iter is the total number of iterations. Time is the CPU time in seconds on a 3.2-GHz Pentium 4 PC

Other Models and Options

Often it is desirable to add jumps to the model of the underlying asset (*see Exponential Lévy Models; Variance-gamma Model; Jump-diffusion Models*). Models with jumps lead to a partial integro differential equation (PIDE) for the price of European options (*see Partial Integro-differential Equations (PIDEs)*) and an LCP with same operator can be derived for the price of American options. The discretization of these problems can lead to nonsparse matrices and the efficient solution of the resulting equations is more challenging. Finite-difference-based methods for pricing American options under jump models have been considered in [3, 10, 19, 31, 37, 38, 40, 41].

Stochastic volatility models like the Heston model (*see Heston Model*) lead to LCPs with partial differential operators with two space dimensions. These can be discretized with finite differences in a fairly straightforward manner. Owing to the correlation between the asset value and its volatility the resulting partial differential operator has a second-order cross derivative that can lead to numerical issues. No direct method like the Brennan–Schwartz algorithm is available for these problems. Furthermore, because of two space dimensions, the systems resulting from the discretization are much larger. Finite difference methods for options under stochastic volatility models have been considered in [9, 24, 25, 33, 45]. Similar discretizations and solution methods can be used when interest rates or dividends are modeled as stochastic.

Asian options lead to partial differential operator with an additional dimension for the average of the underlying asset. Similar finite difference methods can be used for American-style Asian options as for the above-mentioned options. The partial differential operator has only the first derivative present in the direction of the new dimension, and this makes discretizing the operator more involved. American-style Asian options have been priced numerically in [20, 44], for example.

The payoff of a multiasset option depends on several underlying assets. Each underlying asset adds one dimension to the model, leading to high dimensional problems. With a few underlying assets, the standard finite difference methods can still be used. For example, American basket options on two stocks

were priced in [39]. With the standard finite differences, the computational cost grows to be high with several underlying assets; see [34]. A special sparse grid technique can be used to reduce the size of the discrete problem (*see Sparse Grids*). This technique relies on the regularity properties of the price function V . The early exercise possibility reduces the regularity of V and thus the straightforward application of the sparse grid technique for American options might lead to reduced accuracy for the price. Nevertheless, in [35] it was observed that the accuracy for American options was still good.

Related Topics

The grids and time steps are chosen usually on the basis of the behavior of discretization error in numerical experiments. Error estimation gives a more systematic way to choose (nearly) optimal discretizations where the number of grid points and time steps are minimized to reach a desired accuracy. In [30] finite difference discretizations were constructed on the basis of an error estimate for European multiasset options. For finite elements, error estimation has been considered in [1] for European options and in [2] for American options.

Partial Differential Equations

In their seminal 1973 article [3], Black and Scholes derived a partial differential equation (PDE) for the call option price by considering a portfolio containing the option and the underlying asset and using absence of arbitrage arguments. Later, in the 1980s, Harrison, Kreps, and Pliska [10, 11] pioneered the use of stochastic calculus in mathematical finance and introduced martingale methods for option pricing in continuous time. This article is an overview of various contexts in finance where PDEs arise, in particular, for option pricing, portfolio optimization, and calibration. The PDE approach of Black–Scholes and the martingale method are related through the Feynman–Kac formula (*see Markov Processes*).

First, we recall the basic derivation of the Black–Scholes PDE and then present the PDEs for various exotic options and, in particular, American options. A paragraph is devoted to Hamilton–Jacobi–Bellman (HJB) equations, which are nonlinear PDEs arising from stochastic control and portfolio optimization. Finally, we discuss some PDEs associated with calibration problems. Computational aspects are treated in companion entries (*see Finite Difference Methods for Barrier Options; Finite Difference Methods for Early Exercise Options; Finite Element Methods*).

The Black–Scholes PDE

We recall the original arguments in the derivation of the Black–Scholes PDE for option pricing [3, 14]. In the Black–Scholes model, we consider a market with a risk-free bond of constant interest rate r , and a stock with a price process S evolving according to a geometric Brownian motion:

$$dS_t = bS_t dt + \sigma S_t dW_t \quad (1)$$

where the drift rate b and the volatility $\sigma > 0$ are assumed to be constant and W is a standard Brownian motion. We now consider a European call option, characterized by its payoff $(S_T - K)_+$ at the maturity T , and with strike K . We denote by V the value of the call option: $V = V(t, S_t)$ is a function of the spot

price of the underlying asset S_t at time t . At the expiry date of the option, we have $V(T, S_T) = (S_T - K)_+$, and for $t < T$, by assuming that the function V is smooth, we get by Itô's formula

$$\begin{aligned} dV &= \frac{\partial V}{\partial t} dt + \frac{\partial V}{\partial S} dS + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} dt \\ &= \left(\frac{\partial V}{\partial t} + bS \frac{\partial V}{\partial S} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} \right) dt \\ &\quad + \sigma S \frac{\partial V}{\partial S} dW \end{aligned} \quad (2)$$

Now consider a portfolio consisting of the option and a short position Δ in the asset: the portfolio value is then equal to $\Pi = V - \Delta S$, and its self-financed dynamics is given by

$$\begin{aligned} d\Pi &= dV - \Delta dS \\ &= \left(\frac{\partial V}{\partial t} + bS \frac{\partial V}{\partial S} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} - \Delta bS \right) dt \\ &\quad + \sigma S \left(\frac{\partial V}{\partial S} - \Delta \right) dW \end{aligned} \quad (3)$$

The random component in the evolution of the portfolio Π may be eliminated by choosing

$$\Delta = \frac{\partial V}{\partial S} \quad (4)$$

This results in a portfolio with deterministic increment:

$$d\Pi = \left(\frac{\partial V}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} \right) dt \quad (5)$$

Now, by arbitrage-free arguments, the rate of return of the riskless portfolio Π must be equal to the interest rate r of the bond, that is,

$$\frac{\partial V}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} = r\Pi \quad (6)$$

and recalling that $\Pi = V - (\partial V / \partial S)S$, this leads to the *Black–Scholes partial differential equation*:

$$rV - \frac{\partial V}{\partial t} - rS \frac{\partial V}{\partial S} - \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} = 0 \quad (7)$$

This PDE together with the terminal condition $V(T, S) = (S - K)_+$ is a linear parabolic Cauchy

problem, whose solution is analytically known, and this is the celebrated Black–Scholes formula. Moreover, this formula can also be computed as an expectation:

$$V(t, S) = \mathbb{E}^{\mathbb{Q}} \left[e^{-r(T-t)} (S_T - K)_+ \middle| S_t = S \right] \quad (8)$$

where $\mathbb{E}^{\mathbb{Q}}$ denotes the expectation under which the drift rate b in equation (1) is replaced by the interest rate r . $\mathbb{Q}$ is called *risk-neutral probability*.

Linear PDEs for European Options

The derivation presented in the previous paragraph is prototypical. Besides the absence of arbitrage argument, the key points for the derivation of the PDE satisfied by the option price is the Markov property of the stochastic processes describing the market factors. The relation with risk-neutral probability is achieved through the Feynman–Kac formula (see **Markov Processes**). In its basic (multidimensional) version, the Feynman–Kac representation is formulated as follows: let us consider the stochastic differential equation on $\mathbb{R}^n$

$$dX_s = b(X_s) ds + \sigma(X_s) dW_s \quad (9)$$

where b and σ are measurable functions valued, respectively, on $\mathbb{R}^n$ and $\mathbb{R}^{n \times d}$, and W is a n -dimensional Brownian motion. Consider the Cauchy problem

$$rv - \frac{\partial v}{\partial t} - b(x) D_x v - \frac{1}{2} \text{tr}(\sigma \sigma'(t, x) D_x^2 v) = 0 \quad \text{on } [0, T] \times \mathbb{R}^n \quad (10)$$

$$v(T, x) = g(x) \quad \text{on } \mathbb{R}^n \quad (11)$$

Here, $D_x v$ is the gradient, $D_x^2 v$ is the Hessian matrix of v , with respect to the x variable, σ' is the transpose of σ , and tr denotes the trace of a matrix. Then, the solution to this Cauchy problem may be represented as

$$v(t, x) = \mathbb{E} \left[e^{-\int_t^T r(u, X_u^{t,x}) ds} g(X_T^{t,x}) \right] \quad (12)$$

where $X_s^{t,x}$ is the solution to equation (9) starting from x at $s = t$. The Feynman–Kac formula is a

probabilistic interpretation of the integral representation of the solution using the *Green's function*, which is in this case the density of the underlying asset. The Black–Scholes price is a particular case with r constant, $b(t, x) = rx$, $\sigma(t, x) = \sigma x$, and $g(x) = (x - K)_+$. More generally, the interest rate r and the volatility σ may depend on time and spot price.

In the general case, we do not have analytical expression for v , and we have to resort to numerical methods for option pricing. The probabilistic representation (12) is the basis for Monte Carlo methods in option pricing while deterministic numerical methods (finite differences and finite elements) are based on the PDE (11).

Barrier Options

The payoff of these options depends on the fact that the underlying asset crossed or not, some given barriers during the time interval $[0, T]$ (see **Barrier Options**). For example, a down-and-out call option has a payoff $(S_T - K)_+ 1_{\inf_{t \in [0, T]} S_t > L}$. Its price $v(t, x)$ at time t for a spot price $S_t = x$, satisfies the boundary value problem:

$$\begin{aligned} rv - \frac{\partial v}{\partial t} - rx \frac{\partial v}{\partial x} - \frac{1}{2} \sigma^2 x^2 \frac{\partial^2 v}{\partial x^2} &= 0, \\ (t, x) &\in [0, T] \times (L, \infty) \\ v(t, L) &= 0 \\ v(T, x) &= (x - K)_+ \end{aligned} \quad (13)$$

Lookback Options

The payoff of these options involve the maximum or minimum of the underlying asset (see **Lookback Options**). For instance, the floating strike lookback put option pays at maturity $M_T - S_T$ where $M_t = \sup_{0 \leq t \leq T} S_t$. The pair (S_t, M_t) is a Markov process, and the price at time t of this lookback option is equal to $v(t, S_t, M_t)$ where the function v is defined for $t \in [0, T]$, $(S, M) \in \{(S, M) \in \mathbb{R}_+^2 : 0 \leq S \leq M\}$, and satisfies the Neumann problem:

$$\begin{aligned} rv - \frac{\partial v}{\partial t} - rS \frac{\partial v}{\partial S} - \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 v}{\partial S^2} &= 0 \\ \frac{\partial v}{\partial M}(t, M, M) &= 0 \\ v(T, S, M) &= M - S \end{aligned} \quad (14)$$

Asian Options

These options involve the average of the risky asset (see **Asian Options**). For example, the payoff of an Asian call option is $(A_T - K)_+$ where $A_t = \frac{1}{t} \int_0^t S_u du$. The pair (S_t, A_t) is a Markov process, and the price at time t of this Asian option is equal to $v(t, S_t, A_t)$ where the function v is defined for $t \in [0, T]$, $(S, A) \in \mathbb{R}_+^2$, and satisfies the Cauchy problem (see, e.g., [16]):

$$\begin{aligned} rv - \frac{\partial v}{\partial t} - rS \frac{\partial v}{\partial S} - \frac{1}{t}(S - A) \frac{\partial v}{\partial A} \\ - \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 v}{\partial S^2} = 0 \\ v(T, S, A) = (A - K)_+ \end{aligned} \quad (15)$$

American Options and Free Boundary Problems

With respect to European options presented so far, American options give the holder the right to exercise his/her right at any time up to maturity (see **American Options**). For an American put option of payoff $(K - S_t)_+$, $0 \leq t \leq T$, its price at time t and for a spot stock price $S_t = x$ is given by

$$v(t, x) = \sup_{\tau \in \mathcal{T}_{t,T}} \mathbb{E}^{\mathbb{Q}} \left[e^{-r(\tau-t)} (K - S_\tau)_+ \mid S_t = x \right] \quad (16)$$

where $\mathcal{T}_{t,T}$ denotes the set of stopping times valued in $[t, T]$. In terms of PDE, and within the Black–Scholes framework, this leads *via* the dynamic programming principle (see [7]) to a variational inequality:

$$\begin{aligned} \min \left[rv - \frac{\partial v}{\partial t} - rx \frac{\partial v}{\partial x} - \frac{1}{2} \sigma^2 x^2 \frac{\partial^2 v}{\partial x^2}, \right. \\ \left. v(t, x) - (K - x)_+ \right] = 0 \end{aligned} \quad (17)$$

together with the terminal condition: $v(T, x) = (K - x)_+$. This variational inequality maybe written equivalently as

$$rv - \frac{\partial v}{\partial t} - rx \frac{\partial v}{\partial x} - \frac{1}{2} \sigma^2 x^2 \frac{\partial^2 v}{\partial x^2} \geq 0 \quad (18)$$

which corresponds to the supermartingale property of the discounted price process $e^{-rt} v(t, S_t)$

$$v(t, x) \geq (K - x)_+ \quad (19)$$

which results directly from the fact that by exercising his/her right immediately, one receives the option payoff, and

$$\begin{aligned} rv - \frac{\partial v}{\partial t} - rx \frac{\partial v}{\partial x} - \frac{1}{2} \sigma^2 x^2 \frac{\partial^2 v}{\partial x^2} = 0, \\ \text{for } (t, x) \in \mathcal{C} = \{v(t, x) > (K - x)_+\} \end{aligned} \quad (20)$$

which means that as long as we are in the continuation region $\mathcal{C}$, that is, the value of the American option price is strictly greater than its payoff, the holder does not exercise his/her right early. The formulation (18–20) is also called a *free-boundary problem*, and in the case of the American put, there is an increasing function $x^*(t)$, the free-boundary or critical price, which is smaller than K , and such that $\mathcal{C} = \{(t, x) : x > x^*(t)\}$. This free boundary is an unknown part of the PDE and separates the continuation region from the exercise region where the option is exercised, that is, $v(t, x) = (K - x)_+$. The above conditions do not determine the unknown free boundary $x^*(t)$. An additional condition is required, which is the continuous differentiability of the option price across the boundary $x^*(t)$:

$$v(t, x^*(t)) = K - x^*(t), \quad \frac{\partial v}{\partial x}(t, x^*(t)) = -1 \quad (21)$$

This general property is known in optimal stopping theory as the *smooth fit principle*. However, the American option price v is not C^2 , and the nonlinear PDE (17) should be interpreted in a weak sense by means of distributions (see [2] or [12]), or in the viscosity sense (see [5]). Notice that the main difference between PDE for American options and European options is the nonlinearity of the equation

in the former case. This makes the theory and the numerical implementation more difficult than for the European options.

Stochastic Control and Bellman Equations

Stochastic control problems arise in continuous-time portfolio management. This may be formulated in a roughly general framework as follows: we consider a controlled diffusion process in the form

$$dX_s = b(X_s, \alpha_s) ds + \sigma(X_s, \alpha_s) dW_s, \quad \text{in } \mathbb{R}^n \quad (22)$$

where W is a d -dimensional Brownian motion on some filtered probability space $(\Omega, \mathcal{F}, \mathbb{F} = (\mathcal{F}_t), \mathbb{P})$, and $\alpha = (\alpha_t)$ is an adapted process valued in a Borel set $A \subset \mathbb{R}^m$, the so-called control process, which influences the dynamics of the state process X through the drift coefficient b and the diffusion coefficient σ . A stochastic control problem (in a finite horizon) consists of maximizing over the control processes a functional objective in the form

$$\mathbb{E} \left[\int_0^T f(X_t, \alpha_t) dt + g(X_T) \right] \quad (23)$$

where f and g are real-valued measurable functions. The method used to solve this problem, and initiated by Richard Bellman in the 1950s, is to introduce the value function $v(t, x)$, that is the maximum of the objective when starting from state x at time t , and to apply the dynamic programming principle (DPP). The DPP formally states that if a control is optimal from time t until T , then it is also optimal from time $t+h$ until T for any $t+h > t$. Mathematically, the DPP relates the value functions at two different dates t and $t+h$, and by studying the behavior of the value functions when h tends to zero, one obtains a PDE satisfied by v , the so-called Hamilton–Jacobi–Bellman equation:

$$\begin{aligned} -\frac{\partial v}{\partial t} - \sup_{a \in A} \left[b(x, a) D_x v + \frac{1}{2} \text{tr}(\sigma \sigma'(x, a) D_x^2 v) \right. \\ \left. + f(x, a) \right] = 0, \quad \text{on } [0, T) \times \mathbb{R}^n \end{aligned} \quad (24)$$

together with the terminal condition $v(T, x) = g(x)$. Here, and in the sequel, the prime symbol “’” is

for the transpose. The most famous application of Bellman equation in finance is the portfolio selection of Merton [13]. In this problem, an investor can choose to invest at any time between a riskless bond of interest rate r or a stock with Black–Scholes dynamics of rate of return β and volatility γ . By denoting α_t , the proportion of wealth X_t invested in the stock, this corresponds to a controlled wealth process X in equation (22) with $b(x, a) = ax(\beta - r) + rx$ and $\sigma(x, a) = ax\gamma$. The objective of the investor is to maximize his/her expected utility from terminal wealth, which corresponds to a functional objective of the form (23) with $f = 0$, and g an increasing, concave function. A usual choice of utility function is $g(x) = x^p$, with $0 < p < 1$, in which case, there is an explicit solution to the corresponding HJB equation (24). Moreover, the optimal control attaining the argument maximum in equation (24) is a constant equal to $b - r/(1 - p)\gamma^2$. In the general case, there is no explicit solution to the HJB equation. Moreover, the solution is not smooth C^2 and one proves actually that the value function is characterized as the unique weak solution to the HJB equation in the viscosity sense. We refer to the books [9] and [15] for an overview of stochastic control and viscosity solutions in finance.

Related nonlinear PDEs also arise in the uncertain volatility model, where one computes the cost of (super)hedging an option when the volatility is only known to be inside a band (*see Uncertain Volatility Model*).

Diffusion Models and the Dupire PDE

It is well known that the constant coefficient Black–Scholes model is not consistent with empirical observations in the markets. Indeed, given a call option with quoted price C_M on the market, one may associate the so-called *implied volatility*, that is, the volatility σ_{imp} such that the price given by the Black–Scholes formula coincides with C_M . If the Black–Scholes model was sharp, then the implied volatility would not depend on the strike and maturity of the option. However, it is often observed that the implied volatility is far from constant and is actually a convex function of the strike price, a phenomenon known as the volatility *smile*. Several extensions of the Black–Scholes model have been proposed in the literature. We focus here on local volatility models

(see **Local Volatility Model**) where the volatility is a function $\sigma(t, S_t)$ of time and the spot price. In this model, the price $C(t, S_t)$ of a call option of strike K and maturity T satisfies the PDE:

$$rC - \frac{\partial C}{\partial t} - rS \frac{\partial C}{\partial S} - \frac{1}{2} \sigma^2(t, S) S^2 \frac{\partial^2 C}{\partial S^2} = 0, \quad (t, S) \in [0, T) \times (0, \infty)$$

$$C(T, S) = (S - K)_+ \quad (25)$$

The calibration problem in this local volatility model consists of finding a function $\sigma(t, S)$, which reproduces the observed call option prices on the market for all strikes and maturities. In other words, we want to determine $\sigma(t, S)$ in such a way that the prices computed, for example, with the above PDE coincide with the observed prices. The solution to this problem has been provided by Dupire [6]. By fixing the date t and the spot price S , and by denoting $C(t, S, T, K)$ the call option price with strike K and maturity $T \geq t$, Dupire showed that it satisfies the forward (with initial condition) parabolic PDE:

$$\frac{\partial C}{\partial T} + rK \frac{\partial C}{\partial K} - \frac{1}{2} \sigma^2(T, K) K^2 \frac{\partial^2 C}{\partial K^2} = 0, \quad (T, K) \in [t, \infty) \times \mathbb{R}_+ \quad (26)$$

$$C(t, S, t, K) = (S - K)_+ \quad (27)$$

This PDE may be obtained by at least two methods. The first one is based on Itô-Tanaka formula on the risk-neutral expectation representation of the call option price, while the second one is derived by PDE arguments based on the Fokker-Planck equation for the diffusion process (S_t) (see, e.g., [1]). The PDE (26) can be used, in principle, to compute the local volatility function from the call options prices observed at various strikes K and maturities T :

$$\sigma^2(T, K) = 2 \frac{\frac{\partial C}{\partial T} + rK \frac{\partial C}{\partial K}}{K^2 \frac{\partial^2 C}{\partial K^2}} \quad (28)$$

This is known as *Dupire's formula* (see **Dupire Equation**). Notice that equation (28) cannot be used directly since only a finite number of options are quoted on the market. We refer to [1] or [4] for a more advanced discussion of such PDEs.

Semilinear PDEs

We have presented so far three types of PDE in finance: linear PDEs arising from European options and Feynman-Kac formulas, variational inequalities arising from American options and optimal stopping, and nonlinear HJB arising from stochastic control problems. *Semilinear* PDEs the form

$$-\frac{\partial v}{\partial t} - b(x) D_x v - \frac{1}{2} \text{tr}(\sigma \sigma'(x) D_x^2 v) - f(x, v, D_x v' \sigma) = 0, \quad (t, x) \in [0, T) \times \mathbb{R}^n$$

$$v(T, x) = g(x), \quad x \in \mathbb{R}^n \quad (29)$$

Such PDEs arise, for instance, in finance in option pricing with large investor models or in indifference pricing (see **Expected Utility Maximization**). Backward stochastic differential equations [8] provide probabilistic approaches for solving such PDEs arising in finance (see **Backward Stochastic Differential Equations**).

HUYÊN PHAM

Alternating Direction Implicit (ADI) Method

In the Black–Scholes model, option values are characterized as solutions of certain partial differential equations (PDEs) for European options or partial differential inequalities for American options (*see Partial Differential Equations*). In general, these option values have to be evaluated numerically, for example using the finite difference method (*see Finite Difference Methods for Barrier Options; Finite Difference Methods for Early Exercise Options*). Unfortunately, when considering the pricing of options depending on several assets, the finite difference method suffers from the curse of dimensionality. The alternating direction implicit (ADI) algorithm of Peaceman–Rachford [8], first proposed for the numerical solution of heat equation in two space dimensions, is to reduce the numerical solution of higher dimensional PDEs to a sequence of steps involving only one-dimensional finite difference operators, involving a simple tridiagonal matrix. The resulting algorithms are memory efficient and easy to parallelize. We illustrate this method in a Black–Scholes model with two risky assets.

Black–Scholes Equation for Multiasset Options

Consider a filtered probability space $(\Omega, \mathcal{F}, \mathcal{F}_t, IP)$ and let $(W_t)_{t \geq 0}$ be a standard bidimensional $\mathcal{F}_t$ Brownian motion on it. We consider options written on two dividend-paying stocks whose price S_t^1, S_t^2 satisfies the stochastic differential equation:

$$\frac{dS_t^i}{S_t^i} = (r - \delta_i) dt + \sum_{j=1}^2 \sigma_{ij} dW_t^j, \quad i = 1, 2 \quad (1)$$

where r is the interest rate, δ_i is the dividend rate of the stock i , and the matrix $\Sigma = (\sigma_{ij})_{1 \leq i, j \leq n}$ is assumed to be invertible, which ensures that the market is complete. In this setting, the value at time t of an European option with maturity T and payoff function ψ is given by $U(t, S_t)$ where

$$U(t, x) = \mathbb{E} \left(e^{-r(T-t)} \psi(S_T^{t,x}) \right) \quad (2)$$

while the value at time t of an American option with maturity T and payoff function ψ is given by $U_{am}(t, S_t)$ where

$$U_{am}(t, x) = \sup_{\tau \in \mathcal{T}_{0,T-t}} \mathbb{E} \left(e^{-r\tau} \psi(S_\tau^x) \right) \quad (3)$$

where $\mathcal{T}_{0,T-t}$ is the set of all stopping times with values in $[0, T - t]$.

To see this, we shall use the following notation:

- μ is the vector with components $(r - \delta_i - \frac{1}{2} \sum_{j=1}^2 \sigma_{ij}^2)_{i=1,2}$.
- for $x = (x_1, x_2) \in \mathbb{R}^2$; $\exp(x) = (e^{x_1}, e^{x_2})$

Hence, if we denote by $S_t^{\exp(x)}$ the solution of equation (1) with $S_0 = \exp(x)$, we have

$$S_t^{\exp(x)} = \exp(x + \mu t + \Sigma W_t) \quad (4)$$

We make the following change in variables, $\alpha = \Sigma^{-1}\mu$, $\rho = r + (||\alpha||^2/2)$. The Girsanov theorem (**Equivalence of Probability Measures**) ensures that there exists a probability measure $IP^{(\alpha)}$ defined on $(\Omega, \mathcal{F}_T)$ by $\frac{dIP^{(\alpha)}}{dIP} = M_T^{(\alpha)}$, where $M_T^{(\alpha)} = e^{-\alpha \cdot W_T - \frac{|\alpha|^2}{2} T}$ such that $(W_t^{(\alpha)} = W_t + \alpha t)_{0 \leq t \leq T}$ is a standard $IP^{(\alpha)}$ -Brownian motion. Therefore, we have for $x \in \mathbb{R}^2$,

$$\begin{aligned} U(t, \exp(x)) &= \mathbb{E} \left(e^{-r(T-t)} M_{T-t}^{(\alpha)} \right. \\ &\quad \times e^{(\alpha \cdot W_{T-t} + |\alpha|^2/2(T-t))} \psi(\exp(x + \Sigma W_{T-t}^{(\alpha)})) \Big) \\ &= \mathbb{E}^{(\alpha)} \left(e^{-\rho(T-t)} e^{\alpha \cdot W_{T-t}^{(\alpha)}} \psi(\exp(x + \Sigma W_{T-t}^{(\alpha)})) \right) \end{aligned} \quad (5)$$

Define for $y \in \mathbb{R}^2$,

$$V(t, y) = \mathbb{E}^{(\alpha)} \left(e^{-\rho(T-t)} \phi(y + W_{T-t}^{(\alpha)}) \right) \quad (6)$$

with $\phi(y) = e^{\alpha \cdot y} \psi(\exp(\Sigma y))$. We have $U(t, \exp(\Sigma y)) = e^{-\alpha \cdot y} V(t, y)$, the valuation of an European option is now reduced to the computation of V . By means of the same transformation, we have $U_{am}(t, \exp(\Sigma y)) = e^{-\alpha \cdot y} V_{am}(t, y)$, where

$$V_{am}(t, y) = \sup_{\tau \in \mathcal{T}_{0,T-t}} \mathbb{E}^{(\alpha)} \left(e^{-\rho\tau} \phi(y + W_\tau^{(\alpha)}) \right) \quad (7)$$

Introduce the parabolic operator $\mathcal{L}$ defined by

$$\mathcal{L}v = \frac{\partial v}{\partial t} + \frac{1}{2} \Delta v - \rho v \quad (8)$$

where Δ stands for the Laplacian. Then the function V is the solution of the following PDE:

$$\begin{cases} \mathcal{L}v = 0 \\ v(T, \cdot) = \phi \end{cases} \quad (9)$$

while the function V_{am} satisfies the following obstacle problem on $[0, T] \times \mathbb{R}^2$

$$\begin{cases} \max(\mathcal{L}v, \phi - v) = 0 \\ v(T, \cdot) = \phi \end{cases} \quad (10)$$

either in the sense of variational inequalities [7] or in the sense of viscosity solutions [9, Prop 1.2] (*see Monotone Schemes*).

ADI Methods

The idea of Peaceman–Rachford ADI methods can be outlined as follows: consider a two-dimensional PDE arising from the valuation of a European option

$$\frac{\partial u}{\partial t} + \mathcal{A}u = 0 \quad (11)$$

where the operator $\mathcal{A}$ can be decomposed into $\mathcal{A} = \mathcal{A}_1 + \mathcal{A}_2$ where each term acts on one variable. The ADI methods consist in splitting each time interval of length Δt in two subintervals and applying the implicit scheme for $\mathcal{A}_1$ and the explicit scheme for $\mathcal{A}_2$ on the time interval $[t_n, t_{n+1/2}]$ and the implicit scheme for $\mathcal{A}_2$ and the explicit scheme for $\mathcal{A}_1$ on the time interval $[t_{n+1/2}, t_{n+1}]$. If we denote by u_n the vector $u(t_n, \cdot)$, the ADI methods compute u_n from u_{n+1} in two steps as follows: first we compute an intermediate value function $u_{n+1/2}$ applying the implicit scheme for the differential operator $\mathcal{A}_1$

$$u_{n+1} - u_{n+1/2} + \frac{\Delta t}{2} (\mathcal{A}_1 u_{n+1/2} + \mathcal{A}_2 u_{n+1}) = 0 \quad (12)$$

next, we compute u_n from $u_{n+1/2}$ applying an implicit scheme to $\mathcal{A}_2$

$$u_{n+1/2} - u_n + \frac{\Delta t}{2} (\mathcal{A}_1 u_{n+1/2} + \mathcal{A}_2 u_n) = 0 \quad (13)$$

Each intermediate equation are afterwards discretized in space using finite difference approximation.

ADI Methods for American Options

We now treat the example of pricing of two-asset American options. The first step is to formulate (10) in a bounded domain, for example on $Q_l = [0, T] \times \Omega_l$ where $\Omega_l =]-l, l[^2$:

$$\begin{cases} \max(\mathcal{L}v_{am}, \phi - v_{am}) = 0 \\ v_{am}(T, \cdot) = \phi \end{cases} \quad (14)$$

with a Dirichlet boundary condition $v_{am} = \phi$ on $]0, T[\times \partial\Omega_l$.

For the numerical resolution of the obstacle problem (14) by finite difference methods, we shall introduce a grid of mesh points (nk, ih, jh) where h, k are mesh parameters that are thought of as tending to zero. Denote by $N = \lceil T/k \rceil$ and M the greatest integer such that $(M + \frac{1}{2})h \leq l$. For each point $x_{ij} = (ih, jh)$, consider a square

$$C_{ij}^{(h)} =](i - 1/2)h, (i + 1/2)h[\times](j - 1/2)h, (j + 1/2)h[\quad (15)$$

and define

$$\begin{aligned} \Omega_h &= \{x_{ij} ; C_{ij}^{(h)} \subset \Omega_l\} \\ &= \{x_{ij} ; -M \leq i, j \leq M\} \end{aligned} \quad (16)$$

In the sequel, V_h is the space generated by $\chi_{ij}^{(h)}$ where $\chi_{ij}^{(h)}$ is the indicator function of the squares $C_{ij}^{(h)}$. If $u_h \in V_h$, we write $u_h(x) = \sum_{i,j=-M}^M u_{ij} \chi_{ij}^{(h)}(x)$. Note that $u_{ij} = u(ih, jh)$. Moreover, we denote by $\phi_{h,k}$ the approximation of the payoff function ϕ in the grid defined by

$$\begin{aligned} \phi_{h,k}(t, x) &= \sum_{n=0}^N \phi_h(x) \mathbf{1}_{[nk, (n+1)k[}(t) \\ &= \sum_{n=0}^N \left(\sum_{i,j=-M}^M \phi_{ij} \chi_{ij}^{(h)}(x) \right) \mathbf{1}_{[nk, (n+1)k[}(t) \end{aligned} \quad (17)$$

where $\phi_{ij} = \phi(x_{ij})$ and $\mathbf{1}_I$ is the indicator function of the interval I . We replace the Laplacian operator by a finite difference approximation and denote throughout

the paper A, B the linear operators defined on V_h by

$$(Au_h)(x) = \sum_{i,j=-M}^M (Au_h)_{ij} \chi_{ij}^{(h)}(x) \quad (18)$$

$$(Bu_h)(x) = \sum_{i,j=-M}^M (Bu_h)_{ij} \chi_{ij}^{(h)}(x) \quad (19)$$

where

$$(Au_h)_{ij} = 1/2(u_{i+1,j} - 2u_{ij} + u_{i-1,j}) \quad (20)$$

$$(Bu_h)_{ij} = 1/2(u_{i,j+1} - 2u_{ij} + u_{i,j-1}) \quad (21)$$

with the convention $u_{ij} = 0$ if $|i| \geq M+1$ and $|j| \geq M+1$. Finally, we shall denote by $(\cdot, \cdot)_l$ the inner product on Ω_l and $|\cdot|_l = \sqrt{(\cdot, \cdot)_l}$.

Dynamic Programming and ADI Method

Barles *et al.* [1] discuss a splitting method, which can be viewed as an analytic version of the dynamic programming principle: one builds the approximate solution

$$u_{h,k} = \sum_{n=0}^N u_h^n(x) \mathbf{1}_{[nk, (n+1)k]}(t) \quad (22)$$

in a recursive way, starting from $u_h^N = \phi$ and computing u_h^n for $0 \leq n \leq N$ in two steps:

- *First step:* One solves the following Cauchy problem on $[nk, (n+1)k] \times \Omega_l$ with Dirichlet boundary conditions.

$$\begin{cases} \mathcal{L}v = 0 \\ v(n+1, \cdot) = u_h^{n+1}(\cdot) \end{cases} \quad (23)$$

and denote the solution by $S(k)[u_h^{n+1}]$.

- *Second step:* One computes

$$u(n, \cdot) = \max(\phi_h(\cdot), S(k)[u_h^{n+1}]) \quad (24)$$

The ADI method consists in splitting the initial system into two intermediate *unidimensional* linear systems: u^{n+1} given in V_h with $u_{ij}^{n+1} = \phi_{ij}$ if $|i| = M+1$ or $|j| = M+1$.

One computes an intermediate value function $v_h^{n+1/2} = (v_{ij}^{n+1/2})_{-M \leq i, j \leq M}$ by

- for $|i| \leq M-1$ and $|j| \leq M-1$,

$$\begin{aligned} & \frac{u_{ij}^{n+1} - v_{ij}^{n+1/2}}{\frac{k}{2}} + \frac{v_{i+1,j}^{n+1/2} - 2v_{ij}^{n+1/2} + v_{i-1,j}^{n+1/2}}{2h^2} \\ & + \frac{u_{i,j+1}^{n+1} - 2u_{ij}^{n+1} + u_{i,j-1}^{n+1}}{2h^2} \\ & - \frac{\rho}{2} (u_{ij}^{n+1} + v_{ij}^{n+1/2}) = 0 \end{aligned} \quad (25)$$

- for $i = M$ and $|j| \leq M-1$ (right boundary conditions),

$$\begin{aligned} & \frac{u_{M,j}^{n+1} - v_{M,j}^{n+1/2}}{\frac{k}{2}} + \frac{\phi_{M+1,j} - 2v_{M,j}^{n+1/2} + v_{M-1,j}^{n+1/2}}{2h^2} \\ & + \frac{u_{M,j+1}^{n+1} - 2u_{M,j}^{n+1} + u_{M,j-1}^{n+1}}{2h^2} \\ & - \frac{\rho}{2} (u_{M,j}^{n+1} + v_{M,j}^{n+1/2}) = 0 \end{aligned} \quad (26)$$

- for $i = -M$ and $|j| \leq M-1$ (left boundary conditions),

$$\begin{aligned} & \frac{u_{-M,j}^{n+1} - v_{-M,j}^{n+1/2}}{\frac{k}{2}} + \frac{\phi_{-M-1,j} - 2v_{-M,j}^{n+1/2} + v_{-M+1,j}^{n+1/2}}{2h^2} \\ & + \frac{u_{-M,j+1}^{n+1} - 2u_{-M,j}^{n+1} + u_{-M,j-1}^{n+1}}{2h^2} \\ & - \frac{\rho}{2} (u_{-M,j}^{n+1} + v_{-M,j}^{n+1/2}) = 0 \end{aligned} \quad (27)$$

and the symmetric equations for $|j| = M$. In a more compact form:

$$\begin{aligned} & \frac{u^{n+1} - v^{n+1/2}}{\frac{k}{2}} + \frac{Av^{n+1/2} + a}{h^2} + \frac{Bu^{n+1} + b}{h^2} \\ & - \frac{\rho}{2} (u^{n+1} + v^{n+1/2}) = 0 \end{aligned} \quad (28)$$

with

$$\begin{aligned} a_{Mj} &= \frac{1}{2}\phi_{M+1,j}, & a_{-Mj} &= \frac{1}{2}\phi_{-M-1,j} \\ a_{ij} &= 0 & \text{for } |i| \leq M-1 \end{aligned} \quad (29)$$

$$\begin{aligned} b_{iM} &= \frac{1}{2}\phi_{i,M+1}, \quad b_{i,-M} = \frac{1}{2}\phi_{i,-M-1} \\ b_{ij} &= 0 \quad \text{for } |j| \leq M-1 \end{aligned} \quad (30)$$

In the same manner, one computes $v_h^n = (v_{ij}^n)_{-M \leq i, j \leq M}$ by

$$\begin{aligned} \frac{v^{n+1/2} - v^n}{\frac{k}{2}} + \frac{Av^{n+1/2} + a}{h^2} + \frac{Bv^n + b}{h^2} \\ - \frac{\rho}{2}(v^n + v^{n+1/2}) = 0 \end{aligned} \quad (31)$$

Equations (28) and (31) give

$$\begin{aligned} \left[\left(1 + \frac{\rho k}{4} \right) I - \frac{k}{2h^2} A \right] v_h^{n+1/2} \\ = \left[\left(1 - \frac{\rho k}{4} \right) I + \frac{k}{2h^2} B \right] u^{n+1} + \frac{k}{2h^2} (a + b) \end{aligned} \quad (32)$$

and

$$\begin{aligned} \left[\left(1 + \frac{\rho k}{4} \right) I - \frac{k}{2h^2} B \right] v_h^n \\ = \left[\left(1 - \frac{\rho k}{4} \right) I + \frac{k}{2h^2} A \right] v_h^{n+1/2} + \frac{k}{2h^2} (a + b) \end{aligned} \quad (33)$$

If we set $\eta_{h,k} = \frac{k}{2h^2}(a + b)$,

$$\begin{aligned} A_{h,k}^+ &= \left(1 + \frac{\rho k}{4} \right) I - \frac{k}{2h^2} A \\ A_{h,k}^- &= \left(1 - \frac{\rho k}{4} \right) I + \frac{k}{2h^2} A \end{aligned} \quad (34)$$

and

$$\begin{aligned} B_{h,k}^+ &= \left(1 + \frac{\rho k}{4} \right) I - \frac{k}{2h^2} B \\ B_{h,k}^- &= \left(1 - \frac{\rho k}{4} \right) I + \frac{k}{2h^2} B \end{aligned} \quad (35)$$

one obtains

$$\begin{cases} A_{h,k}^+ v^{n+1/2} = B_{h,k}^- u^{n+1} + \eta_{h,k} \\ B_{h,k}^+ v^n = A_{h,k}^- v^{n+1/2} + \eta_{h,k} \end{cases} \quad (36)$$

Finally, the computation of u_h^n may be summarized by:

$$u_h^n = \max(\phi_h, T_{h,k}[u_h^{n+1}])$$

where the operator $T_{h,k}$ is defined on V_h by:

$$\begin{aligned} T_{h,k}[u_h] &= (A_{h,k}^+)^{-1} (B_{h,k}^+)^{-1} A_{h,k}^- B_{h,k}^- [u_h] \\ &\quad + (A_{h,k}^+)^{-1} (B_{h,k}^+)^{-1} A_{h,k}^- \eta_{h,k} \\ &\quad + (B_{h,k}^+)^{-1} \eta_{h,k} \end{aligned} \quad (37)$$

in which one implicitly used the fact that $(A_{h,k}^+)^{-1}$, $(B_{h,k}^+)^{-1}$, $A_{h,k}^-$ and $B_{h,k}^-$ commute.

Villeneuve and Zanette have proved the stability and the convergence of this scheme (see [9, Proposition 2.4 and Theorem 2.1]). Under a condition on the mesh parameters of the form

$$\lim_{h,k \downarrow 0} \frac{k}{h^2} = 0 \quad (38)$$

From a numerical viewpoint, the systems (28) and (31) involve a tridiagonal matrix. Therefore, each intermediate system can be easily solved by Gaussian elimination, which takes part in the accuracy of the ADI method.

Linear Complementarity Problem and ADI Method

In this section, we describe a second numerical method, which adapts the ADI algorithm to solve the linear complementarity problem (LCP) arising from the discretization of the parabolic variational inequalities related to the pricing of American options.

When the American option value is computed using standard finite differences approximation, one obtains finite dimensional LCP as follows:

$$\begin{aligned} AU &\leq b \\ U &\geq \psi \\ (U - \psi)^T (AU - b) &= 0 \end{aligned} \quad (39)$$

where U is the $(M+1)^2$ vector of American option values on the space grid and A is a block tridiagonal matrix.

There is an extensive literature on the resolution of LCPs and a complete survey can be found in [3]. In particular, the matrix A of the LCP arising from a variational inequality exhibits special properties like sparseness, which make it possible to use efficient

algorithms including projected SOR [4] or direct pivoting methods [5].

Once again, the idea of the ADI method is to exploit the rapid LU decomposition algorithm for tridiagonal matrices by solving recursively a sequence of *one-dimensional* linear complementarity problems involving a tridiagonal matrix. Speed and flexibility of ADI methods come again from this decomposition:

$$\begin{aligned} u_{h,k}(t, x) = & \sum_{n=0}^{N-1} (u_h^n(x) \mathbf{1}_{[nk, (n+1/2)k]}(t) \\ & + u_h^{n+1/2}(x) \mathbf{1}_{[(n+1/2)k, (n+1)k]}(t)) \\ & + u_h^N \mathbf{1}_{[Nk, (N+1/2)k]}(t) \end{aligned} \quad (40)$$

where $u_h^0, u_h^{1/2}, \dots, u_h^N$ are the elements of the vector space V_h satisfying the variational inequalities:

$$\begin{cases} u_h^N = \phi_h \text{ and } \forall n \leq N-1 \\ \forall v_h \geq \phi_h \quad \left(\frac{u_h^{n+1} - u_h^{n+1/2}}{\frac{k}{2}} + \frac{1}{h^2} A u_h^{n+1/2} + \frac{1}{h^2} B u_h^{n+1} - \frac{\rho}{2} (u_h^{n+1/2} + u_h^{n+1}), v_h - u_h^{n+1/2} \right)_l \leq 0 \\ \forall v_h \geq \phi_h \quad \left(\frac{u_h^{n+1/2} - u_h^n}{\frac{k}{2}} + \frac{1}{h^2} A u_h^{n+1/2} + \frac{1}{h^2} B u_h^n - \frac{\rho}{2} (u_h^{n+1/2} + u_h^n), v_h - u_h^n \right)_l \leq 0 \end{cases} \quad (41)$$

with the Dirichlet conditions

$$\begin{aligned} \forall n \quad u_h^n(x_{ij}) = u_h^{n+1/2}(x_{ij}) = \phi_{ij} \\ \text{for } |i| = M \text{ and } |j| = M \end{aligned} \quad (42)$$

As usual, we had rather write the system in the following more compact form:

$$\begin{cases} u_h^N = \phi_h \text{ and } \forall n \leq N-1 \\ \forall v_h \geq \phi_h \quad \left(\left(I + \frac{k}{2h^2} B - \frac{\rho}{2} \right) u^{n+1} - \left(I - \frac{k}{2h^2} A + \frac{\rho}{2} \right) u_h^{n+1/2}, v_h - u_h^{n+1/2} \right)_l \leq 0 \\ \forall v_h \geq \phi_h \quad \left(\left(I + \frac{k}{2h^2} B - \frac{\rho}{2} \right) u^n - \left(I - \frac{k}{2h^2} A + \frac{\rho}{2} \right) u_h^{n+1/2}, v_h - u_h^n \right)_l \leq 0 \end{cases} \quad (43)$$

From a theoretical viewpoint, Villeneuve and Zanette [9, Theorem 3.2] have proved the convergence of this approximation procedure, using the weaker notion of quadratic convergence.

From a numerical viewpoint, there are mainly two families for solving variational inequalities in finite dimension by exploiting their link with linear

complementarity problems (see the next proposition): pivoting methods (algorithms of Cryer [5], Brennan–Schwartz [2]) and iterative methods (e.g., PSOR [4]) (see **Finite Difference Methods for Early Exercise Options**). In the sequel, we specify the computational treatment of equation (41). The inner product in R^{d^2} is denoted by (u, v) and we write $u \geq v$ if $u_i \geq v_i$ for all $i \in \{1, \dots, d^2\}$. The variational inequality (41) becomes a linear complementarity problem in finite dimensions:

Proposition 1 (Linear complementarity problem [3, 7]). *Let A a $d^2 \times d^2$ matrix and $u, \theta, \phi \in R^{d^2}$. The following systems are equivalent:*

$$\begin{aligned} \bullet \quad (S) \quad & Au \geq \theta, \quad u \geq \phi \\ & (Au - \theta, \phi - u) = 0 \end{aligned} \quad (44)$$

$$\begin{aligned} \bullet \quad (S') \quad & u \geq \phi, \quad \forall v \geq \phi \\ & (Au - \theta, v - u) \geq 0 \end{aligned} \quad (45)$$

For any matrix $u = (u_{ij})_{1 \leq i, j \leq d}$, we choose one of the most obvious methods of ordering

$$u = [u_{11}, \dots, u_{d1}, \dots, u_{1d}, \dots, u_{dd}] \quad (46)$$

The ADI scheme (41) consists in approximating $u(nk, ih, jh)_{0 \leq n \leq N; -M \leq i, j \leq M}$ by (u_{ij}^n) ordered in the way defined above by

$$u_{ij}^N = \phi(ih, jh) = \phi_{ij} \quad \text{for } -M \leq i, j \leq M \quad (47)$$

and for $0 \leq n \leq N - 1$ and $-M \leq i, j \leq M$,

$$\left\{ \begin{array}{l} u_{ij}^{n+1/2} \geq \phi_{ij} \text{ and } u_{ij}^n \geq \phi_{ij} \\ u_{ij}^{n+1/2} = \phi_{ij} \text{ and } u_{ij}^n = \phi_{ij} \text{ for } |i| = M + 1 \text{ or } |j| = M + 1 \\ \frac{-1}{2}u_{i+1,j}^{n+1/2} + \alpha u_{ij}^{n+1/2} - \frac{1}{2}u_{i-1,j}^{n+1/2} \geq \frac{-1}{2}u_{i+1,j}^{n+1} + \alpha u_{ij}^{n+1} - \frac{1}{2}u_{i-1,j}^{n+1} \\ \left(\left(\frac{-1}{2}u_{i+1,j}^{n+1/2} + \alpha u_{ij}^{n+1/2} - \frac{1}{2}u_{i-1,j}^{n+1/2} \right) - \frac{1}{2}u_{i+1,j}^{n+1} - \alpha u_{ij}^{n+1} + \frac{1}{2}u_{i-1,j}^{n+1}, u_{ij}^{n+1/2} - \phi_{ij} \right) = 0 \\ \frac{-1}{2}u_{i,j+1}^n + \alpha u_{ij}^n - \frac{1}{2}u_{i,j-1}^n \geq \frac{-1}{2}u_{i,j+1}^{n+1/2} + \alpha u_{ij}^{n+1/2} - \frac{1}{2}u_{i,j-1}^{n+1/2} \\ \left(\left(\frac{-1}{2}u_{i,j+1}^n + \alpha u_{ij}^n - \frac{1}{2}u_{i,j-1}^n \right) - \left(\frac{-1}{2}u_{i,j+1}^{n+1/2} + \alpha u_{ij}^{n+1/2} - \frac{1}{2}u_{i,j-1}^{n+1/2} \right), u_{ij}^n - \phi_{ij} \right) = 0 \end{array} \right. \quad (48)$$

where $\alpha = (1 + \frac{\rho k}{4} - \frac{k}{2h^2})$. The Kronecker product of two matrices $M, N \in \mathcal{M}_d(R)$ is the $d^2 \times d^2$ matrix denoted by $M \otimes N$ with entries $(M \otimes N)_{ij} = M_{ij}N$ for $1 \leq i, j \leq d$. To take into account the boundary conditions, for $u \in \mathcal{M}_{d^2}(R)$ with $d = 2M + 1$, we define $\bar{u} \in \mathcal{M}_{d^2}(R)$ with components $i = 1$

$$\left\{ \begin{array}{l} \bar{u}_{11} = u_{11} - \frac{k}{h^2}(\phi(-(M+1)h, -Mh) + \phi(-Mh, -(M+1)h)) \\ \bar{u}_{1j} = u_{1j} - \frac{k}{h^2}(\phi(-(M+1)h, -(M+1+j)h)) \quad 2 \leq j \leq d-1 \\ \bar{u}_{1d} = u_{1d} - \frac{k}{h^2}(\phi(-(M+1)h, Mh) + \phi(-Mh, (M+1)h)) \end{array} \right. \quad (49)$$

$2 \leq i \leq d-1$

$$\left\{ \begin{array}{l} \bar{u}_{i1} = u_{i1} - \frac{k}{h^2}(\phi((-M+1+i)h, -(M+1)h)) \\ \bar{u}_{ij} = u_{ij} \bar{u}_{id} = u_{id} - \frac{k}{h^2}(\phi((-M+1+i)h, (M+1)h)) \end{array} \right. \quad (50)$$

$i = d$

$$\left\{ \begin{array}{l} \bar{u}_{d1} = u_{d1} - \frac{k}{h^2}(\phi((M+1)h, -Mh) + \phi(Mh, -(M+1)h)) \\ \bar{u}_{dj} = u_{dj} - \frac{k}{h^2}(\phi((M+1)h, -(M+1+j)h)) \quad 2 \leq j \leq d-1 \\ \bar{u}_{dd} = u_{dd} - \frac{k}{h^2}(\phi((M+1)h, Mh) + \phi(Mh, (M+1)h)) \end{array} \right. \quad (51)$$

Then, the linear complementary problem can be written as

$$\left\{ \begin{array}{l} u^{n+1/2} \geq \phi_h \text{ and } u^n \geq \phi_h \\ \left[I \otimes \left(I + \frac{\rho k}{2} I - \frac{k}{2h^2} T \right) \right] u^{n+1/2} \geq \left[I \otimes \left(I - \frac{\rho k}{2} I + \frac{k}{2h^2} T \right) \right] \bar{u}^{n+1} \\ \left(I \otimes \left(I + \frac{\rho k}{2} I - \frac{k}{2h^2} T \right) u^{n+1/2} - I \otimes \left(I - \frac{\rho k}{2} I + \frac{k}{2h^2} T \right) \bar{u}^{n+1}, u^{n+1/2} - \phi \right) = 0 \\ \left[\left(I + \frac{\rho k}{2} I - \frac{k}{2h^2} T \right) \otimes I \right] u^n \geq \left[\left(I - \frac{\rho k}{2} I + \frac{k}{2h^2} T \right) \otimes I \right] \bar{u}^{n+1/2} \\ \left(\left[\left(I + \frac{\rho k}{2} I - \frac{k}{2h^2} T \right) \otimes I \right] u^n - \left[\left(I - \frac{\rho k}{2} I + \frac{k}{2h^2} T \right) \otimes I \right] \bar{u}^{n+1/2}, u^n - \phi \right) = 0 \end{array} \right. \quad (52)$$

with

$$T = \begin{pmatrix} -2 & 1 & \cdots & \cdots & 0 \\ 1 & -2 & 1 & \cdots & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & \vdots & 1 & -2 & 1 \\ 0 & \cdots & \cdots & 1 & -2 \end{pmatrix} \quad (53)$$

Hence, the pricing of the American option defined by ϕ is now reduced to the computation of the bidimensional linear complementarity problem (52), which has been split in two intermediate unidimensional linear complementarity problems involving a tridiagonal matrix.

To summarize, ADI methods

- are competitive in terms of speed of computation in comparison with standard iterative methods used in financial literature for solving linear complementarity problems;
- lead to algorithms that are very easy to implement in the Black–Scholes setting; and
- are unconditionally stable for the L^2 norm [6], which simplifies their implementation in practice.

Conjugate Gradient Methods

In option pricing on the basis of the Black–Scholes model [3], the value of an option is governed by a partial differential equation (PDE) (see **Partial Differential Equations**). Except for special cases, analytic solutions generally do not exist and numerical methods are necessary to approximate the solution. For instance, finite difference methods [20] approximate the solution on a mesh of discrete asset prices. An implicit discretization of the PDE then requires in each time step solving a linear system:

$$Ax = b \quad (1)$$

where x is the solution of next time step, b is the right-hand side, and A is an $N \times N$ matrix (see **Finite Difference Methods for Barrier Options; Finite Difference Methods for Early Exercise Options**). It is interesting to note that matrices arising from option pricing PDEs are often sparse and typically have $O(N)$ nonzeros.

The solution time and storage for solving large linear systems can be very significant. Gaussian elimination is a standard method for solving linear systems, but owing to the issue of fill-in [5], it is usually deemed too expensive in practice when the underlying has more than two assets. Iterative methods [10, 18], for example, Jacobi, Gauss–Seidel, and successive over-relaxation (SOR), on the other hand, are simple to apply. However, their convergence rates, typically depending on the mesh size, are very slow for large problems. The ADI method [16] (see **Alternating Direction Implicit (ADI) Method**) has been used in option pricing. While it can be made efficient for some linear PDEs, it is not clear how it can be easily extended to more general and nonlinear equations.

One way to improve on the classical iterative methods is to use dynamically computed parameters based on the current (and previous) iteration information. The hope is that the appropriately selected parameters would compute “optimal” solutions in some sense. Ideally, it would be desirable to have an iterative method, which (i) is simple to implement, (ii) takes advantage of sparsity structure of A , and (iii) generates solutions whose errors are minimized

in some way. It turns out that such a method can be developed, which is known as the *conjugate gradient (CG) method* [11]. We begin the discussion for symmetric matrices and then generalize the idea to general nonsymmetric cases.

Symmetric Case

Consider the linear system (1) and assume for now that A is symmetric positive definite (i.e., all eigenvalues are positive). To search the solution x in the N -dimensional space $\mathbb{R}^N$ is generally difficult when N is large. A simpler problem would be to search an approximate solution x^k from a low-dimensional subspace S_k where the dimension k is typically much smaller than N .

There are different ways to select x^k from S_k . Intuitively, x^k is “optimal” if $\|x - x^k\|$ is minimized. Geometrically, it is equivalent to saying that the error $e^k \equiv x - x^k$ is orthogonal to S_k , that is, $\langle e^k, s \rangle \equiv \sum_{i=1}^N e_i^k s_i = 0$ for all $s \in S_k$. To enforce this condition, one would need e^k , which is not known. To address this issue, the A -inner product, defined as $\langle u, v \rangle_A \equiv \langle Au, v \rangle$, is used instead. The orthogonality condition then becomes

$$0 = \langle e^k, s \rangle_A = \langle Ae^k, s \rangle = \langle r^k, s \rangle \quad \forall s \in S_k \quad (2)$$

where $r^k \equiv b - Ax^k$ is the residual vector, which is computable. What it does is to minimize $\langle e^k, e^k \rangle_A \equiv \|e^k\|_A^2$, the A -norm of the error.

Different choices of S lead to different methods. For instance, the method of Steepest descent (SD) [9, 18] chooses the one-dimensional subspace $S = \text{span}\{p\}$, where p is the residual vector of the current approximation. A new approximate solution is obtained by enforcing the orthogonality condition (2). The procedure is repeated with another search direction. Note that SD does not increase the dimension of the search subspace S but rather changes S from every iteration. The main drawback of SD is slow convergence in practice, typically because the search directions may repeat and so SD may end up searching in the same direction again and again [10].

Conjugate Gradient

To avoid unnecessary duplicated search effort as in SD, the conjugate gradient (CG) method [11, 18]

is used to find an optimal solution x^k from a set of search directions $\{p^i\}$, which are A -orthogonal; that is, $\langle p^i, p^j \rangle_A = 0$ if $i \neq j$. The A -orthogonality property guarantees that each of the p^k searches in a unique subspace and one never has to look in that subspace again.

The basic idea of CG is to start with an initial guess x^0 and then find an approximate solution in a subspace S . It first begins with a small (dimension 1) subspace and then increases the dimension one by one to obtain better approximation. More precisely, at the k th step, the search subspace is

$$S_k = \text{span}\{p^0, p^1, \dots, p^{k-1}\} \quad (3)$$

where $\{p^i\}_{i=1}^{k-1}$ are search vectors computed from previous steps. CG then looks for the best approximate solution $x^k \in x^0 + S_k$, that is,

$$x^k = x^0 + \sum_{i=0}^{k-1} \alpha_i p^i \quad (4)$$

The orthogonality condition (2) and the A -orthogonality property of $\{p^i\}$ yield $\alpha_i = \langle p^i, r^0 \rangle / \langle p^i, p^i \rangle_A$. Note that α_i does not depend on k . Hence,

$$x^k = x^0 + \sum_{i=0}^{k-2} \alpha_i p^i + \alpha_{k-1} p^{k-1} = x^{k-1} + \alpha_{k-1} p^{k-1} \quad (5)$$

Thus, only the last search direction needs to be stored to update x^k from x^{k-1} .

Once x^k is known, SD would use the residual r^k as the new search direction. CG, however, makes r^k A -orthogonalized against all previous $\{p^i\}$ to obtain p^k , that is,

$$p^k = r^k + \sum_{i=0}^{k-1} \beta_i p^i \quad (6)$$

where $\beta_i = -\langle r^k, p^i \rangle_A / \langle p^i, p^i \rangle_A$ given by the A -orthogonality condition. The new search subspace is then defined as $S_{k+1} = \text{span}\{p^0, \dots, p^k\}$ and the new approximate solution x^{k+1} is computed until it is sufficiently accurate.

A potential drawback of CG is to store all $\{p^i\}$ for computing p^k . Simplification is necessary to make the method practical. An important observation in deriving CG is that S_k is the same as the Krylov subspace [9, 10, 18], defined as

$$\mathcal{K}_k \equiv \text{span}\{r^0, Ar^0, \dots, A^{k-1}r^0\} \quad (7)$$

As a result,

$$\begin{aligned} p^i \in \text{span}\{p^0, \dots, p^i\} &= S_{i+1} = \mathcal{K}_{i+1} \\ &= \text{span}\{r^0, \dots, A^i r^0\} \end{aligned} \quad (8)$$

Hence, $Ap^i \in \text{span}\{Ar^0, \dots, A^{i+1}r^0\} \subset \mathcal{K}_{i+2} = S_{i+2}$. By equation (2), $r^k \perp S_j$, $j = 1, \dots, k$ and hence, $r^k \perp S_{i+2}$ for any $i \leq k-2$. Thus, $\langle Ap^i, r^k \rangle = 0 = \beta_i$, $i \leq k-2$, and equation (6) is simplified to

$$p^k = r^k + \beta_{k-1} p^{k-1} \quad (9)$$

Thus, as for x^k , only the last search vector needs to be stored. Besides, more convenient formulas for α_k and β_k can be derived by applying the various orthogonality properties. Finally, the CG algorithm is given as follows:

Algorithm: Conjugate Gradient

```

 $x^0$  = initial guess
 $r^0 = b - Ax^0$ 
( $p^{-1} = 0$ ,  $\beta_{-1} = 0$ )
for  $k = 0, 1, 2, \dots$ , until convergence
     $p^k = r^k + \beta_{k-1} p^{k-1}$ 
     $\alpha_k = \langle r^k, r^k \rangle / \langle p^k, Ap^k \rangle$ 
     $x^{k+1} = x^k + \alpha_k p^k$ 
     $r^{k+1} = r^k - \alpha_k Ap^k$ 
     $\beta_k = \langle r^{k+1}, r^{k+1} \rangle / \langle r^k, r^k \rangle$ 
end
    
```

Note that the CG algorithm only involves simple vector operations and matrix–vector multiply, and hence the sparsity structure of A can be fully and easily explored. Moreover, two-term recurrence formulas exist for the updates of x^k and other variables. As such, the work and storage for one CG iteration are $O(N)$. Note also that the matrix A is not really needed as long as one can compute the matrix–vector product. This property is particularly useful when A is not available explicitly; see the section Application.

Convergence of CG

Compared to other iterative methods, CG has the desirable property that x^k is the “best” approximation from S_k . Thus, the CG solution x^k improves as the dimension of S_k increases. When $k = N$, then $S_N = \mathbb{R}^N$ and so $e^N = 0$. Hence, CG obtains the exact solution in at most N iterations (known as the *finite termination property* [18]). In practice,

however, CG is often treated as an iterative method in the sense that only a small number of iterations are performed. In many cases, the approximate solution x^k is sufficiently accurate for $k \ll N$.

The number of CG iterations needed depends on the rate of convergence, which is very complex in general. A well-known estimate [9, 18] is given as follows:

$$\|e^k\|_A \leq 2 \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^k \|e^0\|_A \quad (10)$$

where κ is the condition number [8] of A . For a parabolic PDE, with timestep size $O(h)$, $\kappa = O(h^{-1})$, where h is the mesh size of the discrete asset prices. The rates of convergence for Jacobi, Gauss–Seidel, and SD are $1 - O(h)$, whereas the rate for CG, based on the above error bound, is $1 - O(\sqrt{h})$, an order of magnitude improvement. SOR also has the same asymptotic convergence rate as CG, but it would require the knowledge of the optimal over-relaxation parameter. In practice, the CG error bound is often too pessimistic and the actual CG convergence is considerably much faster than the classical iterative methods.

Nonsymmetric Case

CG computes an optimal approximation x^k ($\|e^k\|_A$ is minimized) using short (two-term) recurrence update formulas for x^k and other quantities. Could one do the same for nonsymmetric matrices, such as the discretized Black–Scholes equation? Unfortunately, the answer is provably no [6]. Thus, when generalizing CG to the nonsymmetric case, one keeps some desirable properties of CG and sacrifices the others. There are many different possibilities, which yield numerous methods collectively known as the *Krylov subspace methods* [1]. Here, we describe two of these methods commonly used in practice.

The generalized minimal residual (GMRES) method [17] minimizes the norm of the residual vector:

$$\min_{x^k} \|b - Ax^k\|_2, \quad x^k \in x^0 + \mathcal{K}_k \quad (11)$$

As a result, the residual norm is nonincreasing. Furthermore, convergence is guaranteed for a wide class of matrices. However, it needs to store all the basis vectors for $\mathcal{K}_k$. Thus, work and storage increase

with iteration. A remedy is to restart GMRES every m iterations (m small constant). The convergence of the restarted GMRES, however, may stagnate, that is, $\|r^k\| \approx \|r^{k-1}\|$ for many iterations.

The other method is BiCGSTAB [23], which is derived from the biconjugate gradient (BCG) method [7]. BCG enforces a similar orthogonality condition on r^k as in equation (2) but allows two different Krylov subspaces to be used; more precisely,

$$r^k \perp \tilde{\mathcal{K}}_k \quad \text{and} \quad x^k \in x^0 + \mathcal{K}_k \quad (12)$$

where $\tilde{\mathcal{K}}_k = \text{span}\{\tilde{r}^0, A^T \tilde{r}^0, \dots, (A^T)^{k-1} \tilde{r}^0\}$ for some vector $\tilde{r}^0$. By enforcing the so-called bi-orthogonality condition, which makes the basis vectors $\{v^j\}$ for $\mathcal{K}_k$ and the basis vectors $\{w^j\}$ for $\tilde{\mathcal{K}}_k$ orthogonal to each other, two-term recurrence formulas for updating x^k and other quantities can be found. It has an advantage over GMRES in terms of storage. However, since it does not have the minimization property as GMRES, the residual norm can be very irregular as iterations continue. BiCGSTAB essentially is a “smooth” variant of BCG and its convergence is much more stabilized.

A more comprehensive overview of various Krylov subspace methods can be found in [1]. Similar to CG, the algorithms of the nonsymmetric methods involve only simple vector operations and matrix–vector products.

Preconditioning

CG methods would not have been so popular without the powerful technique called *preconditioning*, which can accelerate convergence drastically. Consider a nonsingular matrix M . The main idea is that the preconditioned system

$$M^{-1}Ax = M^{-1}b \quad (13)$$

is equivalent to equation (1) but the convergence of CG now depends on $M^{-1}A$ instead. The key is to construct a preconditioner M such that $\kappa(M^{-1}A) \ll \kappa(A)$ in order to obtain fast convergence. It is clear that if $M \approx A$, then $M^{-1}A \approx I$, which has condition number 1. On the other hand, M should be simple enough that the matrix–vector product by M^{-1} is easy to compute.

Generally speaking, it is difficult to determine what the optimal M is. Often it is problem specific. A

general class of preconditioners widely used in practice is called *incomplete LU* (ILU) factorization [14, 18]. A full LU would result in Gaussian elimination, which is expensive. An approximate LU factorization trades-off between efficiency and accuracy. Other effective preconditioners include multigrid [15, 22], domain decomposition [19], and sparse approximation inverse [2]. Once a preconditioner is chosen, to incorporate preconditioning into any CG algorithms only requires changing a few lines of code.

Application

CG methods have been used for pricing different options, for instance, American options [12], options with stochastic volatility [25], and options on Lévy driven assets [13]. Comparisons of SOR and CG methods for multiasset problem can be found in [21]. As an example, we consider pricing European options in a rather general exponential Lévy model (cf. [24] for more details in the special case of CGMY). The option value, $V(S, \tau)$, satisfies a partial integro-differential equation (*see Partial Integro-differential Equations (PIDEs)*), which is similar to the Black–Scholes equation [3] but with an extra integral term for the jump process:

$$\begin{aligned} \frac{\partial V}{\partial \tau} = & \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + rS \frac{\partial V}{\partial S} - rV \\ & + \int_{-\infty}^{\infty} \nu(y) \left[V(Se^y, \tau) - V(S, \tau) \right. \\ & \left. - S(e^y - 1) \frac{\partial V}{\partial S} \right] dy \end{aligned} \quad (14)$$

where S is the value of the underlying asset, τ the time from expiry, σ the volatility, r the interest rate, and $\nu(y)$ a Lévy measure. Let $\{S_i\}_{i=1}^N$ be a set of discrete asset prices. Also, let $V^n = (V_1^n, \dots, V_N^n)$, where V_i^n is an approximation of $V(S_i, \tau^n)$ at time τ^n . Then a fully implicit finite difference discretization requires solving a linear system (1) at each timestep with $x = V^{n+1}$ and $b = V^n$. (The second order Crank–Nicolson discretization results in a similar matrix and right-hand side.) The matrix A can be written as a sum of two matrices: $A = L + B$, where L corresponds to the discretization of the differential term (which is similar to the Black–Scholes matrix) and B corresponds to the discretization of the integral term. While L is sparse, B is not; it has $O(N^2)$

nonzeros. Since A is dense because of B , it is not practical (time and storage) to form A explicitly even for moderate size N . In this case, Gaussian elimination and the classical iterative methods would not be easily applicable.

CG methods, on the other hand, can be used with ease. Note that B has a special convolution structure so that matrix–vector multiply can be computed efficiently using an FFT [4]. Thus, while A may not be available explicitly, the matrix–vector product by A can be computed, which is all CG methods require. In this problem, A is nonsymmetric and BiCGSTAB is used to solve the linear system [24]. Mesh-independent convergence is obtained for the infinite activity and finite variation case and there is a slight increase in iteration numbers for the infinite variation case. In both the cases, it shows an improvement of factor 4 in CPU times over another iterative method on the basis of a fixed point iteration.

Summary

CG methods generate “optimal” approximate solutions by performing simple vector operations and matrix–vector multiply. More importantly, by combining with the right choice of preconditioners, CG methods have been shown to be robust and efficient for solving option pricing PDEs. The discussion has been mainly focused on linear problems. In more general cases, one can apply preconditioned CG methods to the linearized equations from nonlinear problems without making any special modification.

Multigrid Methods

Multigrid Basics

The multigrid iterative solution method has the unique potential of solving partial differential equations (PDEs) discretized with N^d unknowns in $O(N^d)$ work. This property forms the basis for efficiently solving very large computational problems. Initiated by Brandt [2], the development of multigrid has been particularly stimulated by the work done in computational fluid dynamics toward the end of the twentieth century. Introductions to multigrid can be found in [4, 15].

The insights and algorithms developed can be directly transferred to finance, that is, for solving the higher dimensional versions of convection-diffusion-reaction type PDE operators efficiently. These higher dimensional PDEs arise, for example, when dealing with stochastic volatility or with multiasset options under Black–Scholes dynamics. The aim is to solve these discrete PDE problems in just a few multigrid iterations within a split second.

Linear Multigrid

We would like to solve iteratively the discrete problem resulting from a PDE,

$$A_h u_h = f_h, \text{ on grid } G_h \quad (1)$$

for unknown u_h . For any approximation u_h^m , after iteration m , of the solution u_h , we denote the error by $e_h^m := u_h - u_h^m$, and the defect (or residual) by $d_h^m := f_h - A_h u_h^m$. Multigrid methods are motivated by the fact that many iterative methods, such as the well-known pointwise Gauss–Seidel iteration (PGS), have a smoothing effect on e_h^m . A smooth error can be well represented on a coarser grid, containing substantially fewer points, where its approximation is much cheaper. The defect equation,

$$A_h e_h^m = d_h^m \quad (2)$$

represents the error; it is equivalent to the original equation, since $u_h = u_h^m + e_h^m$. Departing from the insight of a smooth error, e_h^m , the idea is to use an

appropriate approximation, A_H , of A_h on a coarser grid, G_H (for instance, a grid with double the mesh size in each direction). The defect equation is then replaced by

$$A_H \widehat{e}_H^m = d_H^m \quad (3)$$

where $A_H : G_H \rightarrow G_H$, $\dim G_H < \dim G_h$ and A_H is invertible. As d_H^m and $\widehat{e}_H^m$ are grid functions on the coarser grid, G_H , we need two transfer operators between the fine and coarse grid. I_h^H is used to restrict d_h^m to G_H , and I_H^h is used to interpolate (or prolongate) the correction, $\widehat{e}_H^m$, back to G_h :

$$d_H^m := I_h^H d_h^m, \quad \widehat{e}_H^m := I_H^h \widehat{e}_H^m \quad (4)$$

This defines an iterative two-grid solution method, the two-grid correction scheme:

1. ν_1 smoothing steps on the fine grid:
 $\widehat{u}_h \leftarrow S^{\nu_1}(u_h^0, f_h)$;
2. computation of fine-grid residuals:
 $d_h := f_h - A_h \widehat{u}_h$;
3. restriction of residuals from fine to coarse:
 $d_H := I_h^H d_h$;
4. solution of coarse-grid problem: $A_H \widehat{e}_H = d_H$;
5. prolongation of corrections from coarse to fine:
 $\widehat{e}_h := I_H^h \widehat{e}_H$;
6. add correction to fine-grid approximation:
 $\widehat{u}_h \leftarrow \widehat{u}_h + \widehat{e}_h$;
7. ν_2 smoothing steps on the fine grid:
 $u_h^1 \leftarrow S^{\nu_2}(\widehat{u}_h, f_h)$.

Steps (1) and (7) are pre and postsmoothing steps, consisting of a few Gauss–Seidel iterations. Steps (2)–(6) form the “coarse-grid correction cycle”. In a well-converging two-grid method, it is not necessary to solve this coarse-grid defect equation exactly. Instead, one can replace $\widehat{e}_H^m$ by a suitable approximation. A natural way is to apply the two-grid idea again to the coarse-grid equation, now employing an even coarser grid than G_H . This can be done recursively; on each grid γ two-grid iteration steps are applied. With $\gamma = 1$, the multigrid V-cycle is obtained.

The smoothness of the error after Gauss–Seidel iterations depends on the discrete PDE under consideration. For nicely elliptic operators such as the Laplacian, errors will become smooth in all grid directions and grid coarsening can take place along every direction. For the convection-diffusion type equations, we obtain similar smooth errors if we

process the grid points according to the directions governed by the convective term [15]. The choice of coarse grid highly depends on the *smoothness of the error in the approximation*. We coarsen in those directions in which this error is smooth. Coarsening is simple for structured Cartesian grids, where one can remove every second grid point to obtain the coarse grid. For irregular grids, the resulting matrix A_h assists in determining the smoothness of the error. The matrix can accordingly be reduced algebraically (algebraic multigrid, AMG, see, e.g., [15]). In geometric multigrid, coarse grids are defined on the basis of a given fine grid, and coarse-grid corrections are computed from the PDE discretized on the coarse grids.

If N^d is the number of unknowns on G_h and N^d/β is the number of nodes on the coarse grid, then the multigrid algorithm requires $\mathcal{O}(N^d)$ storage and, for accuracy commensurable with discretization accuracy, $\mathcal{O}(N^d \log N^d)$ work, if $\gamma < \beta$. To get $\mathcal{O}(N^d)$ work, the multigrid cycles must be preceded by *nested iteration*, also called *full multigrid* [4, 15].

Multiaspect Options; Dealing with Grid Anisotropies in Multigrid

In this section, we discuss the numerical treatment with multigrid for the multiaspect Black–Scholes operator. Because this operator can be transformed to the multidimensional heat equation [11], we focus the discussion on the Laplacian operator for simplicity.

The major hindrance in the numerical solution of multidimensional PDEs is the so-called *curse of dimensionality*, which implies that with growth in the number of dimensions, we have an exponential growth in the number of grid points on tensor-product grids. Although we do not address this issue, in particular, we would like to stress that a way to handle dimensionality is the sparse-grid method [5, 14, 18]. One of the characteristics of these *sparse grids* is that they are essentially *nonequidistant* and, therefore, efficient multigrid solution methods for this type of grid are quite important.

We therefore consider here the discrete 2D Laplacian, discretized by finite differences on a grid with $h_y \gg h_x$, meaning that the matrix elements related to the x -derivative, $\mathcal{O}(h_x^{-2})$, are significantly larger than those for the y -derivative, $\mathcal{O}(h_y^{-2})$. If we apply

a PGS to this discrete operator, we find that its smoothing effect is very poor in the y -direction. The reason is that PGS has a smoothing effect only with respect to the “strong coupling” in the operator, in this case the x -direction. A multigrid method based on pointwise smoothing and grid coarsening in all directions will not converge well, as we coarsen along directions in which the error is nonsmooth.

An algorithmic improvement is to keep the pointwise relaxation for smoothing, but to *change the grid coarsening* according to the one-dimensional smoothness of errors: the coarse grid defined by doubling the mesh size only in that direction in which the errors are smooth will result in an efficient multigrid method. Figure 1 shows an example of semicoarsening along the x -axis.

A second successful approach is to keep the grid coarsening in all directions, but to change the smoothing procedure from a pointwise to *linewise* iteration. Line relaxations are block iterations in which each block of unknowns corresponds to a line. This smoother generates smooth error in all grid directions in the case of grid anisotropies.

These two strategies for excellent convergence, that is, to maintain standard coarsening and change the smoother, or to keep the pointwise smoothing procedure but adapt the coarsening, remain valid for higher dimensional problems. In a 3D problem, this implies that *planewise relaxation* should be employed (in combination with standard coarsening), in which all unknowns lying in the plane of strongly coupled unknowns are relaxed simultaneously. In contrast to line relaxation, which leads to tridiagonal matrices, in plane relaxation we need to solve a discrete 2D problem. A multigrid treatment of high-dimensional PDEs in finance based on hyperplane relaxation has been proposed in [13], while the use of pointwise

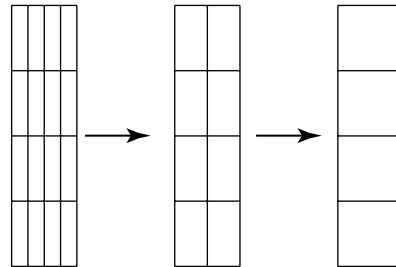

Figure 1 An example of x -semicoarsening using three grids

smoothing and coarsening the grid simultaneously along all dimensions where the errors are strongly coupled by *simultaneous partial grid coarsening* has been employed in [18, 19], until the coarse-grid problem is isotropic to the point where full coarsening is feasible. The resulting multigrid methods are highly efficient.

American Options; Multigrid Treatment of Nonlinear Problems

Next, we discuss multigrid methods for the computation of the value of an American-style option. In [17], it was shown that for American-style options the theory related to free boundary problems, as it was developed in the 1970s [1, 8], applies. It is possible to rewrite the arising free boundary problem as a linear complementarity problem (LCP), of the form

$$Au \leq f_1 \quad \mathbf{x} \in \Omega \quad (5)$$

$$u \geq f_2 \quad \mathbf{x} \in \Omega \quad (6)$$

$$(u - f_2)(Au - f_1) = 0 \quad \mathbf{x} \in \Omega \quad (7)$$

The LCP formulation is beneficial for iterative solution, since the unknown boundary does not appear explicitly and can be obtained in a postprocessing step. The LCP problem is, however, nonlinear, which implies that we have to generalize the linear multigrid algorithm to the nonlinear situation. We can distinguish in solutions of LCPs a so-called active region from an inactive region. In the active region, constraint (6) holds with equality sign, whereas in the inactive region, constraint (5) is valid with equality sign.

Nonlinear Multigrid

The fundamental idea of multigrid for *nonlinear PDEs* of the form

$$N_h u_h = f_h \quad (8)$$

is the same as that for linear equations. First, the errors in the solution have to be smoothed so that they can be approximated on a coarser grid. In the nonlinear case, the fine-grid defect equation is given by

$$N_h(\bar{u}_h^m + e_h^m) - N_h \bar{u}_h^m = d_h^m \quad (9)$$

where $\bar{u}_h^m$ is the approximation of the solution after relaxation in the i th multigrid cycle, e_h^m is the error and d_h^m is the corresponding defect. This equation is approximated on a coarse grid by

$$N_H(\bar{u}_H^m + \hat{e}_H^m) - N_H \bar{u}_H^m = d_H^m \quad (10)$$

Not only is the defect, d_h^m , transferred to the coarse grid by some restriction operator I_h^H but also the relaxed approximation $\bar{u}_h^m$ itself by a restriction operator $\hat{I}_h^H$.

However, as in the linear case, only the coarse-grid corrections, $\hat{e}_H$, are interpolated back to the fine grid, where the fine-grid errors are smoothed again. This forms the basis of the well-known full approximation scheme (FAS) [2]. The nonlinearity of the problems enters in the smoothing operators. If N_h and N_H are linear operators, the FAS method is equivalent to the linear multigrid scheme. For many problems, however, the nonlinearity can also be handled globally, resulting in a sequence of linear problems that can be solved efficiently with linear multigrid.

Multigrid for Linear Complementarity Problems

In 1983, Brandt and Cryer [3] proposed a multigrid method for LCPs arising from free boundary problems. The algorithm is based on the projected successive over-relaxation (SOR) method [7] and is called the *projected full approximation scheme (PFAS)* in [3]. PFAS has been successfully used in the financial community for American options with stochastic volatility in [6, 12].

For the smoothing method in PFAS, one employs a projected version of the PGS, consisting of two partial steps per unknown: In a first step, a Gauss–Seidel iteration is applied to equation (5) at (x_i, y_j) with equality sign. In the second partial step, the solution at (x_i, y_j) is projected, so that constraint (6) is satisfied,

$$\begin{aligned} \bar{u}^m(x_i, y_j) &= \max\{f_2(x_i, y_j), \hat{u}(x_i, y_j)\} \\ \forall (x_i, y_j) &\in G_h \end{aligned} \quad (11)$$

where $\bar{u}^m$ denotes the unknown at (x_i, y_j) after PGS and $\hat{u}$ the unknown after the Gauss–Seidel iteration. A linewise variant of PGS has been applied in [6].

The following LCP holds for $e_h^m := u_h - \bar{u}_h^m$:

$$\begin{aligned} A_h e_h^m &\leq d_h^m \quad \mathbf{x} \in \Omega \\ e_h^m + \bar{u}_h^m &\geq f_{2,h} \quad \mathbf{x} \in \Omega \\ (e_h^m + \bar{u}_h^m - f_{2,h})(A_h e_h^m - d_h^m) &= 0 \quad \mathbf{x} \in \Omega \end{aligned} \quad (12)$$

with defect: $d_h^m = f_{1,h} - A_h \bar{u}_h^m$. A smooth error, e_h^m , can be approximated on a coarse grid without any essential loss of information. The LCP coarse-grid equation for the coarse-grid approximation of the error $\widehat{e}_H^m$ is therefore defined in PFAS by:

$$\begin{aligned} A_H \widehat{e}_H^m &\leq I_H^H d_h^m \\ \widehat{e}_H^m + \widehat{I}_H^H \bar{u}_h^m &\geq f_{2,H} \\ (\widehat{e}_H^m + \widehat{I}_H^H \bar{u}_h^m - f_{2,H})(A_H \widehat{e}_H^m - I_H^H d_h^m) &= 0 \end{aligned} \quad (13)$$

For LCPs, we need to choose “constraint preserving” restriction operators that do not mix information from active and inactive regions on coarse grids. Further, the bilinear interpolation operator I_H^h is applied only to unknowns on the “active” points [3].

We finally mention that in [10], another multigrid variant for LCPs, the so-called monotone multigrid method, has been presented, used in finance in [9].

Multigrid as a Preconditioner

Multigrid as a preconditioner is particularly interesting for *robustness*. An argument for combining multigrid with an acceleration technique is that problems become more and more complex if we treat real-life applications. The fundamental idea of multigrid, to reduce the high-frequency error components by smoothing and to take care of the low frequency error by coarse-grid correction, does not always work optimally if straightforward multigrid approaches are used. In such situations, the combination with Krylov subspace methods, such as conjugate gradient, generalized minimal residual (GMRES), or BiCGSTAB, have the potential to give a substantial convergence acceleration. Often, sophisticated multigrid components may also lead to very satisfactory convergence factors, but they can be difficult to realize and implement.

From the multigrid point of view, multigrid as a preconditioner can also be interpreted as an acceleration of multigrid by iterant recombination. This interpretation easily allows generalizations, for example, to nonlinear problems and to LCPs. Let u_h^0 be an initial approximation for solving $A_h u_h = f_h$, and $d_h^0 = f_h - A_h u_h^0$ its defect. The *Krylov subspace*, K_h^m , is defined by $K_h^m := \text{span}[d_h^0, A_h d_h^0, \dots, A_h^{m-1} d_h^0]$. This subspace can also be represented by $\text{span}[u_h^0 - u_h^m, u_h^1 - u_h^m, \dots, u_h^{m-1} - u_h^m]$, where the u_h^m are previous approximations to the solution. To find an improved approximation $u_{h,\text{acc}}^m$, we now consider a linear combination of the $m+1$ latest approximations:

$$u_{h,\text{acc}}^m = u_h^m + \sum_{i=1}^m \bar{\alpha}_i (u_h^{m-i} - u_h^m) \quad (14)$$

In order to obtain an improved approximation $u_{h,\text{acc}}^m$, the parameters $\bar{\alpha}_i$ are determined in such a way that the defect $d_{h,\text{acc}}^m$ is minimized, for example, with respect to the l_2 -norm $\|\cdot\|_2$. This is a classical defect minimization problem [16]. This technique was generalized to LCPs in [12], where PFAS was used as the method whose iterants were recombined.

CORNELIS W. OOSTERLEE

Finite Element Methods

The finite element method (FEM) has been invented by engineers around 1950 for solving the partial differential equations arising in solid mechanics; the main idea was to use the principle of virtual work for designing discrete approximations of the boundary value problems. The most popular reference on FEM in solid mechanics is the book by Zienckiewicz [14]. Generalizations to other fields of physics or engineering have been done by applied mathematicians through the concept of variational formulations and weak forms of the partial differential equations (see, e.g. [4]).

In finance, partial differential equations (PDEs) or partial integro-differential equations (PIDEs) may be used for option pricing. For approximating their solutions, at least four classes of numerical methods can be used:

- *Finite difference methods* are by far the simplest, except when mesh adaptivity is required in which case it is rather difficult to control the numerical error.
- *Finite volume methods* are not really natural, because these methods are better suited for hyperbolic PDEs. In finance, they may be useful, for example, for Asian options when the PDE becomes close to hyperbolic near maturity.
- *Spectral methods* are Galerkin methods with Fourier series of high degree polynomials. They are ideal when the coefficients of the PDE are constant, which is rarely the case in financial engineering. For a very efficient adaptation of spectral methods to finance, see [10].
- *Finite element methods* seem at first glance unnecessarily complex for finance where a large class of problems are one dimensional in space. Yet, they are very flexible for mesh adaptivity and the implementation difficulties are only apparent.

A Simple Example

Take the simplest case, the Black–Scholes model for a put option with a strike K and a maturity T . The price

of the underlying asset is assumed to be a geometric Brownian motion

$$dS_t = S_t(\mu dt + \sigma dW_t) \quad (1)$$

and the volatility σ is allowed to depend on S_t and t . If the volatility function satisfies suitable regularity conditions, the Black–Scholes formula gives the option's price at time $t < T$:

$$P_t = \mathbb{E}^*(e^{-r(T-t)}(K - S_T)^+ | \mathcal{F}_t) \quad (2)$$

where $\mathbb{E}^*(| \mathcal{F}_t)$ stands for the conditional expectation with respect to the risk neutral probability. It can be proved that with $\sigma = \sigma(S_t, T - t)$, then $P_{T-t} = u(S_{T-t}, T - t)$, where u is the solution of

$$\begin{cases} \partial_t u - \frac{\sigma^2 x^2}{2} \partial_{xx} u - rx \partial_x u + ru = 0 \\ \text{for } x > 0, 0 < t \leq T \\ u(x, 0) = (K - x)^+ \end{cases} \quad (3)$$

The variational formulation of equation (3) consists of finding a continuous function u defined on the time interval $[0, T]$ with value in a Hilbert space V (see equation (5)) such that

$$\begin{aligned} \frac{d}{dt}(u, w) + a_t(u, w) &= 0 \\ \text{for a.a. } t \in (0, T) \quad \forall w \in V \\ u(x, 0) &= (K - x)^+ \end{aligned} \quad (4)$$

where

$$\begin{aligned} V &= \left\{ v \in L^2(\mathbb{R}_+) : x \frac{dv}{dx} \in L^2(\mathbb{R}_+) \right\} \\ a_t(u, w) &= \left(\frac{\sigma^2 x^2}{2} \partial_{xx} u, \partial_x w \right) \\ &\quad + (x \partial_x u, (\sigma^2 + x \sigma \partial_x \sigma - r)w) + (ru, w) \\ (u, w) &= \int_0^\infty u(x)w(x) dx \end{aligned} \quad (5)$$

Problem (4) is obtained by multiplying equation (3) by $w(x)$, integrate on $\mathbb{R}^+$, and integrate by part the term containing $\partial_{xx} u$. The precise meaning of equation (4) and the conditions for equation (4) to have a unique solution are subtle. The choice of the space V is dictated by the following: the integrals in equation (4) must exist, and the bilinear form a_t must be continuous on $V \times V$ uniformly in time and

satisfy Gårding's coercivity inequality, that is, that there exist constants c and λ , $c > 0$ and $\lambda \geq 0$ such that

$$a_t(v, v) \geq c\|v\|_V^2 - \lambda\|v\|_{L^2(\mathbb{R}_+)}^2 \quad \forall v \in V \quad (6)$$

Proposition 1 *If σ is a continuous function such that for all x, t , $\sigma(x, t) \in [\sigma_m, \sigma_M]$, $\sigma_m > 0$, and if $x \mapsto x\sigma$ is Lipschitz continuous with a Lipschitz constant independent of t , then equation (4) has a unique solution.*

The simplest finite element methods are discrete versions of equation (4) obtained by replacing V with a finite dimensional space V_h , that is, finding a continuous function u_h defined on the time interval $[0, T]$ with value in the finite dimensional space $V_h \subset V$ such that

$$\frac{d}{dt}(u_h, w_h) + a_t(u_h, w_h) = 0 \quad \text{for a.a. } t \in (0, T) \quad (7)$$

If $\{w^i\}_1^N$ is a basis of V_h , then equation (6) is equivalent to

$$\begin{aligned} \frac{d}{dt} \left(\sum_1^N u_j w^j, w^i \right) + a_t \left(\sum_1^N u_j w^j, w^i \right) &= 0 \\ \forall i &= 1, \dots, N \end{aligned} \quad (8)$$

which is a system of differential equations

$$\begin{aligned} B \frac{dU}{dt} + A(t)U &= 0 \quad \text{where } B_{ij} = (w^j, w^i) \\ A_{ij}(t) &= a_t(w^j, w^i) \end{aligned} \quad (9)$$

A discrete time stepping scheme has still to be applied to equation (9), for instance, the Euler implicit scheme

$$B \frac{U^{m+1} - U^m}{\delta t_m} + A^{m+1}U^{m+1} = 0 \quad (10)$$

where $A^m = A(t_m)$. The easiest choice is to take V_h as a space of piecewise linear functions (linear finite elements), that is,

$$\begin{aligned} V_h &= \{v_h \text{ continuous, linear on each subinterval} \\ &\quad [x_{i-1}, x_i], v_h(L) = 0\} \end{aligned}$$

where $(x_i)_{i=1, \dots, N}$ is an increasing sequence in the interval $[0, L] \approx \mathbb{R}^+$, with $x_1 = 0$ and $x_N = L$. Then a good choice for w^i is to be the (hat) function of V_h , which is equal to one at x_i and zero at x_j , $j \neq i$ (see [2]). With this basis, called the *nodal basis*, the integrals B_{ij} and A_{ij} can be computed exactly.

It is easy to show that the matrices A and B are tridiagonal so that a resolution of the linear system (10) at each time step is best done with a Gaussian elimination method or an LU factorization. In the end the computational complexity is the same as for a finite difference method with either an explicit or an implicit time scheme.

Convergence in the V -norm can be proved to be of the order of $h + \delta t$ ($h^2 + \delta t$ in the L^2 -norm); it is possible to improve it by using Crank–Nicolson scheme and higher order polynomials instead of the linear ones. Most interesting is the following *a posteriori* estimate:

Proposition 2

$$\begin{aligned} [[u - u_{h, \delta t}]](t_n) &\leq c(u_0)\delta t \\ &+ c \frac{\mu}{\sigma_m^2} \left(\sum_{m=1}^n \eta_m^2 + (1 + \rho)^2 \max(2, 1 + \rho) \right. \\ &\quad \times \sum_{m=1}^n \frac{\delta t_m}{\sigma_m^2} \prod_{i=1}^{m-1} (1 - 2\lambda \delta t_i) \sum_{\omega \in \mathcal{T}_{mh}} \eta_{m, \omega}^2 \left. \right)^{1/2} \end{aligned} \quad (11)$$

where μ is the continuity constant of a_t , $\rho = \max_{2 \leq n \leq N} \delta t_n / \delta t_{n-1}$, $\mathcal{T}_{mh}$ is the partition of $(0, L)$ in small intervals ω at time t_m and

$$\begin{aligned} \eta_m^2 &= \delta t_m e^{-2\lambda t_{m-1}} \frac{\sigma_m^2}{2} |u_h^m - u_h^{m-1}|_V^2 \\ \eta_{m, \omega} &= \frac{h_\omega}{x_{\max}(\omega)} \left\| \frac{u_h^m - u_h^{m-1}}{\delta t_m} - r x \frac{\partial u_h^m}{\partial x} + r u_h^m \right\|_{L^2(\omega)} \end{aligned} \quad (12)$$

and h_ω is the diameter of ω .

Note that everything is known after the computation of u_h ; the mesh can then be adapted by using the error indicators η_m and $\eta_{m, \omega}$. Figure 1 shows the computed *a posteriori* error and the actual error for

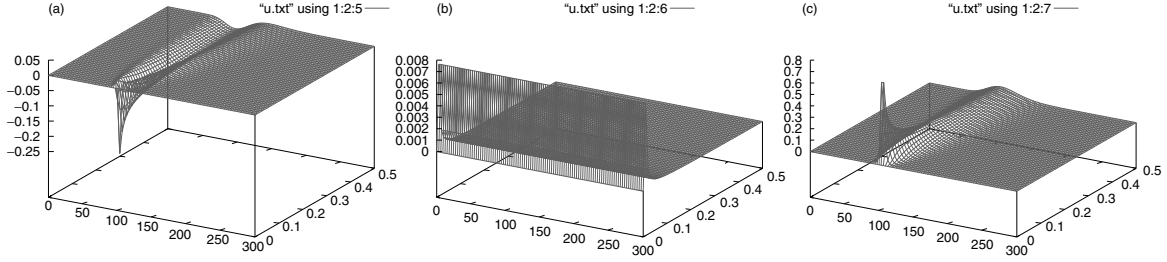

Figure 1 (a) The graph displays the error between the computed solution on a uniform mesh and one computed with Black-Scholes formula. (b) The graph shows $\rho_{\delta t}$; (c) the graphs show $\eta_{n,\omega}$ as a function of x and t . The parameters are $K = 100$, $T = 0.5$, $r = 0$, $\sigma = 0.3$, 50 time steps, and 100 mesh points

a vanilla put with constant volatility and comparison with the Black-Scholes analytic formula.

Stochastic Volatility Models

We now discuss a more involved stochastic volatility model where $dS_t = S_t(\mu dt + \sigma_t dW_t)$, with $\sigma_t = f(Y_t)$ and Y_t is a mean-reverting Ornstein-Uhlenbeck process

$$dY_t = \alpha(m - Y_t) dt + \beta d\hat{Z}_t \quad (13)$$

and $\hat{Z}_t = \rho W_t + \sqrt{1 - \rho^2} Z_t$, W_t and Z_t are two uncorrelated Brownian motions. In the Stein-Stein model, see [12], $f(Y_t) = |Y_t|$.

If $P(S, y, T - t)$ is the pricing function of a put option, it is convenient to introduce

$$u(S, y, t) = P(S, y, T - t) e^{-(1-\eta)(y-m)^2/2v^2} \quad (14)$$

where η is any parameter between 0 and 1 and $v^2 = \beta^2/(2\alpha)$.

A clever financial argument (see [7]) shows that when $\rho = 0$ for simplicity, the new unknown u satisfies, for all $x > 0$, $y \in \mathbb{R}$, $t > 0$

$$\begin{cases} \frac{\partial u}{\partial t} - \frac{1}{2}y^2x^2\frac{\partial^2 u}{\partial x^2} - \frac{1}{2}\beta^2\frac{\partial^2 u}{\partial y^2} - rx\frac{\partial u}{\partial x} + e\frac{\partial u}{\partial y} \\ \quad + fu = 0 \\ u(x, y, 0) = (K - x)^+ \quad \text{for } x > 0, y \in \mathbb{R} \end{cases} \quad (15)$$

whereof

$$e = -(1 - 2\eta)\alpha(y - m) + \beta\gamma$$

$$f = r + 2\frac{\alpha^2}{\beta^2}\eta(1 - \eta)(y - m)^2$$

$$+ 2(1 - \eta)\frac{\alpha}{\beta}(y - m)\gamma - \alpha(1 - \eta) \quad (16)$$

and γ is a *risk premium factor*, possibly a function of x, y, t ; see [1] for the details.

This parabolic equation is degenerate near the axis $y = 0$ because the coefficient in front of $x^2\frac{\partial^2 u}{\partial x^2}$ vanishes on $y = 0$. Following [1], see also [2, 3], let us consider the weighted Sobolev space V on $Q = \mathbb{R}^+ \times \mathbb{R}$:

$$V = \left\{ v : v\sqrt{1 + y^2}, \frac{\partial v}{\partial y}, x|y|\frac{\partial v}{\partial x} \in L^2(Q) \right\} \quad (17)$$

which is a Hilbert space such that all the properties needed by the variational arguments sketched earlier hold.

Theorem 1 *If the data are smooth (see [1, 3]) and if*

$$r(t) \geq r_0 > 0, \quad \alpha^2 > 2\beta^2, \quad 2\alpha^2\eta(1 - \eta) > \beta^2 \quad (18)$$

then equation (15) has a unique weak solution.

Finite Element Solution

As usual, we localize the problem in $\Omega := (0, L_x) \times (-L_y, L_y)$. No boundary condition is needed on the axis $x = 0$ since the PDE is degenerate there. Note also that u is expected to tend to zero as x tends to infinity. For large y , no arguments seem to give a boundary condition. However, if L_y is chosen such that $\alpha(L_y \pm m) \gg \beta^2$, then for $y \sim \pm L_y$, the coefficient of the advection term in the y direction, that is, $\alpha(y - m)$, is much larger in absolute value

than the coefficient of the diffusion in the y direction, that is, $\frac{\beta^2}{2}$. Furthermore, near $y = \pm L_y$, the vertical velocity $\alpha(y - m)$ is directed outward Ω . Therefore, the error caused by an artificial condition on $y = \pm L_y$ is damped away from the boundaries, and localized in boundary layers whose width is of the order of $\frac{\beta^2}{\alpha y}$. We may thus apply a Neumann condition.

Then one must write the problem in variational form: find u in V_0 the subset of V of functions that are zero at $x = L_x$ and

$$\begin{cases} \frac{d}{dt}(u, w) + a(u, w) = 0 & \forall w \in V_0 \\ u(x, y, 0) \text{ given} \end{cases} \quad (19)$$

with

$$\begin{aligned} a(u, w) = & \int_{\Omega} \frac{y^2 x^2}{2} \partial_x u \partial_x w + \frac{\beta^2}{2} \partial_y u \partial_y w \\ & + (y^2 - r)x \partial_x u + (e + \beta \partial_y \beta) \partial_y u + fu)w \end{aligned} \quad (20)$$

Now Ω is triangulated into a set of nonintersecting triangles $\{\omega_k\}_1^K$ in such a way that no vertices lie in the middle of an edge of another triangle. V_0 is approximated by V_{0h} the space of continuous piecewise linear functions on the triangulation, which vanish at $x = L_x$.

The functions of V_{0h} are completely determined by their values at the vertices of the triangles, so if we denote by w^i the function in V_{0h} , which takes the value zero at all vertices except the i th one where it is one, then $\{w^i\}_1^N$ is a basis of V_{0h} if N is the number of vertices not on $x = L_x$ (it is convenient for the presentation to number the nodes on the boundary last).

As in the one-dimensional case

$$u_h^m(x, y) = \sum_1^N u_i^m w^i(x, y) \quad (21)$$

is an approximation of $u(t_m)$ if the u_i^{m+1} are solutions of

$$B \frac{U^{m+1} - U^m}{\delta t_m} + AU^{m+1} = 0 \quad (22)$$

with $B_{ij} = (w^j, w^i)$ and $A_{ij} = a(w^j, w^i)$.

Numerical Implementation

Integrals of polynomial expressions of x, y can be evaluated exactly on triangles (formula (4.19) in [2]). The difficulty is in the strategy to solve the linear systems (22). Multigrid seems to give the best results in term of speed [11], but the computer program may not be so easy to write for an arbitrary triangulation. Since the number of vertices are not likely to exceed a few thousands, fast multifrontal libraries such as SuperLU [6] can be used with a minimum programming effort. Table 1 shows the gain in time over more classical algorithms.

Alternatively one could also use a preconditioned conjugate gradient-like iterative method (see **Conjugate Gradient Methods**). Another way is to use FreeFem++ [9], which is a general two-dimensional PDE solver particularly well suited to these option pricing models, where the coefficients are involved functions and one may want to try to change them often. Results for equation (22) obtained with the following FreeFem++ code are shown in Figure 2.

A similar program has been developed in 3D by S. Delpino: freefem3d. However, mesh refinement is not yet implemented. A basket option has been computed for illustration (Figure 3). The script that drives the program is self-explanatory and gives the values used.

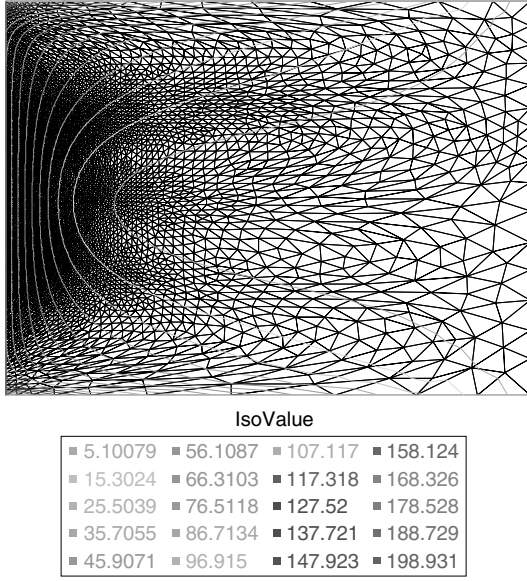

Figure 2 Solution of equation (15) for a put with maturity $T = 1$, strike $K = 100$ with $r = 0.02$, $\beta = \alpha = 1$, and $m = 0.2$. We have used the automatic mesh adaptivity of FreeFem++; the contours and the triangulation are shown

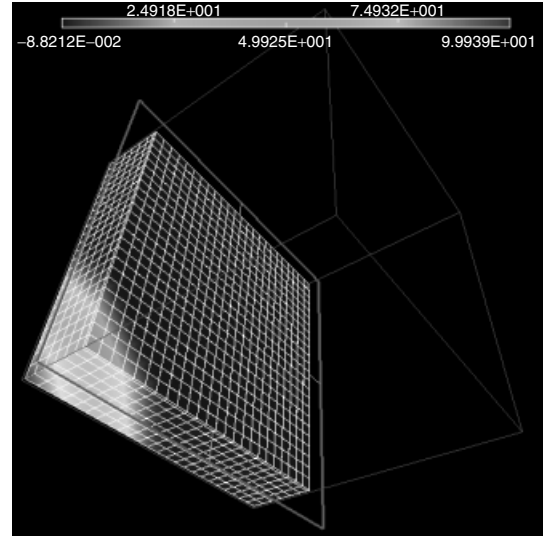

Figure 3 A put on a basket of three assets computed with freefem3d [5] with maturity $T = 0.5$, strike $K = 100$, and so on (see the listing). The visualization is done with medit also public domain [8]

Asian Calls

For the financial modeling of Asian options, we refer to [13] and the references therein.

We consider an Asian put with fixed strike whose payoff is $P_0(S, y) = (y - K)_+$, calling y the average value of the asset in time, $y = 1/t \int_0^t S(\tau) d\tau$. The price of the option is found by solving for all

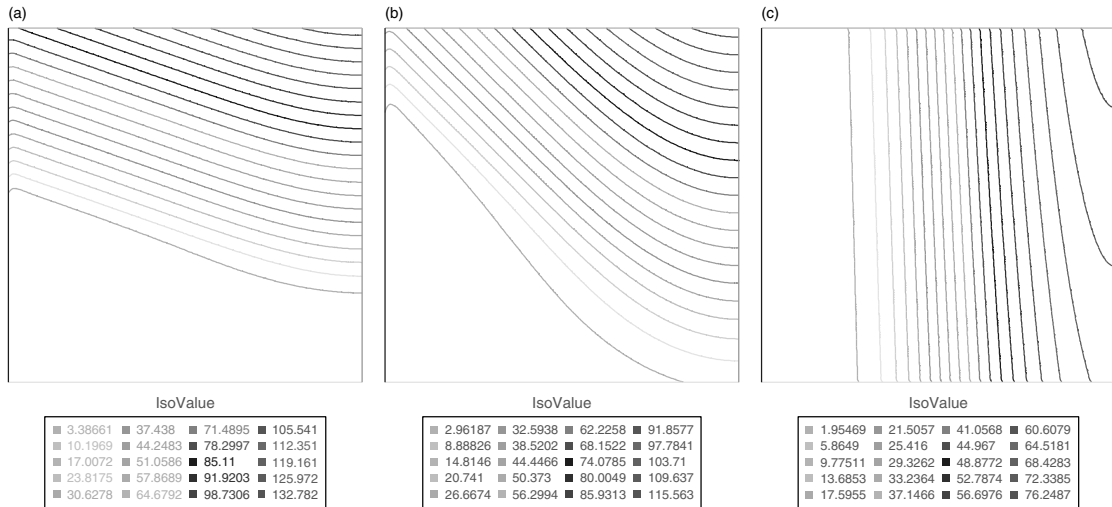

Figure 4 Solution of equation (24) for an Asian option of maturity $T = 4$ and strike $K = 100$ when the interest rate is 0.03 and the volatility 0.3. The figure shows the contours at times 0.96 (a), 1.96 (b), and 3.96 (c)

$$\{x, y, t\} \in \mathbb{R}^+ \times \mathbb{R}^+ \times (0, T]$$

$$\begin{aligned} \partial_t u - \partial_x \left(\frac{\sigma^2 x^2}{2} \partial_x u \right) + (\sigma^2 - r)x \partial_x u \\ + \frac{y-x}{T-t} \partial_y u + ru = 0 \end{aligned} \quad (23)$$

$$\begin{aligned} u(x, y, 0) = (y - K)^+, \quad \partial_x u|_{+\infty, y, t} \\ \approx \begin{cases} \frac{t}{T} e^{-rt} & \text{if } y < \frac{KT}{T-t} \\ \frac{1-re^{-rt}}{Tr} & \text{otherwise} \end{cases} \end{aligned} \quad (24)$$

The difficulties of this problem is that the second-order part of the differential operator is incomplete and the convective velocity $v = ((\sigma^2 - r)x, \frac{y-x}{T-t})^T$ tends to infinity as $t \rightarrow T$; so great care must be taken for the upwinding of these first-order terms. One of the best upwinding is the characteristic finite element method, whereby

$$\partial_t u + v \cdot \nabla u|_{x, y, t_{m+1}} \approx \frac{1}{\delta t} (u^{m+1}(q) - u^m(Q))$$

with

$$Q = q - \delta t v \left(q - v(q) \frac{\delta t}{2} \right) \quad \text{where } q = (x, y)^T \quad (25)$$

The discontinuous P^2 reconstruction with characteristic convection of the gradient and of the value at the center of gravity is applied. The domain is localized to $(0, L) \times (0, L)$, with $L = 250$, that is, greater than twice the contract price $K = 100$, in this example; the interest rate is $r = 3\%$ and the volatility $\sigma = 0.3$. The square domain is triangulated by a uniform 50×50 mesh and we have taken 50 time steps over the four-years period of this example ($T = 4$). The results are shown in Figure 4 at time $t = 0.96, 1.96$, and 3.96 .

Fourier Transform

Discrete Fourier Transform (DFT)

The n th root of unity is denoted by $z_n := \cos \frac{2\pi}{n} + i \sin \frac{2\pi}{n} = e^{i\frac{2\pi}{n}}$. Geometrically, the numbers z_n^j , with $j = 0, \dots, n-1$, represent n equidistantly spaced points on the unit circle in the complex plane. The point z_n^{j+1} is reached from z_n^j by turning $1/n$ th of the full circle anticlockwise.

Definition 1 Given an n -dimensional vector $a = [a_0, a_1, \dots, a_{n-1}]$, we say that

$$\text{rev}(a) := [a_0, a_{n-1}, \dots, a_1] \quad (1)$$

is a in reverse order. Intuitively, if a is written around the circle in the anticlockwise direction, then $\text{rev}(a)$ is obtained by reading from a_0 in the clockwise direction.

Definition 2 The discrete Fourier transform (DFT) of $a = [a_0, a_1, \dots, a_{n-1}] \in \mathbb{C}^n$ is the vector $b = [b_0, b_1, \dots, b_{n-1}] \in \mathbb{C}^n$ such that

$$b_k = \frac{1}{\sqrt{n}} \sum_{j=0}^{n-1} a_j z_n^{jk} = \frac{1}{\sqrt{n}} \sum_{j=0}^{n-1} a_j e^{i\frac{2\pi}{n}jk} \quad (2)$$

We write

$$b = \mathcal{F}(a) \quad (3)$$

Equation (2) represents the forward transform. The inverse transform is given by

$$a_l = \frac{1}{\sqrt{n}} \sum_{k=0}^{n-1} b_k z_n^{-kl} = \frac{1}{\sqrt{n}} \sum_{k=0}^{n-1} b_k e^{-i\frac{2\pi}{n}kl} \quad (4)$$

and we write

$$a = \mathcal{F}^{-1}(b) \quad (5)$$

Proposition 1 The following statements hold:

1. The inverse DFT of sequence b is the same as the forward transform of the same sequence in the reverse order:

$$\mathcal{F}^{-1}(b) = \mathcal{F}(\text{rev}(b)) \quad (6)$$

and vice versa

$$\mathcal{F}^{-1}(\text{rev}(b)) = \mathcal{F}(b) \quad (7)$$

2. $\mathcal{F}^{-1}$ is indeed an inverse transformation to $\mathcal{F}$, that is,

$$\mathcal{F}^{-1}(\mathcal{F}(a)) = \mathcal{F}(\mathcal{F}^{-1}(a)) = a \quad (8)$$

Next, we explain the relationship between binomial option pricing and the DFT.

Binomial Option Pricing

Consider a two-period binomial model (see **Binomial Tree**) with a high rate of return of 25% and a low rate of return of -20%. Assuming that the initial stock price is 100, the evolution of the stock price in the two periods ahead is given in Table 1.

Suppose that we wish to price a call option struck at $K = 100$, maturing two periods from now. The risk-free rate is 0%. The intrinsic value of the option at maturity is

$$C(2, :) = [56.25 \quad 0 \quad 0]^\top \quad (9)$$

As per the asset pricing theory, the no-arbitrage price of the option is given recursively as

$$C(t, j) = \frac{q_u C(t+1, j) + q_d C(t+1, j+1)}{R_f} \quad (10)$$

where the risk-neutral probabilities q_u and q_d satisfy

$$q_u = \frac{R_f - R_d}{R_u - R_d} = \frac{1 - 0.8}{1.25 - 0.8} = \frac{4}{9} \quad (11)$$

$$q_d = 1 - q_u = \frac{5}{9} \quad (12)$$

Here, $R_u = S(t+1, j)/S(t, j)$, $R_d = S(t+1, j+1)/S(t, j)$, and $R_f - 1$ is equal to the risk-free rate. Recursive application of equation (10) with terminal value (9) leads to option prices as given in Table 2.

Option Pricing by Circular Convolution

For any two n -dimensional vectors $a = [a_0, a_1, \dots, a_{n-1}]$ and $b = [b_0, b_1, \dots, b_{n-1}]$, we define *circular* (cyclic) convolution of a and b to be a new vector $c = [c_0, c_1, \dots, c_{n-1}]$,

$$c = a \circledast b \quad (13)$$

Table 1 Binomial stock price lattice

Number of low returns j	$S(0, j)$	$S(1, j)$	$S(2, j)$
0	100	125	156.25
1		80	100
2			64

Table 2 Option prices in a binomial lattice

Number of low returns j	$C(0, j)$	$C(1, j)$	$C(2, j)$
0	$11\frac{1}{9}$	25	56.25
1		0	0
2			0

such that

$$c_j = \sum_{k+l=j \text{ or } k+l=j+n} a_k b_l \quad (14)$$

We use the binomial example to illustrate the use of circular convolution in option pricing. At maturity, the option has three values:

$$C(2, :) = [56.25 \quad 0 \quad 0]^\top \quad (15)$$

Let vector q contain the conditional one-period risk-neutral probabilities $q_u = 0.43523$ and $q_d = 0.56477$. Since there are just two states over one period the remaining entries will be padded by zeros:

$$q = [q_u \quad q_d \quad 0]^\top \quad (16)$$

To compute option prices at time $t = 1$, we evaluate

$$C(1, :) = C(2, :) \circledast \text{rev}(q) / R_f = [25 \quad 0 \quad 31.25]^\top \quad (17)$$

Note that we need only the first two prices in equation (17). The last entry is meaningless—it corresponds to the no-arbitrage price of the payoff $[0 \ 56.25]$. Moving backward in time, we have

$$\begin{aligned} C(0, :) &= C(1, :) \circledast \text{rev}(q) / R_f \\ &= \left[11\frac{1}{9} \quad 17\frac{13}{36} \quad 27\frac{7}{9} \right]^\top \end{aligned} \quad (18)$$

Again, only the first entry is meaningful.

This procedure can be generalized to multinomial lattices as follows.

Proposition 2 Consider an N -period model in which the random variables S_{t+1}/S_t are independent, identically distributed under the risk-neutral measure and such that $\ln S_{t+1}/S_t$ takes k distinct, equidistantly spaced values with probabilities $q_1, \dots, q_k$. Then stock price can be represented by a multinomial lattice with $1 + t(k - 1)$ values at time t . Let $C(N, :) \in \mathbb{R}^n$, $n = 1 + N(k - 1)$, be the payoff of a derivative asset as a function of S_N , and define risk-neutral price of the option recursively by setting

$$\begin{aligned} C(t, j) &= \sum_{l=1}^k q_l C(t+1, j+l-1), \\ 1 \leq l \leq 1 + t(k-1) \end{aligned} \quad (19)$$

Let q be a vector with first k entries $q_1, \dots, q_k$ and padded by zeros to dimension n . Then $C(t, :)$ can also be obtained from the following formula:

$$C(t, :) = C(N, :) \circledast \overbrace{\text{rev}(q) \circledast \text{rev}(q) \circledast \dots \circledast \text{rev}(q)}^{(N-t) \text{ times}} \quad (20)$$

The vector $C(t, :)$ computed in this manner has more entries than required (n in total); the useful $1 + t(k - 1)$ entries are at the top end of the vector.

Pricing via Discrete Fourier Transform

In this section, we reformulate the circular pricing formula (20) using the DFT.

Proposition 3 Consider $a, b \in \mathbb{C}^n$. The following equalities hold:

$$\mathcal{F}(a \circledast b) = \sqrt{n} \mathcal{F}(a) \mathcal{F}(b) \quad (21)$$

$$\mathcal{F}^{-1}(a \circledast b) = \sqrt{n} \mathcal{F}^{-1}(a) \mathcal{F}^{-1}(b) \quad (22)$$

Now applying the inverse transform $\mathcal{F}^{-1}$ to both sides of equation (20) and using property (22) on the

right-hand side

$$\mathcal{F}^{-1}(C_0) = \mathcal{F}^{-1}(C_N) \times \left(\sqrt{\text{dimension of } C_N} \mathcal{F}^{-1}(\text{rev}(q)) / R_f \right)^N \quad (23)$$

Recall from equation (7) that $\mathcal{F}^{-1}(\text{rev}(q)) = \mathcal{F}(q)$, and substitute this into equation (23). Finally, applying the forward transform to both sides again, and using equation (8) on the left-hand side, we obtain

$$C_0 = \mathcal{F} \left(\mathcal{F}^{-1}(C_N) \times \left(\sqrt{\text{dimension of } C_N} \mathcal{F}(q) / R_f \right)^N \right) \quad (24)$$

Fast Fourier Transform (FFT)

A naive implementation of the DFT algorithm with an n -dimensional input requires n^2 complex multiplications. An efficient implementation of DFT, known as the *fast Fourier transform (FFT)*, will only require $Kn \ln n$ operations, but one still has to choose n carefully because the constant K can be very large for some choices of n . There are many instances when FFT of length n_1 is faster than FFT of length n_2 even though $n_1 > n_2$. This slightly counterintuitive phenomenon is illustrated in Table 3. In general, it is advisable to use the transform size of the form $n = 2^p 3^q 5^r$, where q and r should be small compared to p . In the context of option pricing, this is always possible by padding the payoff vector C_N with a sufficient number of zeros.

An efficient implementation of FFT for all transform lengths is suggested in [17]. Efficient implementation of mixed 2, 3, 5-radix algorithm is

Table 3 Execution time of FFT algorithm for different input lengths n

n	Factorization	Execution time (seconds)
999 983	999 983	26.3
2097 150	$2 \times 3 \times 5^2 \times 11 \times 31 \times 41$	1.4
2097 152	2^{21}	0.42
2160 000	$2^7 3^3 5^4$	0.40

Intel Core 2, 2 GHz, 2Gb RAM, Matlab 6.5.

due to Temperton [25]. Duhamel and Vetterli [15] survey a wide range of FFT algorithms. Fast implementation of equation (24) for Gauss and Matlab is discussed in [7].

FFT in Continuous-time Models

In the continuous-time limit, the DFT is replaced by the (continuous) Fourier transform: that is, for a contingent claim with payoff $C_T = f(\ln S_T)$, we wish to find coefficients $\psi(v)$ such that

$$f(x) = \int_{\beta-i\infty}^{\beta+i\infty} \psi(v) e^{vx} dv \quad (25)$$

for some real constant β [19]. The recipe for obtaining the coefficients $\psi(v)$ is known—it is given by the inverse Fourier transform:

$$\psi(v) = \frac{1}{2\pi i} \int_{-\infty}^{+\infty} f(x) e^{-vx} dx \quad (26)$$

For example, the payoff of a European call option with strike price e^k corresponds to $f(x) = (e^x - e^k)^+$, whereby, simple integration yields

$$\psi(v) = \frac{e^{(1-v)k}}{2\pi i v(v-1)} \text{ for } \text{Re } v > 1 \quad (27)$$

Substituting for C_T from equation (25) the risk-neutral pricing formula reads

$$\begin{aligned} C_0(\ln S_0) &= e^{-rT} \mathbb{E}[C_T(\ln S_T)] \\ &= e^{-rT} \mathbb{E} \left[\int_{\beta-i\infty}^{\beta+i\infty} \psi(v) e^{v \ln S_T} dv \right] \\ &= e^{-rT} \int_{\beta-i\infty}^{\beta+i\infty} \psi(v) e^{v \ln S_0} \mathbb{E}[e^{v \ln S_T / S_0}] dv \end{aligned} \quad (28)$$

In practice, one is mainly interested in models where the risk-neutral characteristic function of log stock return $\phi(-iv) := \mathbb{E}[e^{v \ln S_T / S_0}]$ is available in the closed form. This is the case in the class of exponential Lévy models with affine stochastic volatility process, discussed in [6] (*see also Time-changed Lévy Process*). This class contains a large number of popular models allowing for excess kurtosis, stochastic volatility, and leverage effects. It includes, among

others, the stochastic volatility models of Heston [18] (see **Heston Model**), Duffie *et al.* [14], and all exponential Lévy models (cf. [16, 23], see **Exponential Lévy Models**). For a detailed description of affine processes, see [13, 20].

Option pricing, therefore, boils down to the evaluation of integrals of the type

$$\begin{aligned} C_0(\ln S_0) &= S_0 e^{-rT} \int_{\beta-i\infty}^{\beta+i\infty} \frac{e^{(v-1)(\ln S_0-k)}}{2\pi v(v-1)} \phi(-iv) dv \\ &= 2S_0 e^{-rT} \int_{\beta+i0}^{\beta+i\infty} \operatorname{Re} \left(\frac{e^{(v-1)(\ln S_0-k)}}{2\pi v(v-1)} \phi(-iv) \right) dv \end{aligned} \quad (29)$$

where both $\psi(v)$ and $\phi(v)$ are known. To evaluate equation (29), one truncates the integral at a high value of $\operatorname{Im}v$ and then uses a numerical quadrature to approximate it by a sum; see [22] for a detailed exposition. This yields an expression of the following type:

$$\begin{aligned} C_0(\ln S_0) &\approx 2\operatorname{Re} \left(S_0 e^{-rT} \sum_{j=0}^{n-1} w_j \frac{e^{(v_j-1)(\ln S_0-k)}}{2\pi v_j(v_j-1)} \phi(-iv_j) \right) \end{aligned} \quad (30)$$

where the integration weights w_j and abscissas v_j depend on the quadrature rule. It is particularly convenient to use Newton–Cotes rules, which employ equidistantly spaced abscissas. For example, a trapezoidal rule yields

$$v_j = \beta + ij\Delta v \quad (31)$$

$$\operatorname{Im}v_{\max} = (n-1)\Delta v \quad (32)$$

$$w_0 = w_n = \frac{1}{2}\Delta v \quad (33)$$

$$w_1 = w_2 = \dots = w_{n-1} = \Delta v \quad (34)$$

In conclusion, if the characteristic function of log returns is known, one needs to evaluate a single sum (30) to find the option price. Consequently, there is *no need* to use FFT if one wishes to evaluate the option price for *one fixed* log strike k .

FFT Option Pricing with Multiple Strikes

The situation is different if we wish to evaluate the option price (30) for many different strikes simultaneously. Let us consider m values of moneyness $\kappa_l = \ln S_0 - k_l$, ranging from $\kappa_{\max} - m\Delta\kappa$ to $\kappa_{\max}$ with increment $\Delta\kappa$

$$\kappa_l = \kappa_{\max} - l\Delta\kappa \quad (35)$$

$$l = 0, \dots, m-1 \quad (36)$$

The idea of using FFT in this context is due to Carr and Madan [5], who noted that with equidistantly spaced abscissas (31) one can write the option pricing equation (30) for different strike values (35 and 36) as a z -transform with $z_l = e^{-i\Delta v \Delta \kappa l}$:

$$C_{0l} = 2S_0 e^{(\beta-1)\kappa_l - rT} \operatorname{Re} \sum_{k=0}^{n-1} e^{i\Delta v \Delta \kappa kl} a_j \quad (37)$$

$$a_j = w_j \frac{e^{ij\Delta v \kappa_{\max}} \phi(-iv_j)}{2\pi v_j(v_j-1)} \quad (38)$$

Setting $\Delta v \Delta \kappa = \frac{2\pi}{n}$, Carr and Madan obtained a DFT in equation (37). Chourdakis [11] points out that one can evaluate equation (37) by means of a fractional FFT with $\Delta v \Delta \kappa \neq \frac{2\pi}{n}$. For the discussion of relative merits of the two strategies, see [7].

Further Reading

Further applications of FFT appear in [1–4, 10, 12, 24]. For the latest developments in option pricing using (continuous) Fourier transform, see [6, 8, 9, 19, 21]. Proofs of Propositions 1 and 3 can be found in [7].

Acknowledgments

I am grateful to Peter Forsyth and Damien Lamberton for their helpful comments.

ALĚŠ ČERNÝ

Crank–Nicolson Scheme

In a paper published in 1947 [2], John Crank and Phyllis Nicolson presented a numerical method for the approximation of diffusion equations. Starting from the simplest example

$$\frac{\partial V}{\partial t} = \frac{\partial^2 V}{\partial x^2} \quad (1)$$

a spatial approximation on a uniform grid with spacing h leads to the semidiscrete equations

$$\frac{dV_j}{dt} = h^{-2} \delta_j^2 V_j \quad (2)$$

where $V_j(t)$ is an approximation to $V(x_j, t)$ and $\delta_j^2 V_j \equiv V_{j+1} - 2V_j + V_{j-1}$ is a central second difference. Crank–Nicolson time-marching discretizes this in time with a uniform timestep k using the approximation

$$k^{-1} (V_j^{n+1} - V_j^n) = \frac{1}{2} h^{-2} (\delta_j^2 V_j^{n+1} + \delta_j^2 V_j^n) \quad (3)$$

which can be rearranged to give

$$(1 - \frac{1}{2} k h^{-2} \delta_j^2) V_j^{n+1} = (1 + \frac{1}{2} k h^{-2} \delta_j^2) V_j^n \quad (4)$$

This can be viewed as the $\theta = \frac{1}{2}$ case of the more general θ scheme

$$(1 - \theta k h^{-2} \delta_j^2) V_j^{n+1} = (1 + (1-\theta) k h^{-2} \delta_j^2) V_j^n \quad (5)$$

$\theta=0$ corresponds to explicit Euler time-marching, while $\theta=1$ corresponds to fully implicit Euler time-marching. For $\theta > 0$, the θ -scheme defines a tridiagonal system of simultaneous equations, which can be solved very efficiently using the Thomas algorithm to obtain the values for V_j^{n+1} . The scheme is unconditionally stable in the L_2 norm, meaning that the L_2 norm of the solution does not increase for any value of k , provided $\theta \geq 1/2$. The Crank–Nicolson scheme is thus on the boundary of unconditional stability. It is also special in having a numerical error for smooth initial data, which is $O(h^2, k^2)$, whereas the error is $O(h^2, k)$ for other values of θ . The unconditional L_2 stability means that one can choose to make k proportional to h , and, together with the second-order accuracy, this makes the scheme both accurate

and efficient, and hence a very popular choice for approximating parabolic PDEs (see **Partial Differential Equations**).

Application to Black–Scholes Equation

The Crank–Nicolson method is used extensively in mathematical finance for approximating parabolic PDEs such as the Black–Scholes equation, which can be written in reversed-time form (with $\tau \equiv T - t$ being the time to maturity T) as

$$\frac{\partial V}{\partial \tau} = -rV + rS \frac{\partial V}{\partial S} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} \quad (6)$$

Switching to the new coordinate $x \equiv \log S$ gives the transformed equation

$$\frac{\partial V}{\partial \tau} = -rV + (r - \frac{1}{2} \sigma^2) \frac{\partial V}{\partial x} + \frac{1}{2} \sigma^2 \frac{\partial^2 V}{\partial x^2} \quad (7)$$

and its Crank–Nicolson discretization on a grid with uniform timestep k and uniform grid spacing h is

$$(I + \frac{1}{2} D) V_j^{n+1} = (I - \frac{1}{2} D) V_j^n \quad (8)$$

where the discrete operator D is defined by

$$D = r k - \frac{1}{2} k h^{-1} (r - \frac{1}{2} \sigma^2) \delta_{2j} - \frac{1}{2} k h^{-2} \sigma^2 \delta_j^2 \quad (9)$$

with the central first difference operator δ_{2j} defined by $\delta_{2j} V_j \equiv V_{j+1} - V_{j-1}$.

For an European call option with strike K , the initial data at maturity is $V(S, 0) = \max(S - K, 0)$. Figure 1a shows the numerical solution $V(S, 2)$ for parameter values $r=0.05$, $\sigma=0.2$, $K=1$, and timestep/spacing ratio $\lambda \equiv k/h = 10$. The agreement between the numerical solution and the known analytic solution appears quite good, but b and c show much poorer agreement for the approximations to $\Delta \equiv \partial V / \partial S$ and $\Gamma \equiv \partial^2 V / \partial S^2$ (see **Delta Hedging**; **Gamma Hedging**) obtained by central differencing of the numerical solution V_j^n . In particular, note that the maximum error in the computed value for Γ occurs at $S=1$, which is the location of the discontinuity in the first derivative of the initial data. Figure 2a–c show the behavior of the maximum error as the computational grid is refined, keeping fixed the ratio $\lambda \equiv k/h$. It can be seen that for

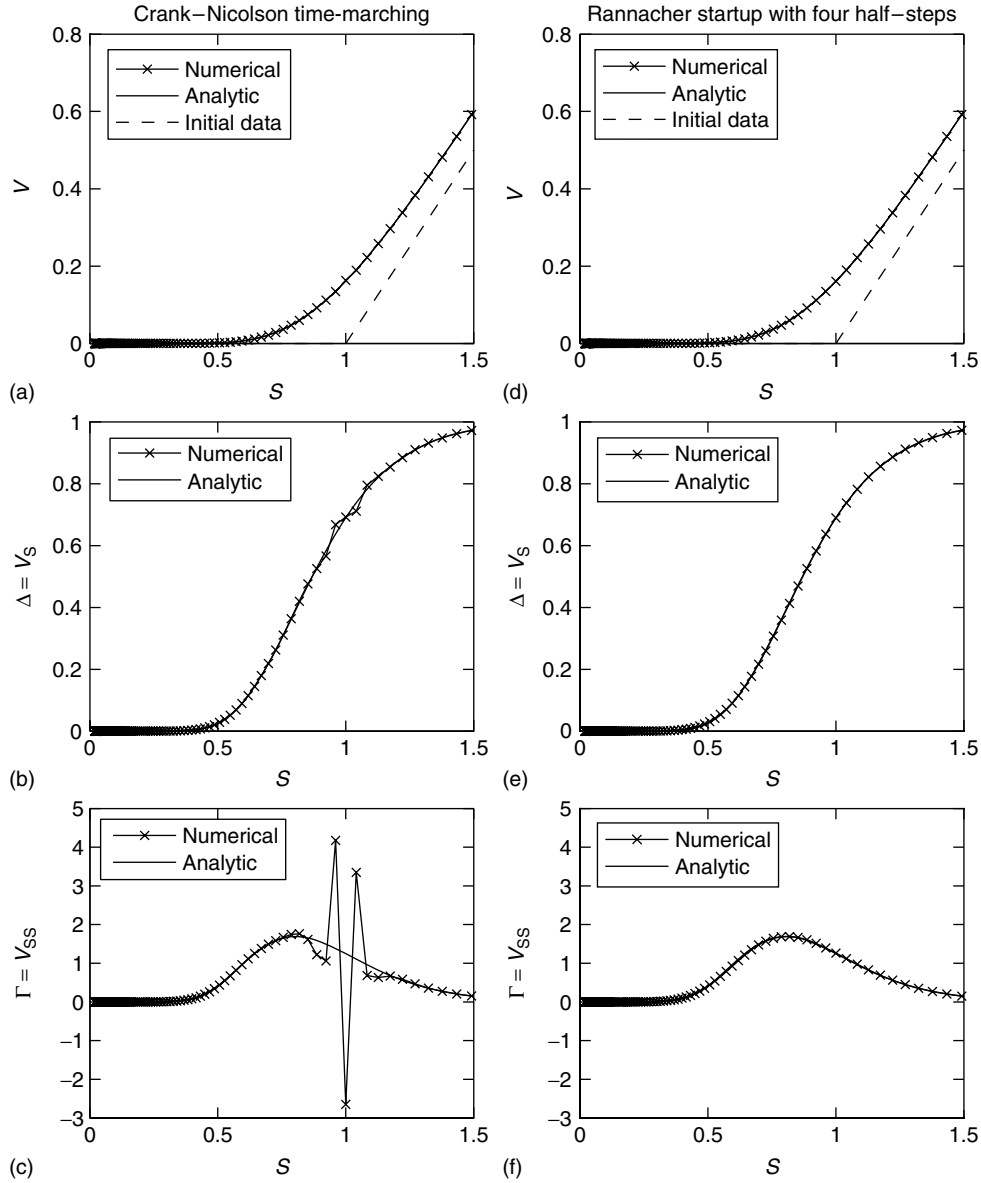

Figure 1 V , Δ and Γ for a European call option, with $\lambda \equiv k/h = 10$

largest value of λ the numerical solution V_j exhibits first-order convergence, while the discrete approximation to Δ does not converge, and the approximation to Γ diverges. For smaller values of λ , it appears that the convergence is better, but, in fact, the asymptotic behavior is exactly the same except that it becomes evident only on much finer grids.

At first sight, this is a little surprising as textbooks almost always describe the Crank–Nicolson method as unconditionally stable and second-order accurate. The key is that it is only unconditionally stable in the L_2 norm, and this only ensures convergence in the L_2 norm for initial data, which has a finite L_2 norm [9]. Furthermore, the order of convergence may be less than second order for initial data, which is not

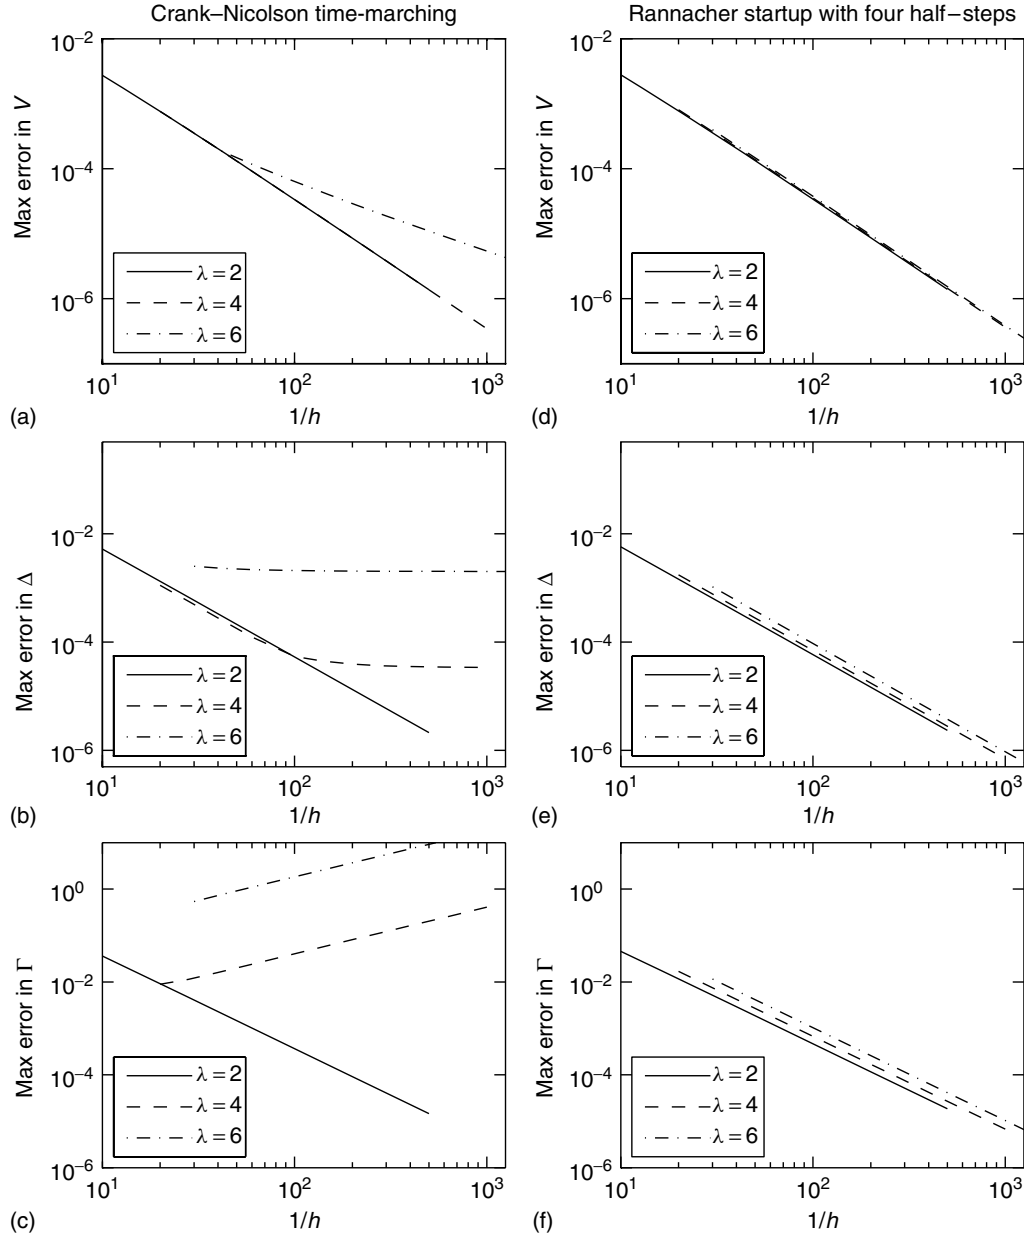

Figure 2 Grid convergence for a European call option, with fixed $\lambda \equiv k/h$

smooth; for example, the L_2 order of convergence for discontinuous initial data is $1/2$. With the European call Black–Scholes application, the initial data for V lies in L_2 , as does its first derivative, but the second derivative is the Dirac delta function, which does not lie in L_2 . This is the root cause of the observed failure

to converge as the grid is refined. Furthermore, it is the maximum error, the L_∞ error, which is most relevant in financial applications.

One solution to this problem is to use an alternative second-order backward difference method, but these methods require special start-up procedures

because they require more than one previous time level, and they are usually less accurate than the Crank–Nicolson method for the same number of timesteps. Better alternatives are higher order backward difference methods [5] or the Rannacher start-up procedure described in the next section.

Rannacher Start-up Procedure

Rannacher analyzed this problem of poor L_2 convergence of convection–diffusion approximations with discontinuous initial data [8], and recovered second-order convergence by replacing the Crank–Nicolson approximation for the very first timestep by two half-timesteps of implicit Euler time integration, and by using a finite element projection of the discontinuous initial data onto the computational grid. This technique, often referred to as *Rannacher timestep-ping*, has been used with success in approximations of the Black–Scholes equations [6, 7], with the half-timestep implicit Euler discretization given by

$$\left(I + \frac{1}{2}D\right) V_j^{n+1/2} = V_j^n \quad (10)$$

The problem has been further investigated by Giles and Carter [4] who analyzed the maximum errors in finance applications and proved that it is necessary to go further and replace the first two Crank–Nicolson timesteps by four half-timesteps of implicit Euler to achieve second-order accuracy in the L_∞ norm for V , Δ and Γ for put, call, and digital options. The improved accuracy is demonstrated by (d–f) in Figures 1 and 2.

Nonlinear and Multifactor Extensions

The use of a nonlinear penalty function in approximating American options (see **Finite Difference Methods for Early Exercise Options**) leads to a nonlinear discretization of the form [3]

$$\left(I + \frac{1}{2}D\right) V_j^{n+1} = \left(I - \frac{1}{2}D\right) V_j^n + P\left(V_j^{n+1}\right) \quad (11)$$

where the nonlinear penalty term $P(V_j^{n+1})$ is negligible in the region where the option is not exercised, and elsewhere ensures that V_j^{n+1} is approximately equal to the exercise value.

This nonlinear system of equations can be solved using a Newton iteration, starting with $V_j^{n+1,0} = V_j^n$

and defining the $m+1^{th}$ iterate to be $V_j^{n+1,m+1} = V_j^{n+1,m} + \Delta V_j$ with the correction ΔV_j given by the linear equations

$$\begin{aligned} & \left(I + \frac{1}{2}D - \frac{\partial P}{\partial V}\right) \Delta V_j \\ &= -\left(I + \frac{1}{2}D\right) V_j^{n+1,m} \\ &+ \left(I - \frac{1}{2}D\right) V_j^n + P\left(V_j^{n+1,m}\right) \end{aligned} \quad (12)$$

Alternatively, one can use just one step of the Newton iteration, in which case one has $V_j^{n+1} = V_j^n + \Delta V_j$ with the change ΔV_j given by

$$\left(I + \frac{1}{2}D - \frac{\partial P}{\partial V}\right) \Delta V_j = -D V_j^n + P(V_j^n) \quad (13)$$

In one dimension, the linear equations are a tridiagonal system that can be solved very efficiently. In higher dimensions, the direct solution cost is much greater and alternative approaches are usually adopted. One is to use an **Alternating Direction Implicit (ADI) Method** approximate factorization into a product of operators, each of which involves differences in only one direction [9]. To maintain second-order accuracy, it is necessary to use the Craig–Sneyd treatment for any cross-derivative term [1]. Another approach is to use a preconditioned iterative solver such as BiCGStab with ILU preconditioning (see **Conjugate Gradient Methods**).

Monotone Schemes

Monotone numerical schemes are particularly relevant for partial differential equations (PDEs) occurring in finance, for example, in the pricing of American options, exotic options, and in portfolio problems [4]. Although naive numerical schemes for such problems may not converge, or if they converge, may converge to an incorrect solution, monotone schemes converge to the correct solution under very weak assumptions on the schemes, equations, and boundary conditions. The drawback is that these schemes may converge slowly, as they are only first- or second-order accurate.

result. Finally, we discuss error estimates for convex problems.

Viscosity Solutions

The concept of viscosity solution was introduced by Crandall and Lions in 1983. A general reference on the subject is the User's Guide [14]. Several books have also been written on the subject, see for example, [1–3, 19, 21]. Viscosity solutions are particularly important for nonlinear or degenerate PDEs of first and second order. There are many such problems in finance, we show some examples taken from [4]. Lower indices denote partial derivatives.

$$\begin{cases} -u_t - \frac{1}{2}\sigma^2 S^2 u_{SS} - rSu_S + ru - \frac{S}{T}u_Z = 0 & \text{in } \mathbb{R}^+ \times \mathbb{R}^+ \times (0, T) \\ u(S, Z, T) = (Z - S)^+ & \text{in } \mathbb{R}^+ \times \mathbb{R}^+ \end{cases} \quad (1)$$

$$\begin{cases} \min\{-u_t - \frac{1}{2}\sigma^2 S^2 u_{SS} - rSu_S + ru, u - (K - S)^+\} = 0 & \text{in } \mathbb{R}^+ \times (0, T) \\ u(S, T) = (K - S)^+ & \text{in } \mathbb{R}^+ \end{cases} \quad (2)$$

$$\begin{cases} \min \left\{ \inf_{c \geq 0} \left[-v_t - \frac{1}{2}\sigma^2 y^2 u_{yy} - (rx - c)u_x - byv_y - U(c) + \beta v \right], \right. \\ \left. -v_y + (1 + \lambda)v_x, -(1 - \mu)v_x + v_y \right\} = 0 \\ \text{in } \{(x, y) : x + (1 - \mu)y \geq 0, x + (1 + \lambda)y \geq 0\} \times (0, T) \end{cases} \quad (3)$$

Convergence results and error estimates for monotone schemes can be obtained using the concept of *viscosity solution*. The main goal of this survey is to introduce these methods and describe the results they lead to. The main results are (i) a general convergence theorem and (ii) error estimates for convex problems.

Viscosity solutions are (very) weak solutions of linear and nonlinear first- and second-order equations. They are closely related to the maximum (comparison) principle from which uniqueness of solutions follows. Viscosity solutions are useful for proving convergence of numerical schemes, because they are stable under very weak continuity assumptions: if a sequence of equations and their viscosity solutions converge locally uniformly, then the limit solution is a viscosity solution of the limit equation. The general convergence results is an extension of this statement.

We first motivate and define viscosity solutions and discuss basic facts about them. Then we discuss monotone schemes and give the general convergence

and in the last case we also impose state-constrained boundary conditions. The first two problems are related to the pricing of Asian and American options. The first equation is degenerate in the Z -direction and at $S = 0$ (meaning there is no diffusion here), the second equation is an obstacle problem with degeneracy at $S = 0$. The last one, related to an investment-consumption model by Tourin and Zariphopoulou, is nonlinear, degenerate, and has difficult boundary conditions.

Note that to solve these problems numerically, we must reduce to bounded domains and hence we need to impose further boundary conditions. All of these equations are *degenerate elliptic* equations that can be written in the following abstract form:

$$F(x, u(x), Du(x), D^2u(x)) = 0 \quad \text{in } \Omega \quad (4)$$

for some domain (open connected set) Ω in $\mathbb{R}^N$ and function $F(x, r, p, X)$ on $\Omega \times \mathbb{R} \times \mathbb{R}^N \times \mathcal{S}_N$ where $\mathcal{S}_N$ is the space of all real symmetric $N \times N$ matrices,

and where F satisfies the condition

$$F(x, r, p, X) \leq F(x, s, p, Y) \quad \text{whenever } r \leq s \quad \text{and } X \geq Y \quad (5)$$

Here, $X \geq 0$ means that X is a positive semidefinite matrix. The assumption that F is nonincreasing in X is called *degenerate ellipticity*. Note that assumption (5) rules out many quasi-linear equations like, for example, conservation laws, and that we represent both time-dependent and time-independent problems in the form (4). In the time-dependent case, we take $x = (t, x')$ for $t \geq 0$, $x' \in \mathbb{R}^{N-1}$. It is an instructive exercise to check that the above equations satisfy equation (5). This abstract formulation will help us formulate results in an economical way.

A *classical solution* of equation (4) is a function u in $C^2(\Omega)$ (twice continuous differentiable functions on Ω) satisfying equation (4) in every point in Ω . We now define viscosity solution for equation (4) starting with the following observation: if u is a classical solution of equation (4), ϕ belongs to $C^2(\Omega)$, and $u - \phi$ has local maximum at $x_0 \in \Omega$, then

$$Du(x_0) = D\phi(x_0) \quad \text{and} \quad D^2u(x_0) \leq D^2\phi(x_0) \quad (6)$$

and hence by equations (4) and (5) we must have

$$F(x_0, u(x_0), D\phi(x_0), D^2\phi(x_0)) \leq 0 \quad (7)$$

On the other hand, if x_0 is a local minimum point of $u - \phi$, then we get the opposite inequality. If these inequalities hold for *all test functions* ϕ and *all maximum/minimum points* x_0 of $u - \phi$ and the function u belongs to C^2 , then it easily follows that u is a classical solution of equation (4).

This second definition of classical solutions can be used to define viscosity solutions simply by relaxing the regularity assumption on u from C^2 to continuous. Note that in this definition, only test functions need to be differentiated.

Definition 1 A viscosity solution of equation (4) is a continuous function u on Ω satisfying

$$F(x_0, u(x_0), D\phi(x_0), D^2\phi(x_0)) \leq 0 \quad (8)$$

for all C^2 test functions ϕ and all maximum points x_0 of $u - \phi$, and

$$F(x_1, u(x_1), D\phi(x_1), D^2\phi(x_1)) \geq 0 \quad (9)$$

for all C^2 test functions ϕ and all minimum points x_1 of $u - \phi$.

By the previous discussion, we see that all classical solutions are viscosity solutions and that all C^2 viscosity solutions are classical solutions.

A problem that is often encountered when you study nonlinear equations is that classical solutions may not exist and weak solutions are not unique [2, 18]. To pick out the physically relevant solution (and solve the nonuniqueness problem), we often have to require that additional (entropy) inequalities are satisfied by the solution. One of the main strengths of viscosity solutions is that they are unique under very general assumptions—in some sense the additional constraints are built into the definition.

Example 1 Consider the following initial value problem,

$$\begin{aligned} u_t + |u_x| &= 0 \quad \text{in } \mathbb{R} \times (0, +\infty), \\ u(0, x) &= |x| \quad \text{in } \mathbb{R} \end{aligned} \quad (10)$$

It has *no* classical solutions, *infinitely many* generalized solutions (functions satisfying the equation a.e.), and one *unique* viscosity solution. Two generalized solutions are $|x| - t$ and $(|x| - t)^+$, and the last one is also the viscosity solution.

Now we explain how to impose boundary conditions for degenerate equations satisfying equation (5). Consider

$$\begin{cases} F(x, u(x), Du(x), D^2u(x)) = 0 & \text{in } \Omega \\ G(x, u, Du) = 0 & \text{in } \partial\Omega \end{cases} \quad (11)$$

where G gives the boundary conditions. Dirichlet and Neumann boundary conditions are obtained by choosing

$$\begin{aligned} G(x, r, p) &= r - g(x) \\ \text{and} \quad G(x, r, p) &= p \cdot n(x) - h(x) \end{aligned} \quad (12)$$

respectively, where $n(x)$ is the exterior unit normal vector field of $\partial\Omega$. The problem here is that under assumption (5), the equation may be degenerate on all or a part of the boundary $\partial\Omega$. This part of the boundary may not be *regular* with respect to the

equation, meaning that boundary conditions imposed here do not influence the solution of equation (11) in Ω . In Ω , a solution of equation (11) is determined only by the equation and the boundary conditions on $\partial\Omega_{\text{reg}}$, the regular part of the boundary. Imposing boundary conditions in $\partial\Omega_{\text{irreg}} = \partial\Omega \setminus \partial\Omega_{\text{reg}}$ therefore makes the solution *discontinuous* in $\partial\Omega_{\text{irreg}}$ in general. We refer to [5, 14, 28] for a more detailed discussion.

Note that the continuous extension $\tilde{u}$ of the solution u from Ω to $\bar{\Omega}$, satisfies by continuity $F = 0$ also in $\partial\Omega_{\text{irreg}}$ (under suitable assumptions). Hence at any boundary point, $\tilde{u}$ satisfies *either* the boundary condition *or* the equation.

Now we give the precise definition of discontinuous viscosity solutions. This concept is crucial for the main convergence result of this survey, and as we have just seen, the boundary value problem (11) is well posed in general only if solutions can be discontinuous on the boundary. To this end, we define the upper and lower semicontinuous envelopes of u ,

$$u^*(x) = \limsup_{\Omega \ni y \rightarrow x} u(y) \quad \text{and} \quad u_*(x) = \liminf_{\Omega \ni y \rightarrow x} u(y) \quad (13)$$

A function u is upper semicontinuous, lower semicontinuous, or continuous at $x \in \Omega$ if and only if $u(x) = u^*(x)$, $u(x) = u_*(x)$, or $u(x) = u^*(x) = u_*(x)$, respectively. At a boundary point, the definition requires that either the boundary condition or the equation holds.

Definition 2 A discontinuous viscosity subsolution of equation (11) is a locally bounded function u on $\bar{\Omega}$ satisfying for all $\phi \in C^2(\bar{\Omega})$ and all local maximum points $x_0 \in \bar{\Omega}$ of $u^* - \phi$,

$$\begin{cases} F(x_0, u^*(x_0), D\phi(x_0), D^2\phi(x_0)) \leq 0 & \text{if } x_0 \in \Omega \\ \min \left\{ F(x_0, u^*(x_0), D\phi(x_0), D^2\phi(x_0)), \right. \\ \quad \left. G(x_0, u^*(x_0), D\phi(x_0)) \right\} \leq 0 & \text{if } x_0 \in \partial\Omega \end{cases} \quad (14)$$

A discontinuous viscosity supersolution of equation (11) is a locally bounded function u on $\bar{\Omega}$ satisfying for all $\phi \in C^2(\bar{\Omega})$ and all local minimum points

$x_0 \in \bar{\Omega}$ of $u_* - \phi$,

$$\begin{cases} F(x_0, u_*(x_0), D\phi(x_0), D^2\phi(x_0)) \geq 0 & \text{if } x_0 \in \Omega \\ \max \left\{ F(x_0, u_*(x_0), D\phi(x_0), D^2\phi(x_0)), \right. \\ \quad \left. G(x_0, u_*(x_0), D\phi(x_0)) \right\} \geq 0 & \text{if } x_0 \in \partial\Omega \end{cases} \quad (15)$$

A discontinuous viscosity solution of equation (11) is sub and supersolution at the same time.

Viscosity solutions are unique under very weak assumptions and stable under continuous perturbations of the equation. From the strong comparison result (a uniqueness result) and Perron's method, interior continuity and existence follows. We refer to [14] for precise statements and a wider discussion.

A classical way to compute the solution of degenerate boundary value problem is via elliptic/parabolic regularization. This method is called the *vanishing viscosity method*: if u^ϵ , $\epsilon > 0$, are classical (or viscosity) solutions of

$$\begin{cases} -\epsilon \Delta u + F(x, u, Du, D^2u) = 0 & \text{in } \Omega \\ G(x, u, Du) = 0 & \text{in } \partial\Omega \end{cases} \quad (16)$$

then u_ϵ converge pointwise as $\epsilon \rightarrow 0$ to the discontinuous viscosity solution of equation (11) under mild assumptions [14]. In the regularized problem, boundary conditions are assumed continuously, but as $\epsilon \rightarrow 0$ there will be formation of boundary layers near $\partial\Omega_{\text{irreg}}$, and in the limit the solution will be discontinuous here.

Example 2 Let $\epsilon > 0$ and consider the boundary value problem

$$\begin{cases} -\epsilon u''(x) + u'(x) - 1 = 0, & x \in (0, 1) \\ u(x) = 0, & x \in \{0, 1\} \end{cases} \quad (17)$$

Here, the unique (classical) solution u_ϵ converges pointwise (but not uniformly) as $\epsilon \rightarrow 0$ to a discontinuous function u :

$$u_\epsilon(x) = x - \frac{1 - e^{-\frac{1}{\epsilon}x}}{1 - e^{-\frac{1}{\epsilon}}} \xrightarrow{\epsilon \rightarrow 0} u = \begin{cases} 0, & x = 0 \\ x - 1, & x \in (0, 1] \end{cases} \quad (18)$$

By formally taking the limit in equation (17), we get the following boundary value problem,

$$\begin{cases} u'(x) - 1 = 0, & x \in (0, 1) \\ u(x) = 0, & x \in \{0, 1\} \end{cases} \quad (19)$$

We write this problem in the form (11) by taking $F(p) \equiv p - 1$ and $G(r) \equiv r$. Then, since $u^* \equiv u$ and $u_* \equiv x - 1$ in $[0, 1]$, it is easy to see that in the viscosity sense,

$$\begin{aligned} & \begin{cases} F\left(\frac{du^*}{dx}\right) \leq 0, & x \in (0, 1), \\ G(u^*) \leq 0, & x = 0, \\ G(u^*) \leq 0, & x = 1, \end{cases} \\ \text{and} \quad & \begin{cases} F\left(\frac{du_*}{dx}\right) \geq 0, & x \in (0, 1) \\ F\left(\frac{du_*}{dx}\right) \geq 0, & x = 0 \\ G(u_*) \geq 0, & x = 1 \end{cases} \end{aligned} \quad (20)$$

Hence, u is a viscosity solution of equation (19) according to Definition 2.

To have an even more compact notation, we define

$$H(x, r, p, X) = \begin{cases} F(x, r, p, X) & \text{if } x \in \Omega \\ G(x, r, p) & \text{if } x \in \partial\Omega \end{cases} \quad (21)$$

and note that H^* , H_* equals H in Ω and $\max(F, G)$, $\min(F, G)$, respectively, on $\partial\Omega$. Hence, by the above discussion, u is viscosity solution of equation (11), or equivalently, of

$$H(x, u, Du, D^2u) = 0 \quad \text{in } \bar{\Omega} \quad (22)$$

if the following inequalities hold in the viscosity sense:

$$H_*(x, u, Du, D^2u) \leq 0 \quad \text{in } \bar{\Omega} \quad (23)$$

$$H^*(x, u, Du, D^2u) \geq 0 \quad \text{in } \bar{\Omega} \quad (24)$$

Monotone Schemes and Convergence

Monotone schemes, or schemes of *positive type*, were introduced by Motzkin and Wasow [26] for linear equations and later extended to nonlinear equations (see [27]). Monotone schemes satisfy the discrete maximum principle (under natural assumptions) and the principal error term in the formal error expansion is elliptic. Hence, the schemes produce “smooth” and

monotone approximations to a regularized version of the original problem.

The main advantage of monotone schemes is that they “always” converge to the physically relevant solution [10]. For nonlinear or degenerate elliptic/parabolic equations, weak solutions are not unique in general, and extra conditions are needed to select the physically relevant solution. Nonmonotone schemes do not converge in general [27], and can even produce nonphysical solutions [29].

The main *disadvantage* of monotone schemes is the low order of convergence: first order for first-order PDEs and at most second order for second-order PDEs [27].

The main result of this section is the general convergence result of Barles and Souganidis for monotone, consistent, and stable schemes. We write a numerical scheme for the boundary value problem (22) or (11) as

$$S(h, x, u_h(x), u_h) = 0 \quad \text{on } \Omega_h \quad (25)$$

where S is a real-valued function defined on $\mathbb{R}^+ \times \Omega_h \times \mathbb{R} \times B(\Omega_h)$ where $B(\Omega_h)$ is the set of bounded functions on Ω_h . Typically, $\{u_h(x), u_h\}$ is the stencil of the method and u_h denotes the values at the neighbors of x . The “grid” Ω_h satisfies

$\Omega_h \subset \Omega$ is closed and

$$\lim_{h \rightarrow 0} \Omega_h = \{x : \exists \{x_h\}, x_h \in \Omega_h, x_h \rightarrow x\} = \bar{\Omega} \quad (26)$$

that is, any point in $\bar{\Omega}$ can be reached by a sequence of grid points. This assumption is satisfied for any natural family of grids, and it is necessary to have convergence. The grid Ω_h may be discrete or continuous ($\Omega_h = \bar{\Omega}$) depending on the scheme. We assume that the scheme (25) is

Monotone: For any $h > 0$, $x \in \Omega_h$, r , and $u, v \in B(\Omega_h)$

$$u \geq v \implies S(h, x, r, u) \leq S(h, x, r, v) \quad (27)$$

Consistent: For any smooth function ϕ ,

$$\begin{aligned} & \liminf_{\substack{h \rightarrow 0, \xi \rightarrow 0 \\ \Omega_h \ni x_h \rightarrow x}} S(h, x_h, \phi(x_h) + \xi, \phi + \xi) \\ & \geq H_*(x, \phi(x), D\phi(x), D^2\phi(x)) \quad \text{and} \end{aligned}$$

Table 1 Monotone explicit and implicit finite-difference schemes

Equation	Scheme	CFL
$u_t = \sigma^2 u_{xx}$ $\frac{2\sigma^2 \Delta t}{\Delta x^2} \leq 1$ $-$	$\begin{cases} u_m^{n+1} = u_m^n + \frac{\sigma^2 \Delta t}{\Delta x^2} [u_{m+1}^n - 2u_m^n + u_{m-1}^n] \\ u_m^{n+1} = u_m^n + \frac{\sigma^2 \Delta t}{\Delta x^2} [u_{m+1}^{n+1} - 2u_m^{n+1} + u_{m-1}^{n+1}] \end{cases}$	
$u_t = H(u_x)$	$u_m^{n+1} = u_m^n + \Delta t \left[H \left(\frac{u_{m+1}^n - u_{m-1}^n}{\Delta x} \right) + \ H'\ \frac{u_{m+1}^n - 2u_m^n + u_{m-1}^n}{\Delta x} \right]$	$\frac{2\ H'\ \Delta t}{\Delta x} \leq 1$

$$\begin{aligned} & \limsup_{\substack{h \rightarrow 0, \xi \rightarrow 0 \\ \Omega_h \ni x_h \rightarrow x}} S(h, x_h, \phi(x_h) + \xi, \phi + \xi) \\ & \leq H^*(x, \phi(x), D\phi(x), D^2\phi(x)) \end{aligned} \quad (28)$$

Stable (L^∞ stable): For any $h > 0$, there is a solution u_h of equation (25). Moreover, u_h is uniformly bounded, that is, there is a constant $K \geq 0$ such that for any $h > 0$,

$$|u_h| \leq K \quad \text{in} \quad \Omega_h \quad (29)$$

Example 3 Monotone, consistent, and stable schemes are given in Table 1. Note that an explicit scheme is monotone (and stable) only when a CFL condition hold.

Here, $u_m^n \approx u(x_m, t_n)$ and $\|\cdot\| = \|\cdot\|_{L^\infty}$. The second equation is a Hamilton–Jacobi equation and the corresponding scheme is called the *Lax-Friedrich scheme* [15].

We assume that the boundary value problem (22) satisfies the following:

Strong Comparison Result: If $u, v \in B(\bar{\Omega})$ are upper and lower semicontinuous respectively, u is a subsolution of equation (22), and v is a supersolution of equation (22), then

$$u \leq v \quad \text{in} \quad \Omega \cup \Gamma \quad \text{where} \quad \Gamma \subset \partial\Omega \quad (30)$$

Under the above assumptions, we have the following convergence result:

Theorem 1 *The solution u_h of equation (25) converge locally uniformly (uniformly on compact subsets) in $\Omega \cup \Gamma$ to the unique viscosity solution of equation (22).*

The result is due to Barles and Souganidis and it gives sufficient conditions for locally uniform convergence of approximations. It applies to a very large class of equations, initial/boundary conditions, and (monotone) schemes, see for example, [4, 10, 19]. The only regularity required of the approximating sequence is uniform boundedness. The proof makes use of the Barles-Perthame method of “half relaxed limits” and can be found in [10].

Outline of proof: Define

$$\begin{aligned} \underline{u}(x) &= \liminf_{\substack{h \rightarrow 0 \\ \Omega_h \ni x_h \rightarrow x}} u_h(x_h) \\ \text{and} \quad \bar{u}(x) &= \limsup_{\substack{h \rightarrow 0 \\ \Omega_h \ni x_h \rightarrow x}} u_h(x_h) \end{aligned} \quad (31)$$

These functions are upper and lower semicontinuous in $\bar{\Omega}$, and by monotonicity and consistency they are respectively sub- and supersolutions of the limiting equation (22). Then, by the strong comparison result it follows that $\bar{u} \leq \underline{u}$ in $\Omega \cup \Gamma$. But by definition $\bar{u} \geq \underline{u}$ in $\bar{\Omega}$, and hence we have

$$\bar{u} = \underline{u} \quad \text{in} \quad \Omega \cup \Gamma \quad (32)$$

This immediately implies pointwise convergence. Locally, uniform convergence is followed by a variation of Dini’s theorem.

Remark 1 In Theorem 1 and the strong comparison result, the set Γ always contains all regular points on the boundary ($\partial\Omega_{\text{reg}} \subset \Gamma$) and may equal $\emptyset$, $\partial\Omega$, or a proper subset of $\partial\Omega$. It is equal to $\partial\Omega$ for Neumann problems or when $\partial\Omega_{\text{reg}} = \partial\Omega$. For Dirichlet problems, we refer to papers given in Table 2 below for the precise definition of Γ . When

$\Gamma \neq \partial\Omega$, then the solution of equation (22) may be discontinuous in $\partial\Omega \setminus \Gamma$, see the discussion in the section Viscosity Solutions. In this case, there will be formation of boundary layers in the numerical solutions that prevents (locally) uniform convergence in $\partial\Omega \setminus \Gamma$.

Example 4 A boundary value problem for a heat equation on $(0, 1)$ and its finite-difference approximation may be written in the forms (22) and (25) choosing

$$\begin{aligned} G(u, u_t, u_{xx}) \\ = \begin{cases} u_t - \sigma^2 u_{xx} + bu_x, & t > 0, x \in (0, 1) \\ u, & t > 0, x \in \{0, 1\} \end{cases} \end{aligned} \quad (33)$$

where $b \geq 0$, and for $\Delta x = 1/N$, $(0, 1)_{\Delta x} = \{m\Delta x\}_{m=1}^{N-1}$, and $\Delta t = c\Delta x^2$

$$\begin{aligned} S(\Delta x, u_m^{n+1}, \{u_m^n, u_{m\pm 1}^n\}) \\ = \begin{cases} \frac{u_m^{n+1} - u_m^n}{c\Delta x^2} - \sigma^2 \frac{u_{m+1}^n - 2u_m^n + u_{m-1}^n}{\Delta x^2} \\ + b \frac{u_m^n - u_{m-1}^n}{\Delta x}, & x_m \in (0, 1)_{\Delta x} \\ u_m^{n+1}, & x_m \in \{0, 1\} \end{cases} \end{aligned} \quad (34)$$

The (explicit) scheme is monotone if $c \leq (1/2\sigma^2 + b\Delta x)$, and consistent:

$$\begin{aligned} |G[\phi] - S[\phi]| \leq \\ \begin{cases} \left[\|\phi_t\|c + \frac{\sigma^2}{12} \|\phi_{xxx}\| \right] \Delta x^2 \\ + \frac{b}{2} \|\phi_{xx}\| \Delta x, & \text{at } x_m \in (0, 1)_{\Delta x} \\ 0, & \text{at } x_m \in \{0, 1\} \end{cases} \end{aligned} \quad (35)$$

The scheme is also stable if $c \leq (1/2\sigma^2 + b\Delta x)$ and $\max_m |u_m^{n+1}| \leq \max_m |u_m^0|$. If $\sigma \neq 0$, $b \geq 0$ are constants, $u(x, 0)$ is continuous, and $u(0, 0) = u(1, 0)$, then the strong comparison result holds in $[0, 1]$ [13]. Hence by Theorem 1, the finite-difference solution converge locally uniformly as $\Delta x \rightarrow 0$ to the solution of the equation.

Example 5 (Degeneracy, boundary layers). In Example 4, we replace σ, b by functions, either

$$\begin{aligned} \text{(i) } b = 0, \sigma(x) = \begin{cases} \frac{1}{4} - x, & x \in (0, \frac{1}{4}) \\ 0, & x \in (\frac{1}{4}, \frac{3}{4}) \\ x - \frac{3}{4}, & x \in (\frac{3}{4}, 1) \end{cases} \\ \text{or } \text{(ii) } b = 1, \sigma(x) = x \end{aligned} \quad (36)$$

In both cases, the strong comparison result follows from [13], see also [5, 14].

In case (i), the equation degenerates for $x \in (\frac{1}{4}, \frac{3}{4})$ and the solution is not more than continuous here. But there are no degeneracies at the boundary (it is regular) so the comparison result holds on $[0, 1]$ and Theorem 1 implies uniform convergence of the numerical solution in $[0, 1]$.

In case (ii), the equation degenerates only at the boundary $x = 0$. At this point, the exact solution will be discontinuous for $t > 0$, and the strong comparison result holds only on $(0, 1]$. This is also where the numerical solution will converge by Theorem 1. *Uniform* convergence in $x = 0$ is not possible because of formation of boundary layers as the numerical solution is refined, see also Example 2.

Remark 2 (The strong comparison result). A main difficulty in applying Theorem 1 is that the boundary value problem must satisfy the strong comparison result. There are general results that cover most (but probably not all) applications in finance, see Table 2.

In particular, the results of [13] cover Dirichlet (and state constrained) problems for linear and convex second-order PDEs (with or without time) when the domain satisfies an outer ball condition. This includes, for example, all box and convex polyhedral domains in $\mathbb{R}^n$.

Remark 3 (Assumptions on the scheme). See also the discussion in [4, 27].

Monotonicity: This condition is analogous to ellipticity of the equation [4, 10, 27], see the discussion at the beginning of this section. For approximations

Table 2 Strong comparison results

BC	Equation	Domain	Paper
Dirichlet	Linear in second derivatives	Smooth	[5]
	Convex fully nonlinear	Smooth	[8]
	(includes linear equations)	Nonsmooth	[13]
	Second-order quasilinear	Smooth	[9]
Neumann/ Robin	Second-order quasi/fully nonlinear	—	see [14]

of stationary linear equations on a grid $\{x_m\}_m$, monotonicity means [26]:

$$u_m = \sum_{k \neq 0} a_k u_{m+k} \quad \text{for } a_k \geq 0 \quad (u_m \approx u(x_m)) \quad (37)$$

Consistency: The strange formulation above is necessary since we consider the equation and the boundary conditions at the same time, see Example 4.

Stability: The type of stability required here is L^∞ stability and it is more restrictive than L^2 or von Neumann stability. For example, the Crank–Nicolson scheme is unconditionally von Neumann stable but not L^∞ stable in general [7].

Generally speaking, stability (in L^∞) follows if $S(h, x, r, v)$ defined in equation (25) is monotone and strictly increasing in r . This is typically the case for approximations of

- parabolic problems;
- degenerate elliptic problems where F def. in equation (4) is strictly increasing in u ;
- uniformly elliptic problems.

Some very general stability results can be found in [7, 27] for whole space problems, while [17, 25, 26] deal with more particular problems on domains.

Error Estimates for Convex Equations

For linear and nondegenerate problems satisfying condition (5), error estimates follow from classical (L^2) methods that can be found in most advanced textbooks on numerical solutions of PDEs. For degenerate and/or nonlinear problems these methods do not

apply, and there exists no general theory today. For equations (4) satisfying condition (5) there are results in the following cases:

1. General first-order equations [15];
2. Convex or concave second-order equations [7, 17];
3. Nondegenerate second-order equations [12].

In the first case, and to some degree also in the second case, there are rather satisfactory and extensive results. In the rest of this section, we concentrate on the case (ii), since most PDEs in finance belong to this category (including linear ones). The first result in this direction came in two papers of Krylov [22, 23], and his ideas have been developed and improved by several authors since, we refer to [7, 17] for the most general results at this time.

In what follows, we rewrite the available results in a framework inspired by Barles and Jakobsen [6, 7] and present them in the context of the following possibly degenerate, fully nonlinear, convex model equation:

$$u_t + \sup_{\vartheta \in \Theta} \left\{ -\text{tr}[\sigma^\vartheta \sigma^{\vartheta T} D^2 u] - b^\vartheta Du + c^\vartheta u + f^\vartheta \right\} = 0 \quad \text{in } \mathbb{R}^N \times (0, T) \quad (38)$$

where σ (matrix), b (vector), c , f are functions of t, x, ϑ , and $^T/\text{tr}$ denotes transpose/trace of matrices. Note that equation (38) is linear if Θ is a singleton. All the results in this section requires that the initial value problem for equation (38) has a unique solution, which is Lipschitz continuous in x uniformly in t . This is the case [7] if, for example,

$$|u(\cdot, 0)|_1 + |\sigma^\vartheta|_1 + |b^\vartheta|_1 + |c^\vartheta|_1 + |f^\vartheta|_1 \leq K \quad \text{for some } K \text{ independent of } \vartheta \quad (39)$$

where $|\phi|_1 = \sup_{x,t} |\phi(x, t)| + \sup_{x \neq y, t} (|\phi(x, t) - \phi(y, t)|/|x - y|)$. Without loss of generality we also assume that $c^\vartheta \geq 0$.

We approximate equation (38) by a scheme (25), which we assume to be as follows:

Monotone and parabolic: $\phi(t) \in C^1$, $u \leq v$ in Ω_h

$$\begin{aligned} \implies S(h, t, x, r + \phi(t), u + \phi) &\geq S(h, t, x, r, v) \\ &+ \phi'(t) - \frac{Kh^2}{2} \|\phi''\|_\infty \end{aligned} \quad (40)$$

Continuous: $S(h, t, x, r, u)$ uniformly continuous in r uniformly in t, x .

Consistent: $\phi(t, x) \in C^\infty$

$$\begin{aligned} \implies & |F(t, x, \phi, \partial_t \phi, D_x \phi, D_x^2 \phi) \\ & - S(h, t, x, \phi(t, x), \phi)| \\ & \leq \sum_{i,j} K_{i,j} \|\partial_t^i D_x^j \phi\|_\infty h^{\alpha_{i,j}} \end{aligned} \quad (41)$$

Here $K, K_{ij}, \alpha_{ij} \geq 0$ are constants independent of h and (t, x) . Under all of the previously mentioned assumptions, we have the following upper bound on the error:

Theorem 2 (Upper bound).

$$u - u_h \leq C_u \min_{\epsilon > 0} \left\{ \epsilon + \sum_{i,j} K_{i,j} \epsilon^{1-2i-j} h^{\alpha_{i,j}} \right\} \quad \text{in } \Omega_h \quad (42)$$

This result was first proved in [23], and we refer to [7] for a discussion on the present formulation. For the most common monotone finite-difference schemes, this result produces the upper bound $Kh^{1/2}$ [20, 24], which is optimal [16] in this setting.

To get a lower bound, we need additional assumptions as follows:

Convexity: $S(h, t, x, r, u)$ is convex in (r, u) and commutes with translations in x .

Approximation and regularity: For h small enough and $0 \leq \epsilon < 1$, there is unique solution u_h^ϵ of the scheme

$$\max_{0 \leq s \leq \epsilon^2, |e| \leq \epsilon} S(h, t + s, x + e, u_h^\epsilon(x), u_h^\epsilon) = 0 \quad \text{on } \Omega_h \quad (43)$$

where $u_h := u_h^0$ solves equation (25), and there is a constant C such that for all s, t, x, y, h, ϵ ,

$$\begin{aligned} |u_h^\epsilon(t, x) - u_h^\epsilon(s, y)| &\leq C(|t - s|^{1/2} + |x - y|), \\ |u_h^0(t, x) - u_h^\epsilon(t, x)| &\leq C\epsilon \end{aligned} \quad (44)$$

Under all of the above assumptions, we have the first lower bound:

Theorem 3 (Lower bound I).

$$u - u_h \geq -C_{l_1} \min_{\epsilon > 0} \left\{ \epsilon + \sum_{i,j} K_{i,j} \epsilon^{1-2i-j} h^{\alpha_{i,j}} \right\} \quad \text{in } \Omega_h \quad (45)$$

Alternatively, we may replace the last two assumptions on the scheme (25) by slightly stronger assumptions on the equation (38):

Continuity in ϑ : Θ is a separable metric space, and σ, b, c, f are continuous in ϑ for every (t, x) .

Then we have the second lower bound:

Theorem 4 (Lower bound II).

$$u - u_h \geq -C_{l_2} \min_{\epsilon > 0} \left\{ \epsilon^{1/3} + \sum_{i,j} K_{i,j} \epsilon^{1-2i-j} h^{\alpha_{i,j}} \right\} \quad \text{in } \Omega_h \quad (46)$$

The typical lower bounds produced by Theorems 3 and 4 are $Kh^{1/2}, Kh^{1/5}$, respectively. The first bound is again optimal, but the result applies only to particular schemes and equations [6, 20, 22, 24]. The second result is not optimal in general, but it applies to *any* consistent monotone scheme, see [7] for the most general results and a wider discussion. Theorem 3 was (essentially) stated in the present general form in [6, 20] and follows from arguments of [22, 23]. Theorem 4 was stated and proved in [6].

Remark 4 (Approximation and regularity). Under quite general assumptions, see [24], it is possible to show that the ‘‘Approximation and regularity’’ assumption of Theorem 3 holds for any $\epsilon \in [0, 1)$ whenever it holds for $\epsilon = 0$, that is, what we need is a uniform in h Hölder estimate on the solution of u_h of the scheme (25).

Remark 5 (Proofs). There are 3–4 main ideas.

1. Mollification of the equation produce a smooth subsolution by convexity. An upper bound on the error then follows from classical L^∞ -argument using monotonicity and consistency [22].
2. The method of shaking the coefficients allows to treat general problems with variable coefficients [23].
3. The lower bound. Either you (i) interchange the role of the scheme and the equation in

part (1) to get bound I, or (ii) you introduce additional approximations to avoid working with the scheme and get a type II bound [7, 23]. In case (i), you need a uniform Lipschitz bound on the solutions of the scheme, which is very difficult to obtain in general.

Remark 6 (Extensions). Stationary problems have been considered in several papers, including some boundary value problems, *see* [7, 17]. There have been papers treating more general equations like parabolic obstacle problems, impulse control problems, and integro-differential problems (*see* **Partial Integro-differential Equations (PIDEs)**). When solutions are less regular (Hölder continuous), lower rates have been obtained in [6, 7] and in some cases when solutions are more regular, higher order of convergence can be obtained [16].

Example 6 Consider a special case of equation (38),

$$u_t + \sup_{\vartheta \in \Theta} \left\{ - \sum_{\beta} \left[(\bar{\sigma}_{\beta}^{\vartheta})^2 D_{\beta}^2 + \bar{b}^{\vartheta} D_{\beta} \right] u + c^{\vartheta} u + f^{\vartheta} \right\} = 0 \quad \text{in } \mathbb{R}^N \times (0, T) \quad (47)$$

where $\bar{b} \geq 0$, $\bar{\sigma}$ are scalar functions, $D_{\beta} = \beta \cdot D$ is a directional derivative, and $\{\beta\}$ is a finite collection of vectors in $\mathbb{Z}^N$. We approximate on a uniform grid $\Omega_h = h\mathbb{Z} \times ch^2\mathbb{Z}^+$ by an implicit finite-difference scheme proposed in [11, 24]

$$u_{\alpha}^{n+1} = u_{\alpha}^n + \Delta t \sup_{\theta \in \Theta} \left\{ - \sum_{\beta} \left[(\bar{\sigma}_{\beta}^{\theta})^2 \Delta_{h\beta} + \bar{b}^{\theta} \delta_{\beta h}^+ \right] \times u_{\alpha}^{n+1} + c^{\theta} u_{\alpha}^{n+1} - f^{\theta} \right\} = 0 \quad (48)$$

for $n \in \mathbb{Z}^+$, $\alpha \in \mathbb{Z}^n$, and where

$$\Delta_{h\beta} w(x) = \frac{w(x + h\beta) - 2w(x) + w(x - h\beta)}{h^2 |\beta|^2}$$

and $\delta_{h\beta}^+ w(x) = \frac{w(x + \beta h) - w(x)}{h |\beta|} \quad (49)$

This scheme is obviously monotone and a Taylor expansion shows that

$$|F(t, x, \phi, \partial_t \phi D\phi, D^2 \phi) - S(h, t, x, \phi(t, x), \phi)| \leq C(ch^2 |\phi_{tt}|_0 + h |D^2 \phi|_0 + h^2 |D^4 \phi|_0) \quad (50)$$

If $\bar{\sigma}, \bar{b}, c, f, u(0, \cdot)$ are uniformly x -Lipschitz, then u_h is also uniformly x -Lipschitz [24], and by Theorems 2 and 3 we get

$$|u - u_{\alpha}^n| \leq Ch^{1/2} \quad (51)$$

From a practical or probabilistic point of view, $\bar{\sigma}$ need not be Lipschitz. In this case, Theorems 2 and 4 yield a worse bound:

$$|u - u_{\alpha}^n| \leq Ch^{1/5} \quad (52)$$

Note that we have imposed the CFL condition $\Delta t = c\Delta x^2$ ($\Delta x = h$). If this condition is not satisfied, then the rates will be reduced. We refer to [7] for more general explicit and implicit schemes of this kind.

Sparse Grids

The sparse grid method is a general *numerical discretization* technique for multivariate function representation, integration and partial differential equations. This approach, first introduced by the Russian mathematician Smolyak in 1963 [26], constructs a multidimensional multilevel basis by a special truncation of the tensor product expansion of a one-dimensional multilevel basis (see Figure 1 for an example of a sparse grid).

Discretizations on sparse grids involve only $O(N(\log N)^{d-1})$ degrees of freedom, where d is the problem dimension and N denotes the number of degrees of freedom in one coordinate direction. The accuracy obtained this way is comparable to one using a full tensor product basis involving $O(N^d)$ degrees of freedom, if the underlying problem is smooth enough, that is, if the solution has bounded mixed derivatives.

This way, the *curse of dimension*, that is, the exponential dependence of conventional approaches on the dimension d , can be overcome to a certain extent. This makes the sparse grid approach particularly attractive for the numerical solution of moderate and higher dimensional problems. Still, the classical sparse grid method is not completely independent of the dimension due to the above logarithmic term in the complexity.

Sparse grid methods are known under various names, such as hyperbolic cross points, discrete blending, Boolean interpolation, or splitting extrapolation. For a comprehensive introduction to sparse grids, see [5].

In computational finance, sparse grid methods have been employed for the valuation of *multiasset options* such as basket [24] (see **Basket Options**) or outperformance options [12], various types of *path-dependent derivatives*, due to the high dimension of the arising partial differential equations, or integration problems.

One-dimensional Multilevel Basis

The first ingredient of a sparse grid method is a one-dimensional multilevel basis. In the classical sparse grid approach, a hierarchical basis based on standard

hat functions,

$$\phi(x) := \begin{cases} 1 - |x| & \text{if } x \in [-1, 1], \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

is used. Then, a set of equidistant grids Ω_l of level l on the unit interval $\bar{\Omega} = [0, 1]$ and mesh width 2^{-l} is considered. The grid points $x_{l,i}$ are given by

$$x_{l,i} := i \cdot h_l, 0 \leq i \leq 2^l \quad (2)$$

The standard hat function is then taken to generate a family of basis functions $\phi_{l,i}(x)$ having support $[x_{l,i} - h_l, x_{l,i} + h_l]$ by dilation and translation, that is,

$$\phi_{l,i}(x) := \phi\left(\frac{x - i \cdot h_l}{h_l}\right) \quad (3)$$

Thereby, the index i indicates the location of a basis function or a grid point. This basis is usually termed as *nodal basis* or *Lagrange basis* (see Figure 2, bottom). These basis functions are then used to define function spaces V_l consisting of piecewise linear functions^a

$$V_l := \text{span} \{ \phi_{l,i} : 1 \leq i \leq 2^l - 1 \} \quad (4)$$

With these function spaces, the hierarchical increment spaces W_l ,

$$W_l := \text{span} \{ \phi_{l,i} : i \in I_l \} \quad (5)$$

using the index set

$$I_l = \{ i \in \mathbb{N} : 1 \leq i \leq 2^l - 1, i \text{ odd} \} \quad (6)$$

are defined. These increment spaces satisfy the relation

$$V_l = \bigoplus_{k \leq l} W_k \quad (7)$$

The basis corresponding to W_l is *hierarchical basis* (see Figure 2, top) and any function $u \in V_l$ can be uniquely represented as

$$u(x) = \sum_{k=1}^l \sum_{i \in I_k} v_{k,i} \cdot \phi_{k,i}(x) \quad (8)$$

with coefficient values $v_{k,i} \in \mathbf{R}$. Note that the supports of all basis functions $\phi_{k,i}$ spanning W_k are mutually disjoint.

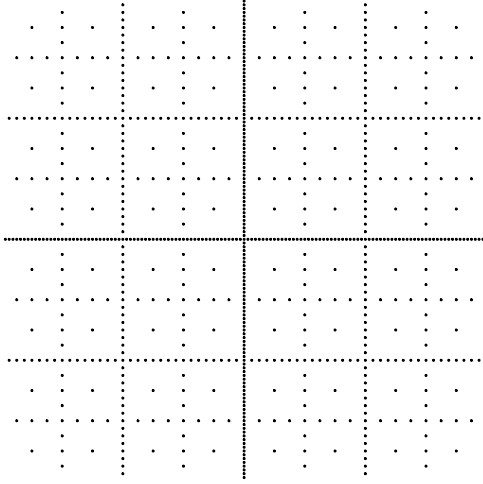

Figure 1 A regular two-dimensional sparse grid of level 7

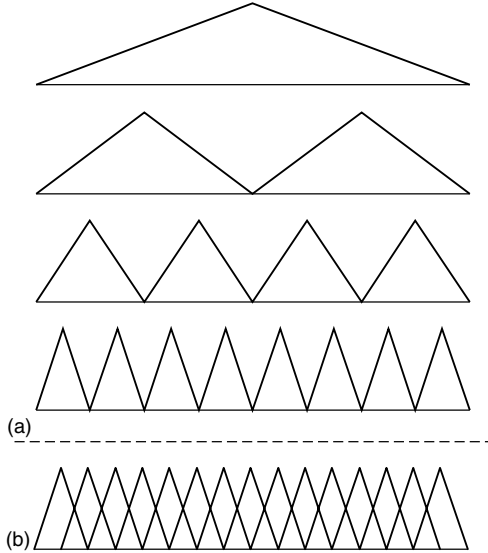

Figure 2 Piecewise linear hierarchical basis (a) versus nodal basis (b) of level 4

Tensor Product Construction

From this one-dimensional hierarchical basis, a multi-dimensional basis on the d -dimensional unit cube $\bar{\Omega} := [0, 1]^d$ is obtained by a tensor product construction. With the multiindex $\mathbf{l} = (l_1, \dots, l_d) \in \mathbf{N}^d$, which indicates the level in a multivariate sense, the set of d -dimensional standard rectangular grids $\Omega_{\mathbf{l}}$ on $\bar{\Omega}$ with mesh size $\mathbf{h}_{\mathbf{l}} := (h_{l_1}, \dots, h_{l_d}) := 2^{-\mathbf{l}}$ are

considered. Each grid $\Omega_{\mathbf{l}}$ is equidistant with respect to each individual coordinate direction, but, in general, may have varying mesh sizes in the different directions. The grid points $\mathbf{x}_{\mathbf{l}, \mathbf{i}}$ of the grid $\Omega_{\mathbf{l}}$ are the points

$$\mathbf{x}_{\mathbf{l}, \mathbf{i}} := (x_{l_1, i_1}, \dots, x_{l_d, i_d}), \quad \mathbf{1} \leq \mathbf{i} \leq 2^{\mathbf{l}} - \mathbf{1} \quad (9)$$

where for the above multiindices, all arithmetic operations are to be understood component-wise.

Then, for each grid point $\mathbf{x}_{\mathbf{l}, \mathbf{i}}$, an associated piecewise d -linear basis function $\phi_{\mathbf{l}, \mathbf{i}}(\mathbf{x})$ (see Figure 3) is defined as the product of the one-dimensional basis functions

$$\phi_{\mathbf{l}, \mathbf{i}}(\mathbf{x}) := \prod_{j=1}^d \phi_{l_j, i_j}(x_j) \quad (10)$$

Each of the multidimensional (nodal) basis functions $\phi_{\mathbf{l}, \mathbf{i}}$ has a support of size $2 \cdot \mathbf{h}_{\mathbf{l}}$. These basis functions are again used to define function spaces $V_{\mathbf{l}}$ consisting of piecewise d -linear functions, which are 0 on the boundary of $\bar{\Omega}$,

$$V_{\mathbf{l}} := \text{span} \{ \phi_{\mathbf{l}, \mathbf{i}} : \mathbf{1} \leq \mathbf{i} \leq 2^{\mathbf{l}} - \mathbf{1} \} \quad (11)$$

Similar to the one-dimensional case, the hierarchical increments $W_{\mathbf{l}}$ are defined by

$$W_{\mathbf{l}} := \text{span} \{ \phi_{\mathbf{l}, \mathbf{i}} : \mathbf{i} \in \mathbf{I}_{\mathbf{l}} \} \quad (12)$$

with the index set

$$\mathbf{I}_{\mathbf{l}} := \{ \mathbf{i} \in \mathbf{N}^d : \mathbf{1} \leq \mathbf{i} \leq 2^{\mathbf{l}} - \mathbf{1}, \\ i_j \text{ odd for all } 1 \leq j \leq d \} \quad (13)$$

This way, the hierarchical increment spaces $W_{\mathbf{l}}$ are related to the nodal spaces $V_{\mathbf{l}}$ by

$$V_{\mathbf{l}} = \bigoplus_{\mathbf{k} \leq \mathbf{l}} W_{\mathbf{k}} \quad (14)$$

Again, the supports of all multidimensional hierarchical basis functions $\phi_{\mathbf{l}, \mathbf{i}}$ spanning $W_{\mathbf{l}}$ are mutually disjoint. Also, again each function $u \in V_{\mathbf{l}}$ can uniquely be represented by

$$u_{\mathbf{l}}(\mathbf{x}) = \sum_{\mathbf{k}=1}^{\mathbf{l}} \sum_{\mathbf{i} \in \mathbf{I}_{\mathbf{k}}} v_{\mathbf{k}, \mathbf{i}} \cdot \phi_{\mathbf{k}, \mathbf{i}}(\mathbf{x}) \quad (15)$$

with hierarchical coefficients $v_{\mathbf{k}, \mathbf{i}} \in \mathbf{R}$.

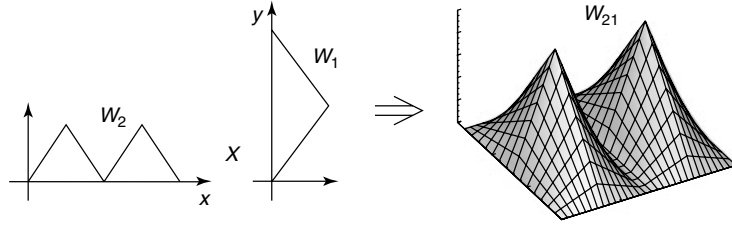

Figure 3 Tensor product approach to generate the piecewise bilinear basis functions $\phi_{(2,1),(1,1)}$ and $\phi_{(2,1),(1,1)}$ from the one-dimensional basis functions $\phi_{2,1}$, $\phi_{2,2}$ and $\phi_{1,1}$

Classical Sparse Grids

The classical sparse grid construction arises from a cost-to-benefit analysis in function approximation. Thereby, functions $u : \Omega \rightarrow \mathbf{R}$ which have bounded mixed second derivatives

$$D^\alpha u := \frac{\partial^{|\alpha|_1} u}{\partial x_1^{\alpha_1} \dots \partial x_d^{\alpha_d}} \quad (16)$$

for $|\alpha|_\infty \leq 2$ are considered. These functions belong to the Sobolev space $H_2^{\text{mix}}(\bar{\Omega})$ with

$$H_2^{\text{mix}}(\bar{\Omega}) := \{u : \bar{\Omega} \rightarrow \mathbf{R} : D^\alpha u \in L_2(\Omega), \\ \times |\alpha|_\infty \leq 2, u|_{\partial\Omega} = 0\} \quad (17)$$

Here, the two norms $|\alpha|_1$ and $|\alpha|_\infty$ for multiindices are defined by

$$|\alpha|_1 := \sum_{j=1}^d \alpha_j \text{ and } |\alpha|_\infty := \max_{1 \leq j \leq d} \alpha_j \quad (18)$$

For functions $u \in H_2^{\text{mix}}(\bar{\Omega})$, the hierarchical coefficients $v_{1,i}$ decay as

$$|v_{1,i}| = O(2^{-2|\mathbf{l}_1|}) \quad (19)$$

On the other hand, the size (i.e., the number of degrees of freedom) of the subspaces W_1 is given by

$$|W_1| = O(2^{|\mathbf{l}_1|}) \quad (20)$$

An optimization with respect to the number of degrees of freedom and the resulting approximation accuracy directly leads to *sparse grid* spaces $\hat{V}_n$ of level n defined by

$$\hat{V}_n := \bigoplus_{|\mathbf{l}_1| \leq n+d-1} W_1 \quad (21)$$

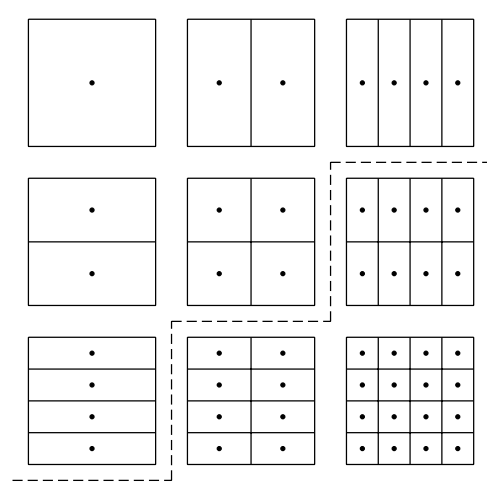

Figure 4 All subspaces W_1 for levels $|\mathbf{l}|_\infty \leq 3$ which together form the full grid space V_3 . The corresponding sparse grid space $\hat{V}_3$ consists of all subspaces above the dashed line ($|\mathbf{l}|_1 \leq 4$)

In comparison to the standard *full grid* space

$$V_n := V_{(n,\dots,n)} = \bigoplus_{|\mathbf{l}|_\infty \leq n} W_1 \quad (22)$$

which corresponds to cubic sectors of subspaces, sparse grids use triangular or simplicial sectors, see Figure 4. The dimension of the space $\hat{V}_n$, that is, the number of degrees of freedom or grid points is given by

$$|\hat{V}_n| = \sum_{i=0}^{n-1} 2^i \cdot \binom{d-1+i}{d-1} \\ = O(h_n^{-1} \cdot |\log_2 h_n|^{d-1}) \quad (23)$$

This shows the order $O(2^n n^{d-1})$, which is a significant reduction of the number of degrees of freedom

and, thus, of the computational and storage requirement compared to the order $O(2^{nd})$ of the dimension of the full grid space $|V_n|$.

On the other hand, the approximation accuracy of the sparse grid spaces for functions $u \in H_2^{\text{mix}}(\bar{\Omega})$ is in the L_p norms for $1 \leq p \leq \infty$ given by

$$\|u - \hat{u}_n\|_p = O(h_n^2 \cdot n^{d-1}) \quad (24)$$

For the corresponding full grid spaces, the accuracy is

$$\|u - u_n\|_p = O(h_n^2) \quad (25)$$

This shows the crucial advantage of the sparse grid space $\hat{V}_n$ in comparison with the full grid space V_n : the number of degrees of freedom is significantly reduced, whereas the accuracy is only slightly deteriorated. This way, the curse of dimensionality can be overcome, at least to some extent. The dimension still enters through logarithmic terms both in the computational cost and the accuracy estimate as well as in the constants hidden in the order notation.

Extensions and Applications

The classical sparse grid concept has been generalized in various ways. First, there are special sparse grids, which are optimized with respect to the energy seminorm [4]. These energy-based sparse grids are further sparsified and possess a cost complexity of $O(h_n^{-1})$ for an accuracy of $O(h_n)$. Thus, the dependence on the dimension d in the order is completely removed (but is still present in the hidden constants [8]). A generalization to sparse grids, which is optimal with respect to other Sobolev norms, can be found in [13]. In case the underlying space is not known *a priori*, dimension-adaptive methods [11] can be applied to find optimized sparse grids.

The sparse grid approach based on piecewise linear interpolation can be generalized to higher order polynomial [5] or wavelet discretizations (e.g., interpolants or prewavelets) [15, 25], which allows to utilize additional properties (such as higher polynomial exactness or vanishing moments) of the basis.

Furthermore, sparse grid methods can be applied to nonsmooth problems by using spatially adaptive refinement methods [2], see Figure 5 for an adaptively refined sparse grid. Spatial adaptivity helps if the original smoothness conditions for the sparse grid approach are not fulfilled. This is the case in nearly

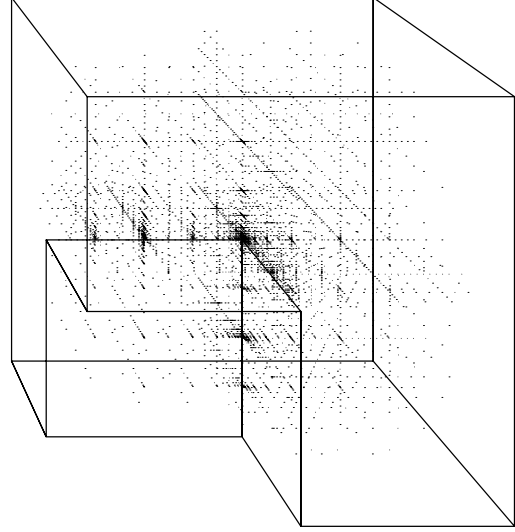

Figure 5 An at-a-corner singularity adaptively refined three-dimensional sparse grid

all option pricing problems since they lead to discontinuities in the initial conditions, which can, in some cases, extend into the interior of the domain. Here, adaptive refinement methods can often attain the same convergence rates as for smooth problems, which can be shown using approximation theory in Besov spaces [20]. Additionally, transformations that align areas of discontinuities with coordinate axes can significantly enhance the efficiency of sparse grid methods, as was shown in [24].

Sparse grids have been applied for the solution of different kinds of low- and moderate-dimensional partial differential equations, such as elliptic [5, 27], parabolic [1, 14], and hyperbolic [17] problems. In this context, finite element methods [2], finite difference methods [7], and finite volume methods [19] have been used in the discretization process.

For the solution of partial differential equations, often the so-called combination technique [9] is employed. Here, a sparse grid solution is obtained by a combination of anisotropic full grid solutions according to the combination formula

$$\hat{u}_n(\mathbf{x}) = \sum_{n \leq |\mathbf{l}|_1 \leq n+d-1} (-1)^{n+d-|\mathbf{l}|_1-1} \binom{d-1}{|\mathbf{l}|_1-n} u_{\mathbf{l}}(\mathbf{x}) \quad (26)$$

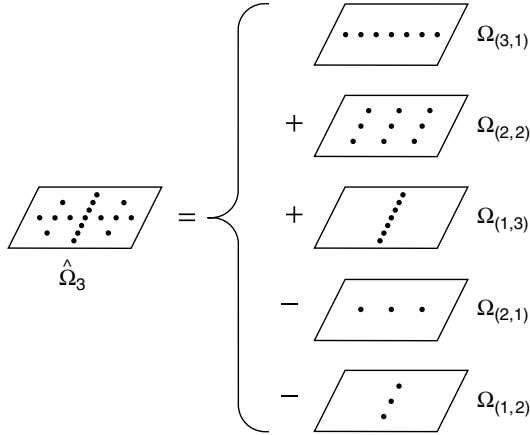

Figure 6 The combination technique in two dimensions for level $n = 3$: combine coarse full grids Ω_l , $|\mathbb{I}_l| \in \{3, 4\}$, with mesh widths 2^{-l_1} and 2^{-l_2} to get a sparse grid $\hat{\Omega}_n$ corresponding to $\hat{V}_n$

where $u_l(\mathbf{x})$ is a full grid solution on an anisotropic grid with mesh width 2^{-l} , see Figure 6 for a two-dimensional example. The combination technique can be further optimized with respect to the underlying differential operator [18].

The sparse grid approach can also be used for numerical integration, for example, for the computation of expectations [10, 23]. Thereby, the classical sparse grid construction starts with a sequence of one-dimensional quadrature formulas $Q_l f$ using n_l points to integrate a function f on the unit interval $[0, 1]$,

$$Q_l f := \sum_{i=1}^{n_l} w_{li} \cdot f(x_{li}) \quad (27)$$

Using the difference quadrature formulas

$$\Delta_k f := (Q_k - Q_{k-1})f \text{ with } Q_0 f := 0 \quad (28)$$

the sparse grid quadrature formula $\hat{Q}_n f$ of level n for a d -dimensional function f on the cube $[0, 1]^d$ is then defined by

$$\hat{Q}_n f := \sum_{|\mathbb{I}_l| \leq n+d-1} (\Delta_{l_1} \otimes \cdots \otimes \Delta_{l_d}) f \quad (29)$$

Again, this construction can be improved by using spatially adaptive or dimension-adaptive refinement [3, 11].

The sparse grid methodology has also been successfully applied to the solution of integral equations

[16], interpolation and approximation [21], and data analysis [6, 22].

End Notes

^aIn order to simplify this exposition, we assume that the functions in V_l are 0 on the boundary of $\bar{\Omega}$. This restriction can be overcome by adding appropriate boundary basis functions.

Optimization Methods

No area of computational mathematics plays a greater role in the support of financial decision making and strategy development than numerical optimization. The full gamut of optimization methodologies are applied to this end—linear and quadratic, nonlinear and global, stochastic and deterministic, discrete and continuous—and applications propagate throughout the front office, back office, analysis, and trading operations. The use of optimization is deep, pervasive, and growing.

We organize our presentation in three “levels”. The top level in our presentation is the management of portfolios based on quadratic programming, the second level is stochastic programming for portfolio optimization, and the lowest (but perhaps the most important) level is model calibration (*see* **Model Calibration**).

While some of the methodological issues that arise are specific to the different levels, there are three dominant themes that cut across all levels: speed, robustness, and quality of solution. Speed often dominates thinking in financial circles since rapid informed decision making (sometimes, “automatic”) can translate into capital gains (conversely, lack of sufficient speed can lead to losses). Nevertheless, a “wrong” answer computed at record speed is not of much value (and could be quite disastrous). A solution can be wrong in several ways. For example, if the computed solution is not robust, then the resultant strategy may be a very poor strategy under slight tweaking of the parameters defining the problem. This is a serious practical problem because problem parameters are almost always determined in an approximate manner (i.e., they are not known exactly). Other solution quality issues can arise. For example, some optimization problems are too hard to solve in reasonable time and so approximation schemes must be used. But how good is the approximate solution?

As we discuss some of the optimization challenges that arise under the organizing levels mentioned above, we make particular note of these three unifying numerical concerns.

Portfolio Management: Quadratic Programming

The most famous optimization application in finance is the mean–variance portfolio optimization problem, first introduced by Markowitz [19]; *see also* **Risk–Return Analysis**. The question that is addressed by “mean–variance portfolio optimization” is both easy to understand and practical: how should one distribute, across a given set of financial instruments, a finite investment in order to balance (according to the investors preference) risk and expected return? In its pure form, this question can be formulated as a positive definite quadratic programming problem.

Let $\mu \in \Re^n$ be a vector of expected returns for n assets, and an n -by- n matrix Q be the covariance matrix of asset returns. Assume that the vector $x \in \Re^n$ denotes the percentage of asset holdings. Then the mean-variance portfolio optimization problem can be formulated as

$$\begin{aligned} \min_x \quad & -\mu^T x + \lambda x^T Q x \\ \text{subject to} \quad & \sum_{i=1}^n x_i = 1 \end{aligned} \quad (1)$$

where $\lambda \geq 0$ is a risk aversion parameter. Additional (linear) constraints can be imposed, for example, no short selling constraints correspond to $x \geq 0$. There are many good algorithms, and codes (e.g., MOSEK and LOQO [24]) to solve positive definite quadratic programming problems, but the situation becomes more complex (and more interesting) as financial (and numerical) concerns are introduced.

One complication arises in the equity setting: portfolios held in many firms can be quite large—in several thousands—and typically have a dense matrix Q ; nevertheless, there is serious need to determine a solution rapidly. Moreover, because many of the subsets of instruments in the portfolio behave in a highly correlated way the matrix Q can be ill-conditioned. This means numerical algorithms can have a hard time computing accurate answers, and small changes in the input data can lead to very different proposed strategies and portfolios. One approach to address these difficulties is to use a factor model. However, algorithm implementation needs to exploit this special structure of the covariance matrix for optimal computational efficiency.

Another complication is the need to use additional terms, for example, to capture transaction costs (see **Transaction Costs**). These additional terms yield a more realistic model; however, they may also change the objective function into a more nonlinear function. This apparent small change has a big impact—general nonlinear codes (even with linear constraints) are more complex and have fewer “guarantees” relative to quadratic objective functions.

Recently, there has been considerable attention paid to the fact that the objective function in equation (1) is just an approximation to reality. Estimation of expected returns is notoriously difficult; the expected return parameter may be closer to wishful thinking than reality. Specifically, return μ and covariance matrix Q are supposed to represent the return and risk going forward in time but are typically, in fact, the return and risk going backward. The question is, how well does our chosen portfolio (i.e., the optimization solution based on these estimated parameters) perform as reality rolls forward under real conditions? Unfortunately, the answer is that it may not do very well at all; see for example, [5, 6].

There is now considerable attention being paid to this very practical concern, generally under the label “robust optimization”; see for example, [14, 15, 23], and **Robust Portfolio Optimization**. The goal of robust optimization is to guarantee the best performance in the worse case. Since the support for an uncertain parameter may be infinite, a robust portfolio is typically determined by considering optimal performance in the worst case within some uncertainty sets for model parameters. For example, the min–max robust formulation for equation (1) can be expressed as

$$\begin{aligned} \min_x \quad & \max_{\mu \in S_\mu, Q \in S_Q} -\mu^T x + \lambda x^T Q x \\ \text{subject to} \quad & \sum_{i=1}^n x_i = 1 \end{aligned} \quad (2)$$

where S_μ and S_Q are uncertainty sets for the expected return μ and covariance matrix Q , respectively. The uncertainty sets are often either intervals or ellipsoids (typically corresponding to some confidence intervals). Efficient computational methods for conic optimization and semidefinite programming can be used to solve some of these robust optimization problems; see, for example, [11].

There is need for still more research here though since much of the work to date takes an unduly conservative—and expensive—point of view: given a range to capture the possibility values of the parameters, solve the problem in the worst case. This solution provides protection but is certainly on the extreme risk-averse side. Recently, a conditional Value-at-Risk (CVaR) robust formulation is considered in [25] to address uncertainty in the parameters for mean–variance portfolio optimization.

CVaR Minimization and Optimal Executions: Stochastic Programming

Optimal financial decisions often need to be made using uncertain parameters which describe the optimization problems. This view leads to stochastic programming problems.

Even in a single-period portfolio optimization framework, if instrument values (e.g., options) depend nonlinearly on the risk factors, a different risk measure, instead of standard deviation, for example, Value-at-Risk (VaR) (see **Value-at-Risk**) or CVaR (see **Expected Shortfall**), needs to be used. Both these measures quantify near-worst case losses and both present interesting optimization challenges.

VaR is essentially a quantile of a loss distribution. For a confidence level β , for example, 95%, the VaR of a portfolio is the loss in the portfolio’s market value over a specified time horizon that is exceeded with probability $1 - \beta$. When VaR is used as a risk measure, the portfolio optimization problem is, in general, a nonconvex programming problem. Computing a global minimizer remains a computationally challenging task.

An alternative risk measure to VaR is CVaR. When the distribution of the portfolio loss is continuous, for a given time horizon and a confidence level β , CVaR is the conditional expectation of the loss exceeding VaR. In contrast to VaR, CVaR provides additional information on the magnitude of the excess loss. It has been shown that CVaR is a coherent risk measure; see for example, [3, 21]. In addition, minimizing CVaR typically leads to a portfolio with a small VaR.

Assume that $L(x)$ is the random variable denoting loss of a portfolio $x \in \mathcal{R}^n$ within a given time horizon. If x is a vector of instrument holdings and δV is (random) change in the instrument values, then $L(x) = -x^T(\delta V)$. For a given confidence level,

CVaR is given by

$$\begin{aligned} & \text{CVaR}_\beta(L(x)) \\ &= \min_{\alpha} \left(\alpha + (1 - \beta)^{-1} \mathbf{E}((L(x) - \alpha)^+) \right) \end{aligned} \quad (3)$$

where $(L(x) - \alpha)^+ = \max(L(x) - \alpha, 0)$ and $\mathbf{E}(\cdot)$ denotes the expectation of a random variable. When the loss distribution is continuous, the above relation follows directly from the optimality condition [22]. Unlike VaR, the CVaR portfolio optimization problem,

$$\min_{x, \alpha} \left(\alpha + (1 - \beta)^{-1} \mathbf{E}((L(x) - \alpha)^+) \right) \quad (4)$$

is a convex optimization problem [22].

Assume that $\{(\delta V)_i\}_{i=1}^m$ are independent samples of the change in the instrument values over the given horizon. Then the following is a scenario CVaR optimization problem, which approximates the above continuous CVaR optimization problem:

$$\min_{(x, \alpha)} \left(\alpha + \frac{1}{m(1 - \beta)} \sum_{i=1}^m [-(\delta V)_i^T x - \alpha]^+ \right) \quad (5)$$

This piecewise linear optimization problem has an equivalent linear programming formulation, which can be solved using standard linear programming methods. The resulting linear program has $O(m + n)$ variables and $O(m + n)$ constraints, where m is the number of Monte Carlo samples and n is the number of instruments. Note that any additional linear constraints can easily be included. Although this linear programming problem can be solved using standard linear programming software, a smoothing technique is proposed in [1]; this smoothing method is shown to be significantly more computationally efficient when the number of instruments and scenarios become large.

Frequently, portfolio optimal decision problem is also a multistage dynamic programming problem. Recently, there has been much interest in the optimal execution of a portfolio of large trades under the market impact consideration; see, for example, [2, 4, 13].

The optimal execution problem can be formulated as a continuous time stochastic control problem. We illustrate the problem here in the discrete setting. Suppose that a financial institution wants to sell a

large number of shares $\bar{S} \in \mathbb{R}^m$ in m assets by trading at $t_0 = 0 < t_1 < \dots < t_N = T$, where $t_{i+1} - t_i = \tau = \frac{T}{N}$ and $T > 0$ is the time horizon. Let the trades between t_{k-1} and t_k be denoted by vectors n_k , $k = 1, 2, \dots, N$.

Let us assume that, at time t_k , $k = 0, 1, \dots, N$, the vector P_k are the prices per share of assets that are publicly available in the market and $\tilde{P}_k$ are the execution prices of one unit of the assets. The *execution cost* (see **Execution Costs**) of the trades is often defined as $P_0^T \bar{S} - \sum_{k=1}^N n_k^T \tilde{P}_k$. Owing to uncertainties in price movements and in realized prices, this implementation cost is a random variable. Hence, the mean-variance formulation of the execution cost problem with a risk-aversion parameter $\lambda \geq 0$ is

$$\begin{aligned} & \min_{n_1, n_2, \dots, n_N} \mathbf{E} \left(P_0^T \bar{S} - \sum_{k=1}^N n_k^T \tilde{P}_k \right) + \\ & \quad \lambda \cdot \mathbf{Var} \left(P_0^T \bar{S} - \sum_{k=1}^N n_k^T \tilde{P}_k \right) \\ & \text{s.t.} \quad \sum_{k=1}^N n_k = \bar{S} \\ & \quad n_k \geq 0, \quad k = 1, 2, \dots, N \end{aligned} \quad (6)$$

where $\mathbf{E}(\cdot)$ and $\mathbf{Var}(\cdot)$ denote the expectation and the variance of a random variable, respectively.

The complexity level of equation (6) depends on assumptions on the price dynamics and the impact functions. In [2], the price vector P_k is assumed to follow the dynamics:

$$P_k = P_{k-1} + \tau^{1/2} \Sigma \xi_k - \tau g \left(\frac{n_k}{\tau} \right) \quad (7)$$

where $\xi_k^T \in \mathbb{R}^l$ represents an l -vector of independent standard normals, and Σ is an $m \times l$ volatility matrix of the asset prices. The m -vector function $g(\cdot)$ measures the permanent price impact (see **Price Impact**), which is, in general, relatively small. The execution prices are given by

$$\tilde{P}_k = P_{k-1} - h \left(\frac{n_k}{\tau} \right) \quad (8)$$

where the m -vector nonlinear function $h(\cdot)$ describes the temporary price impact.

Even in this simple price dynamic and market impact models, there are many interesting and important issues for the optimal execution problem. Price impact functions represent the *expected* price depression caused by trading assets at a unit rate. Estimating both temporary and permanent impact functions can incur large estimation errors. The sensitivity of the optimal execution strategy to the estimation error in the impact matrices has recently been studied in [20]. In addition, if the price dynamics and impact functions depend on additional state variables as considered in [4], solving a portfolio execution problem with many assets is computationally challenging, especially when no short selling constraints are imposed.

Nonlinear Programming

One of the most active roles optimization plays in finance is the calibration of models (*see Model Calibration*) yield curve construction (*see Yield Curve Construction*) and statistical estimation problems (*see Generalized Method of Moments (GMM); Entropy-based Estimation; Simulation-based Estimation*). Mathematical models are used to represent the behavior of financial instruments, and portfolios of such instruments, and such models almost always require parameters to be estimated. These parameters can be scalars, vectors, matrices, tensors, lines, curves, and surfaces. The estimation processes can lead to linear, nonlinear, convex, and nonconvex optimization problems (see examples in **Model Calibration**).

The usual situation leads to a data-fitting problem: given a model with unknown parameters, and given some real data (say, market prices), determine the “best” value for the parameters. An important class of such problems is the option model calibration problem in which one determines a model so that model values best fit market prices. Such problems are known as *inverse* problems and there is a significant literature on the creation and solution of inverse problems in engineering.

To illustrate, assume that a family of models are described by the model parameters x in a feasible set Ω . The feasible set constraints (such as non-negativity, upper-bound constraints) can be used to impose certain conditions on the model parameters.

Calibration problems determine the best fit to the market option prices; the best fitting parameters can be determined by solving the following nonlinear least-squares problem:

$$\min_{x \in \Omega} \frac{1}{2} \sum_{j=1}^m (V_0(K_j, T_j; x) - V_0^{\text{mkt}}(K_j, T_j))^2 \quad (9)$$

where $V_0^{\text{mkt}}(K_j, T_j)$ denote today’s market prices for standard options with strike K_j and expiry T_j , $j = 1, \dots, m$, and $\{V_0(K_j, T_j; x), j = 1, \dots, m\}$ denote today’s model values corresponding to model parameters x .

Let $F(x) : \Re^n \rightarrow \Re^m$ denote the residual vector

$$F(x) \stackrel{\text{def}}{=} \begin{bmatrix} V_0(K_1, T_1; x) - V_0^{\text{mkt}}(K_1, T_1) \\ \vdots \\ V_0(K_m, T_m; x) - V_0^{\text{mkt}}(K_m, T_m) \end{bmatrix} \quad (10)$$

The calibration problem is a *nonlinear least-squares* problem

$$\min_{x \in \Omega} \frac{1}{2} \|F(x)\|_2^2$$

There are a host of numerical challenges and issues that arise in the calibration setting but we only mention a few of them here. The foremost, without a doubt, is the reliability of the data (and the volume of data to be used). Data reliability can lead to preprocessing steps such as filtering, and, in some cases, choosing an optimization formulation that is relatively insensitive to data errors (e.g., least-squares minimization is much more sensitive to (erroneous) outliers than absolute-value minimization).

Avoiding overfitting is also a major issue. In order for a model to calibrate some market information, for example, market option prices, one needs to consider a family of sufficiently complex models. For example, it is well known that the classical Black–Scholes model is inadequate to calibrate equity option prices and more complex models such as local volatility function models (*see Local Volatility Model*), jump models (*see Exponential Lévy Models*), and stochastic volatility models (*see Heston Model*) have been proposed. When a family of complex models such as local volatility function models are considered, it is crucial to avoid overfitting data; see for example, [8]. Even when

a family of models are described by a few model parameters, the question of whether there exists sufficient information to robustly determine model parameters still remains; see, for example, jump model calibration problems [10, 18]. See also **Tikhonov Regularization** for additional discussion on regularization techniques.

In addition, option model calibration problems face computational challenges. The problem is often nonconvex and it is possible for this calibration optimization problem to have multiple local minimizers; see for example, [17]. Also note that each initial model value $V_0(K_j, T_j; x)$ is a complex nonlinear function of the model parameters x . The Levenberg–Marquardt method or Gauss–Newton method can be used to solve the nonlinear least-squares problem; see, for example, [12]. If the calibration problem has additional bound constraints, an interior point trust region method [7] can be applied. Genetic algorithms have also been used for the calibration problem; see, for example, [17]. Optimization software for this nonlinear least-squares problem requires repeated evaluation of each initial model value $V_0(K_j, T_j; x)$, which is typically done through numerical computation methods for partial differential equations or using Monte Carlo simulations. A good initial guess for the model parameters can also be crucial in ensuring success in obtaining a solution. We note that automatic differentiation may also be a useful computational tool in accurately computing the Jacobian matrices ∇F , which are often required by an optimization software. For more information on automatic differentiation, see, for example, [9, 16].

Lattice Methods for Path-dependent Options

Path-dependent options are options whose payoffs depend on some specific function F of the entire trajectory of the asset price $F_t = F(t, (S_u)_{u \leq t})$. The most well-known examples are the lookback options and Asian options. In a lookback option, the payoff function is dependent on the realized maximum or minimum price of the asset over a certain period within the life of the option. The Asian options are also called *average options* since the payoff depends on a prespecified form of averaging of the asset price over a certain period. Consider an arithmetic average Asian option that is issued at time 0 and expiring at $T > 0$, its terminal payoff is dependent on the arithmetic average A_T of the asset price process S_t over period $[0, T]$. The running average value A_t is defined as

$$A_t = \frac{1}{t} \int_0^t S_u du \quad (1)$$

with $A_0 = S_0$. We are interested in the correlated evolution of the path function with the asset price process. In the above example of arithmetic averaging, the law of evolution of A_t is given as

$$dA_t = \frac{1}{t} (S_t - A_t) dt \quad (2)$$

A variant of the lattice tree methods (binomial/trinomial methods), called the *forward shooting grid* (FSG) approach, has been successfully applied to price a wide range of strong path-dependent options, such as the lookback options, Asian options, convertible bonds with reset feature and Parisian feature, reset strike feature in shout options, and so on. The FSG approach is characterized by augmenting an auxiliary state vector at each node in the usual lattice tree, which serves to capture the path-dependent feature of the option. Under the discrete setting of lattice tree calculations, let G denote the function that describes the correlated evolution of F with S over the time step Δt , which can be expressed as

$$F_{t+\Delta t} = G(t, F_t, S_{t+\Delta t}) \quad (3)$$

For example, let A^n denote the discretely observed arithmetic average defined as

$$A^n = \frac{\sum_{i=0}^n S^i}{n+1} \quad (4)$$

where S^i is the observed asset price at time t_i , $i = 0, 1, \dots, n$. The correlated evolution of A^{n+1} with S^{n+1} is seen to be

$$A^{n+1} = A^n + \frac{S^{n+1} - A^n}{n+2} \quad (5)$$

Another example is provided by the correlated evolution of the realized maximum price M_t and its underlying asset price process S_t . Recall $M_t = \max_{0 \leq u \leq t} S_u$ so that

$$M_{t+\Delta t} = \max(M_t, S_{t+\Delta t}) \quad (6)$$

In the construction of the auxiliary state vector, it is necessary to know the number of possible values that can be taken by the path-dependent state variable. For the lookback feature, the realized maximum asset price is necessarily one of the values taken by the asset price in the lattice tree. However, the number of possible values for the arithmetic average grows exponentially with the number of time steps. To circumvent the problem of dealing with exceedingly large number of nodal values, the state vector is constructed such that it contains a set of predetermined nodal values that cover the range of possible values of arithmetic averaging. Since the realized arithmetic average does not fall on these nodal values in general, we apply interpolation between the nodal values as an approximation.

The FSG approach is pioneered by Hull and White [4] and Ritchken *et al.* [10] for pricing American and European style Asian and lookback options. Theoretical studies on the construction and convergence analysis of the FSG schemes are presented by Barraquand and Pudet [1], Forsyth *et al.* [3], and Jiang and Dai [5]. A list of various applications of the FSG approach in lattice tree algorithms for pricing strongly path-dependent options/derivative products is given as follows:

- options whose underlying asset price follows various kinds of GARCH processes [11];
- path-dependent interest rate claims [9];
- Parisian options, alpha-quantile options, and strike reset options [6];

- soft call requirement in convertible bonds [7];
- target redemption notes [2]; and
- employee stock options with repricing features [8].

In this article, we illustrate the application of the FSG lattice tree algorithms for pricing options with path-dependent lookback and Asian features, convertible bonds with the soft call requirement (Parisian feature), and call options with the strike reset feature.

Lookback Options

Let the risk neutral probabilities of upward, zero, and downward jump in a trinomial tree be represented by p_u , p_0 , and p_d , respectively. In the FSG approach for capturing the path dependence of the discrete asset price process, we append an augmented state vector at each node in the trinomial tree and determine the appropriate grid function that models the discrete correlated evolution of the path dependence. Let $V_{j,k}^n$ denote the numerical option value of the path-dependent option at the n th-time level and j upward jumps from the initial asset value S_0 . Here, k denotes the numbering index for the values assumed by the augmented state vector at the (n, j) th node in the trinomial tree. Let u and d denote the proportional upward and downward jump of the asset price over one time step Δt , with $ud = 1$. Let $g(k, j)$ denote the grid function that characterizes the discrete correlated evolution of the path-dependent state variable F_t and asset price process S_t . When applied to the trinomial tree calculations, the FSG scheme takes the following form:

$$V_{j,k}^n = e^{-r\Delta t} \left[p_u V_{j+1, g(k, j+1)}^{n+1} + p_0 V_{j, g(k, j)}^{n+1} + p_d V_{j-1, g(k, j-1)}^{n+1} \right] \quad (7)$$

where $e^{-r\Delta t}$ denotes the discount factor over one time step (Figure 1).

We consider the floating strike lookback option whose terminal payoff depends on the realized maximum of the asset price, namely, $V(S_T, M_T, T) = M_T - S_T$. The corresponding discrete analogy of the correlated evolution of M_t and S_t is given by the following grid function (equation 6):

$$g(k, j) = \max(k, j) \quad (8)$$

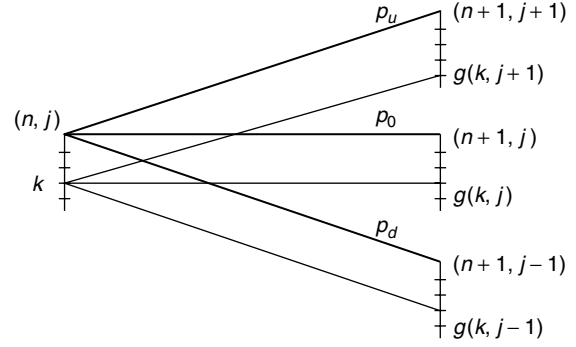

Figure 1 The discrete correlated evolution of the path-dependent state variable F_t and asset price process S_t is characterized by the grid function $g(k, j)$

As in usual trinomial calculations, we apply the backward induction procedure, starting with the lattice nodes at maturity. Suppose that there are a total of N time steps in the trinomial tree so that the maximum value of the discrete asset price process is $S_0 u^N$, corresponding to N successive jumps from the initial value S_0 . The possible range for realized maximum asset price would be $\{S_0, S_0 u, \dots, S_0 u^N\}$. When these possible values of the path-dependent state variable are indexed by k , then k assumes values from $0, 1, \dots$, to N . The terminal option value at the (N, j) th node and k th value in the state vector is given as

$$\begin{aligned} V_{j,k}^N &= S_0 u^k - S_0 u^j, \\ j &= -N, -N+1, \dots, N \text{ and} \\ k &= \max(j, 0), \max(j, 0) + 1, \dots, N \end{aligned} \quad (9)$$

Applying backward induction over one time step from expiry, the option values at the $(N-1)$ th time level are given as

$$\begin{aligned} V_{j,k}^{N-1} &= e^{-r\Delta t} \left[p_u V_{j+1, \max(k, j+1)}^N + p_0 V_{j, \max(k, j)}^N + p_d V_{j-1, \max(k, j-1)}^N \right] \\ j &= -N+1, -N+2, \dots, N-1, \\ k &= \max(j, 0) + 1, \dots, N-1 \end{aligned} \quad (10)$$

where the terminal option values are defined in equation (9). The backward induction procedure is then repeated to obtain numerical option values at the lattice nodes at earlier time levels. Note that the range

of the possible values assumed by the path-dependent state variable narrows as we proceed backward in a stepwise manner until we reach the tip of the trinomial tree.

Asian Options

Recall that the asset price S_j^n at the (n, j) th node in the trinomial tree is given as

$$S_j^n = S_0 u^j = S_0 e^{j\Delta W}, \quad j = -n, -n+1, \dots, n \quad (11)$$

where $u = e^{\Delta W}$ with $\Delta W = \sigma\sqrt{\Delta t}$. Here, σ is the volatility of the asset price. The average asset price at the n th time level must lie between $\{S_0 u^{-n}, S_0 u^n\}$. We take $\rho < 1$ and let $\Delta Y = \rho\Delta W$. Let $\text{floor}(x)$ denote the largest integer less than or equal to x and $\text{ceil}(x) = \text{floor}(x) + 1$. We set the possible values taken by the average asset price to be

$$A_k^n = S_0 e^{k\Delta Y}, \quad k = \text{floor}\left(-\frac{n}{\rho}\right), \dots, \text{ceil}\left(\frac{n}{\rho}\right) \quad (12)$$

The earlier FSG schemes choose ρ to be a sufficiently small number that is independent of Δt . The larger the value chosen for $1/\rho$, the finer the quantification of the average asset price. In view of numerical convergence of the FSG schemes, Forsyth *et al.* [3] propose to choose ρ to depend on $\sqrt{\Delta t}$ (say, $\rho = \lambda\sqrt{\Delta t}$, where λ is independent of Δt), though this would result in an excessive amount of computation in actual implementation. Further details on numerical convergence of various versions of the FSG schemes are presented later.

Suppose that the average is A_k^n and the asset price moves upward from S_j^n to S_{j+1}^{n+1} , then the new average is given as (equation 5)

$$A_{k^+}^{n+1} = A_k^n + \frac{S_{j+1}^{n+1} - A_k^n}{n+2} \quad (13)$$

Next, we set $A_{k^+}^{n+1}$ to be $S_0 e^{k^+(j)\Delta Y}$ for some value $k^+(j)$, that is,

$$k^+(j) = \frac{\ln A_{k^+}^{n+1}/S_0}{\Delta Y} \quad (14)$$

Note that $k^+(j)$ is not an integer in general, so $A_{k^+}^{n+1}$ does not fall onto one of the preset values for the average. Recall that $\text{floor}(k^+(j))$ is

the largest integer less than or equal to $k^+(j)$ and $\text{ceil}(k^+(j)) = \text{floor}(k^+(j)) + 1$. By the above construction, $A_{\text{floor}(k^+(j))}^{n+1}$ and $A_{\text{ceil}(k^+(j))}^{n+1}$ now fall onto the set of preset values. Similarly, we define

$$\begin{aligned} A_{k^-}^{n+1} &= A_k^n + \frac{S_{j-1}^{n+1} - A_k^n}{n+2} \\ A_{k^0}^{n+1} &= A_k^n + \frac{S_j^{n+1} - A_k^n}{n+2} \end{aligned} \quad (15)$$

corresponding to the new average at the $(n+1)$ th time level when the asset price experiences a downward jump and zero jump, respectively. In addition, $\text{floor}(k^-(j))$, $\text{ceil}(k^-(j))$, $\text{floor}(k^0(j))$, and $\text{ceil}(k^0(j))$ are obtained in a similar manner.

Let V_{j,k^+}^n denote the Asian option value at node (n, j) with the averaging state variable A_t assuming the value $A_{k^+}^n$, and assuming similar notation for $V_{j,\text{floor}(k^+(j))}^n$, and so on. In the lattice tree calculations, numerical option values for $V_{j,k}^n$ are obtained only for the case when k is an integer. Since $k^+(j)$ assumes a noninteger value in general, V_{j,k^+}^n is approximated through interpolation using option values at the neighboring nodes. Suppose that linear interpolation is adopted; we approximate V_{j,k^+}^n by the following interpolation formula:

$$V_{j,k^+}^n = \epsilon_{j,k}^+ V_{j,\text{ceil}(k^+(j))}^n + (1 - \epsilon_{j,k}^+) V_{j,\text{floor}(k^+(j))}^n \quad (16)$$

where

$$\epsilon_{j,k}^+ = \frac{\ln A_{k^+}^n - \ln A_{\text{floor}(k^+(j))}^n}{\Delta Y} \quad (17)$$

The FSG algorithm with linear interpolation for pricing an Asian option can be formulated as follows (Figure 2):

$$\begin{aligned} V_{j,k}^n &= e^{-r\Delta t} \left(p_u V_{j,k^+}^{n+1} + p_0 V_{j,k^0}^{n+1} + p_d V_{j,k^-}^{n+1} \right) \\ &= e^{-r\Delta t} \left\{ p_u \left[\epsilon_{j,k}^+ V_{j,\text{ceil}(k^+(j))}^{n+1} + (1 - \epsilon_{j,k}^+) V_{j,\text{floor}(k^+(j))}^{n+1} \right] \right. \\ &\quad + p_0 \left[\epsilon_{j,k}^0 V_{j,\text{ceil}(k^0(j))}^{n+1} + (1 - \epsilon_{j,k}^0) V_{j,\text{floor}(k^0(j))}^{n+1} \right] \\ &\quad + p_d \left[\epsilon_{j,k}^- V_{j,\text{ceil}(k^-(j))}^{n+1} + (1 - \epsilon_{j,k}^-) V_{j,\text{floor}(k^-(j))}^{n+1} \right] \left. \right\} \end{aligned} \quad (18)$$

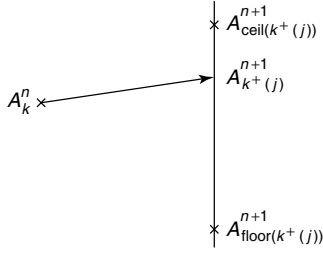

Figure 2 The average value A_k^n at the n th time step changes to $A_{k^+}^{n+1}$ at the $(n+1)$ th time step upon an upward move of the asset price from S_j^n to S_{j+1}^{n+1} . The option value at node $(n+1, j+1)$ with asset price average $A_{k^+}^{n+1}$ is approximated by linear interpolation between the option values with asset price average $A_{\text{floor}(k^+)}^{n+1}$ and $A_{\text{ceil}(k^+)}^{n+1}$

Numerical Convergence of FSG Schemes

Besides linear interpolation between two neighboring nodal values, other forms of interpolation can be adopted (say, quadratic interpolation between 3 neighboring nodal values or nearest node point interpolation). Forsyth *et al.* [3] remark that the FSG algorithm using ρ that is independent of Δt and the nearest node point interpolation may exhibit large errors as the number of time steps increases. They also prove that this choice of ρ in the FSG algorithm together with linear interpolation converges to the correct solution plus a constant error term. Unfortunately, the error term cannot be reduced by decreasing the size of the time step. To ensure convergence of the FSG calculations to the true Asian option price, they propose to use ρ that depends on $\sqrt{\Delta t}$, though this would lead to a large number of nodes in the averaging direction. More precisely, if ρ is independent of $\sqrt{\Delta t}$, then the complexity of the FSG method is $O(n^3)$, but convergence cannot be guaranteed. If we set $\rho = \lambda\sqrt{\Delta t}$, which guarantees convergence, then the complexity becomes $O(n^{7/2})$.

Soft Call Requirement in Callable Convertible Bonds

Most convertible bonds contain the call provision that allows the issuer to have the flexibility to manage the debt–equity ratio in the company’s capital structure. To protect the conversion premium paid upfront by the bondholders to be called away too soon, the bond indenture commonly contains the hard call protection

clause that prevents the issuer from initiating a call during the early life of the convertible bond. In addition, the soft call clause further requires the stock price to stay above the trigger price (typically 30% higher than the conversion price) for a consecutive or cumulative period before initiation of issuer’s call. The purpose of the soft call clause is to minimize the potential of market manipulation by the issuer.

The path-dependent feature that models the phenomenon of the asset price staying above some threshold level for a certain period of time is commonly called the *Parisian feature*. Let B denote the trigger price and the “Parisian” clock starts counting (cumulatively or consecutively) when the asset price stays above B . In the discrete trinomial evolution of the asset price, we construct the grid function $g_{\text{cum}}(k, j)$ that models the correlated evolution of the discrete asset price process and the cumulative counting of the number of time steps that $S_j \geq B$. Given that k is the cumulative counting of the number of time steps that the asset price has been staying above B , the index k increases its value by 1 when $S_j \geq B$. Then we have

$$g_{\text{cum}}(k, j) = k + \mathbf{1}_{\{S_j \geq B\}} \quad (19)$$

where $\mathbf{1}_{\{S_j \geq B\}}$ denotes the indicator function associated with the event $\{S_j \geq B\}$. In a similar manner, the grid function $g_{\text{con}}(k, j)$ that models the consecutive counting of the number of time steps that $S_j \geq B$ is defined as

$$g_{\text{con}}(k, j) = (k + 1)\mathbf{1}_{\{S_j \geq B\}} \quad (20)$$

Using the FSG approach, the path dependence of the soft call requirement can be easily incorporated into the pricing algorithm for a convertible bond with call provision [7]. Suppose that the number of cumulative time steps required for activation of the call provision is K ; then the dynamic programming procedure that enforces the interaction of the game option of holder’s optimal conversion and issuer’s optimal call is applied at a given lattice grid only when the condition $g_{\text{cum}}(k, j) \geq K$ is satisfied.

Call Options with Strike Reset Feature

Consider a call option with strike reset feature where the option’s strike price is reset to the prevailing asset price on a preset reset date if the option is out of the money on that date. Let $t_i, i = 1, 2, \dots, M$, denote

the reset dates and X_i denote the strike price specified on t_i based on the above reset rule. Write X_0 as the strike price set at initiation; then, X_i is given as

$$X_i = \min(X_0, X_{i-1}, S_{t_i}) \quad (21)$$

where S_{t_i} is the prevailing asset price at reset date t_i . Note that the strike price at expiry of this call option is not fixed since its value depends on the realization of the asset price at the reset dates. When we apply the backward induction procedure in the trinomial calculations, we encounter the difficulty in defining the terminal payoff since the strike price is not yet known. These difficulties can be resolved easily using the FSG approach by tracking the evolution of the asset price and the reset strike price through an appropriate choice of the grid function [6].

Recall that S_0 is the asset price at the tip of the trinomial tree and the asset price after j net upward jumps is $S_0 u^j$. In our notation, the index k is used as the one-to-one correspondence to the asset price level $S_0 u^k$. Say, suppose that the original strike price X_0 corresponds to the index k_0 , this would mean $X_0 = S_0 u^{k_0}$. For convenience, we may choose the proportional jump parameter u such that k_0 is an integer. In terms of these indexes, the grid function that models the correlated evolution between the reset strike price and asset price is given as (see equation 21)

$$g_{\text{reset}}(k, j) = \min(k, j, k_0) \quad (22)$$

where k denotes the index that corresponds to the strike price reset in the last reset date and j is the index that corresponds to the prevailing asset price at the reset date.

Since the strike price is reset only on a reset date, we perform the usual trinomial calculations for those time levels that do not correspond to a reset date while the augmented state vector of strike prices are adjusted according to the grid function $g_{\text{reset}}(k, j)$ for those time levels that correspond to a reset date. The FGS algorithm for pricing the reset call option is given as

$$V_{j,k}^n = \begin{cases} p_u V_{j+1,k}^{n+1} + p_0 V_{j,k}^{n+1} + p_d V_{j-1,k}^{n+1} & \text{if } (n+1)\Delta t \neq t_i \text{ for some } i \\ p_u V_{j+1, g_{\text{reset}}(k, j+1)}^{n+1} + p_0 V_{j, g_{\text{reset}}(k, j)}^{n+1} & \\ \quad + p_d V_{j-1, g_{\text{reset}}(k, j-1)}^{n+1} & \\ \text{if } (n+1)\Delta t = t_i \text{ for some } i \end{cases} \quad (23)$$

Lastly, the payoff values along the terminal nodes at the N th time level in the trinomial tree are given as

$$V_{j,k}^N = \max(S_0 u^j - S_0 u^k, 0), \quad j = -N, -N+1, \dots, N \quad (24)$$

and k assumes values that are taken by j and k_0 .

Wavelet Galerkin Method

Wavelet methods in finance are a particular realization of the finite element method (see **Finite Element Methods**) that provides a very general PDE-based numerical pricing technique. The methods owe their name to the choice of a wavelet basis in the finite element method. This particular choice of basis allows the method to solve partial integro-differential equations (PIDEs) arising from a very large class of market models. Therefore, wavelet-based finite element methods are well suited for the analysis of model risk and pricing in multidimensional and exotic market models. Since wavelet methods are mesh-based methods they allow for the efficient calculation of Greeks and other model sensitivities.

As for any finite element method, the general setup for wavelet methods can be described as follows. Consider a basket of $d \geq 1$ assets whose log returns X_t are modeled by a Lévy or, more generally, a Feller process with state space $\mathbb{R}^d$ and $X_0 = x$. By the fundamental theorem of asset pricing, the arbitrage-free price u of a European contingent claim with payoff $g(\cdot)$ on these assets is given by the conditional expectation

$$u(x, t) = \mathbb{E} [g(X_t) \mid X_0 = x] \quad (1)$$

under an *a priori* chosen equivalent martingale measure (see **Exponential Lévy Models**). Provided sufficient smoothness of u , the price can be obtained as the solution of a PIDE (see **Partial Differential Equations; Partial Integro-differential Equations (PIDEs)**):

$$\begin{aligned} \frac{\partial u}{\partial t} + \mathcal{A}u &= 0 \\ u(\cdot, 0) &= g \end{aligned} \quad (2)$$

where $\mathcal{A}$ denotes the infinitesimal generator of the process X . For the Galerkin-based finite element implementation, equation (2) is converted into variational form on a suitable test space V (cf., e.g., [11, 20] and the references therein). The variational pricing equation then reads: find $u \in V$ such that

$$\left\langle \frac{d}{dt}u, v \right\rangle + \mathcal{E}(u, v) = 0 \quad \text{for all } v \in V \quad (3)$$

where $\mathcal{E}(u, v) := \langle \mathcal{A}u, v \rangle_{L^2 \times L^2}$ denotes the bilinear form associated to the process X . Note that this bilinear form is the central object of discretization in wavelet methods. Owing to the variational formulation (3), wavelet methods are also referred to as *variational methods*.

In one dimension, wavelet methods have been introduced by Matache *et al.* [20, 21]. They were successively applied to American-type contracts (cf. [19, 27]) as well as stochastic volatility models (cf. [14]). In [11], this approach was extended to multidimensional market models based on the sparse tensor product approach and wavelet compression techniques as described in [23, 26] and the references therein.

Admissible Pricing Models

Wavelet-based finite element methods are applicable whenever the variational equation (3) admits a unique solution. Some admissible market models are the multidimensional Black–Scholes model, local volatility models, Kou’s model (see **Kou Model**), stochastic volatility models (see **Barndorff-Nielsen and Shephard (BNS) Models; Heston Model; Hull–White Stochastic Volatility Model**), one-dimensional Lévy models (see **Variance-gamma Model; Jump-diffusion Models; Time-changed Lévy Process; Exponential Lévy Models**), multidimensional Lévy copula models (see [11]), as well as models based on time inhomogeneous or nonstationary processes (see [6]). The particular choice of market model determines the particular form of the bilinear form $\mathcal{E}(\cdot, \cdot)$ in equation (3). In all the above market models, the bilinear form is governed by the characteristic triplet $(\gamma, \mathcal{Q}, \nu)$ of the underlying Lévy process. It consists of a drift vector $\gamma \in \mathbb{R}^d$, a covariance matrix $\mathcal{Q} \in \mathbb{R}^{d \times d}$, and a Lévy-type measure ν that is assumed to be absolutely continuous with density $k(z)dz = \nu(dz)$. Then, $\mathcal{E}(\cdot, \cdot)$ is of the abstract form

$$\begin{aligned} \mathcal{E}(u, v) &= \langle \gamma \nabla u, v \rangle + \frac{1}{2} \langle \mathcal{Q} \nabla u, \nabla v \rangle \\ &\quad - \int \int_{\mathbb{R}^d \times \mathbb{R}^d} (u(x + f(z)) - u(x) \\ &\quad - f(z) \cdot \nabla u(x)) v(x) \nu(dz) dx \end{aligned} \quad (4)$$

Note that in case the underlying process X is not stationary or time inhomogeneous, the parameters $(\gamma, \mathcal{Q}, \nu) = (\gamma(x, t), \mathcal{Q}(x, t), \nu(x, t))$ as well as the function $f(\cdot)$ may depend on space and time (e.g., in models based on Sato processes [6]). Furthermore, the parameters are allowed to degenerate (e.g., in stochastic volatility models). Under rather weak conditions, wavelet-based finite elements methods are still applicable in these cases.

Wavelet-based Finite Element Discretization

The wavelet-based finite element implementation of equation (3) is obtained in three steps: first, the original space domain $\mathbb{R}^d$ has to be *localized* to a bounded domain $\square := [-R, R]^d$, $R > 0$. Second, the test space V needs to be *discretized* by an increasing sequence of finite dimensional subspaces $V^L \subset V$, $L \in \mathbb{N}$. Third, a *time-stepping* scheme has to be applied to discretize in time.

Localization

For the localization, we find that in finance truncation of the original x -domain $\mathbb{R}^d$ to $\square$ corresponds to approximating the solution u of equation (2) by the price u_R of a corresponding barrier option on $[e^{-R}, e^R]^d$. In case the underlying stochastic process X admits semiheavy tails, the solution of the localized problem u_R converges pointwise exponentially to the solution u of equation (3). There exist constants $\alpha, \beta > 0$ such that

$$|u(t, x) - u_R(t, x)| \lesssim e^{-\alpha R + \beta \|x\|_\infty} \quad (5)$$

It therefore indeed suffices to replace the original price space domain $\mathbb{R}^d$ by $\square = [-R, R]^d$ with sufficiently large $R > 0$. For details we refer to [24].

Space Discretization

In wavelet methods, the space discretization is based on the concepts of classical finite element methods (see **Finite Element Methods**). To this end, for any level index $L \in \mathbb{N}$, let $V^L \subset V$ be a subspace of dimension $N := \dim V^L = \mathcal{O}(h^{-d})$ generated by a tensor product finite element basis $\Phi_L := \{\phi_{j,L} : j \in \Delta_L\}$ with some suitable index set Δ_L corresponding to a mesh of width $h = 2^{-L}$. There holds $V^L \subset V^{L+1}$

for all $L \in \mathbb{N}$. For further details on classical finite element approximations see, for example [10].

Denote by $\underline{U}_L$ the coefficient vector of u with respect to Φ_L . Then equation (3) is equivalent to: find $\underline{U}_L(t) \in \mathbb{R}^N$ such that $\underline{U}_L(0) = \underline{U}_0$ and

$$\mathbf{M}\underline{U}'_L(t) + \mathbf{A}\underline{U}_L(t) = 0, \quad t \in (0, T) \quad (6)$$

where $\mathbf{M}$ and $\mathbf{A}$ are the so-called mass and stiffness matrices.

Straightforward application of standard finite element schemes to calculate the stiffness matrix $\mathbf{A} = (\mathcal{E}(\phi_{i,L}, \phi_{j,L}))_{i,j \in \Delta_L}$ arising from general market models fails due to two reasons. For high-dimensional models, we have the “curse of dimension”: the number of degrees of freedom on a tensor product finite element mesh of width h in dimension d grows like $\mathcal{O}(h^{-d})$ as $h \rightarrow 0$. For jump models, the nonlocality of the underlying operator implies that the standard finite element stiffness matrix $\mathbf{A}$ consists of $\mathcal{O}(h^{-2d})$ nonzero entries, which is not practicable even in one dimension with small mesh widths.

Wavelets can overcome these issues while still being easy to compute. There are three main advantages.

- Break the curse of dimension using sparse tensor products (see **Sparse Grids**) $\Rightarrow$ dimension-independent complexity (up to log-factors).
- Multiscale compression of jump measure of $X \Rightarrow$ complexity of jump models can asymptotically be reduced to Black–Scholes complexity.
- Efficient preconditioning.

In one dimension, biorthogonal *complement* or *wavelet bases* $\Psi_L = \{\psi_{j,L} : j \in \nabla_L\}$, $\nabla_L := \Delta_{L+1} \setminus \Delta_L$ are constructed from the single-scale bases Φ_L ; for details see [7, 9, 22]. Denoting by W^L the span of Ψ_L , the spaces V^{L+1} admit a splitting

$$V^{L+1} = W^L \oplus V^L, \quad L > 0 \quad (7)$$

Each wavelet space W^L can be thought of as describing the increment of information when refining the finite element approximation from V^L to V^{L+1} . Furthermore, equation (7) implies that for any $L > 0$ the finite element space V^L can be written as a direct *multilevel* sum of the wavelet spaces W^ℓ , $\ell < L$. Thus, any $u_L \in V^L$ has the representation

$$u_L = \sum_{\ell=0}^{L-1} \sum_{j \in \nabla_\ell} d_{j,\ell} \psi_{j,\ell} \quad (8)$$

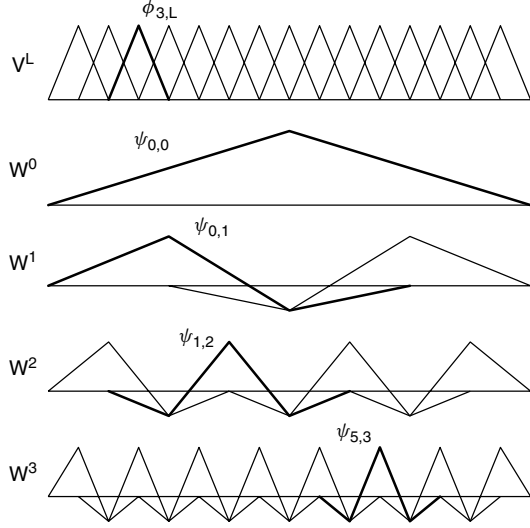

Figure 1 Schematic of single-scale space V^L and its decomposition into multiscale wavelet spaces W^ℓ

with suitable coefficients $d_{j,\ell} \in \mathbb{R}$. Figure 1 illustrates the decomposition of the finite element space V^L , $L = 4$, spanned by continuous, piecewise linear (nodal) basis functions $\phi_{i,L}$ into its increment spaces W^ℓ , $\ell = 0, \dots, 3$, spanned by wavelets $\psi_{j,\ell}$. In the multidimensional setting, we obtain multivariate wavelet basis functions by using tensor products. The finite element spaces V^L can then be characterized by

$$V^L = \text{span} \{ \psi_{j_1, \ell_1}(x_1) \cdots \psi_{j_d, \ell_d}(x_d) : \ell_1, \dots, \ell_d \leq L, j_i \in \nabla_{\ell_i} \} \quad (9)$$

Since these multivariate wavelet bases comprise of products of one-dimensional wavelets, they form *hierarchical bases* as in [12]. Thus, the spaces V^L can be replaced by *sparse tensor product* spaces

$$\widehat{V}^L = \text{span} \{ \psi_{j_1, \ell_1}(x_1) \cdots \psi_{j_d, \ell_d}(x_d) : \ell_1 + \dots + \ell_d \leq L, j_i \in \nabla_{\ell_i} \} \quad (10)$$

In [3, 26] it is shown that, under certain smoothness assumptions on the solution u of equation (3), the sparse tensor product spaces preserve the approximation properties of the full tensor product spaces, while there holds $\widehat{N} := \dim \widehat{V}^L = \mathcal{O}(h^{-1} |\log h|^{d-1}) \ll N$. Herewith, the complexity of the finite element

stiffness matrix can be reduced to $\mathcal{O}(h^{-2} |\log h|^{2(d-1)})$ instead of the original $\mathcal{O}(h^{-2d})$ nonzero entries.

Furthermore, wavelet basis functions give rise to certain *cancellation properties* and *norm equivalences* as illustrated in, for example [2, 7]. One therefore obtains sharp estimates for the entries of the corresponding stiffness matrix, cf. [20, 23]. Herewith *a priori* compression schemes can be defined that further reduce the complexity of the stiffness matrix. The compression exploits the fact that the position of large entries in the stiffness matrix arising from a model with jumps resembles the structure of a Black–Scholes stiffness matrix. The remaining entries can *a priori* be proved to be negligible. Therefore, the compression scheme (asymptotically) reduces the complexity of a model with jumps to that of the Black–Scholes model. To give a brief illustration of this idea, in Figure 2, the density pattern of the stiffness matrix of the Black–Scholes model (a) and a Lévy model of tempered-stable-type (b) in one dimension is given.

Combining the compression scheme with the sparse tensor product spaces results in a computational complexity of $\mathcal{O}(h^{-1} |\log h|^{2(d-1)})$ instead of the original $\mathcal{O}(h^{-2d})$. It is proved that these wavelet schemes preserve stability and convergence of the classical finite element schemes, cf. [23].

Time Stepping

To finally obtain a fully discrete solution of equation (3), there are various methods to approximate the solution of the ordinary differential equation (6). These time-stepping methods are not specific to wavelet-based finite element methods. We therefore mention only a few examples here: one obtains algebraic convergence $\mathcal{O}((\Delta t)^\alpha)$ in the time step size Δt for all the above market models using the implicit Euler scheme, then $\alpha = 1$ or the Crank–Nicholson scheme, then $\alpha = 2$; see, for example [1]. Furthermore, exponential convergence rates can be obtained by discretizing equation (6) by a *hp*-discontinuous Galerkin (dG) method as in [14, 25].

American Contracts

The price u of an American-type contract is given by an optimal stopping, free boundary problem:

$$u(t, x) = \sup_{t \leq \tau \leq T} \mathbb{E}[g(X_\tau) \mid X_t = x] \quad (11)$$

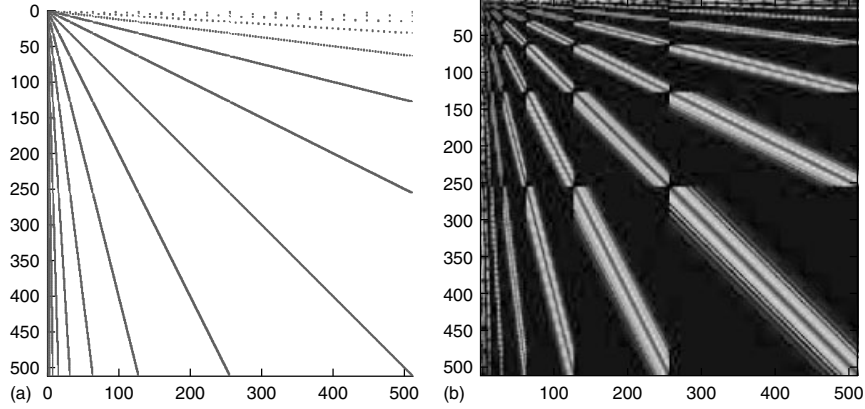

Figure 2 Density pattern for the stiffness matrix $\mathbf{A}$ for $L = 8$ refinement steps. Matrix for Black–Scholes model (a) and for tempered stable process (b)

with τ running over stopping times. The solution of equation (11) then solves a partial integro-differential *inequality* (see [19]). Similar to the variational formulation for European contracts, the wavelet-based finite element implementation solves the corresponding variational inequality: Find $u(t, \cdot) \in K_g := \{v \in V \mid v \geq g \text{ a.e.}\}$ such that

$$\left\langle \frac{\partial u}{\partial t}, v - u \right\rangle + \mathcal{E}(u, v - u) \leq 0 \quad \text{for all } v \in K_g \quad (12)$$

Choosing finite dimensional subspaces $V^L \subset V$, as above, to discretize in space and applying a time-stepping scheme leads to a sequence of matrix linear complementary problems. For large size $N = \dim V^L$, standard solution methods such as projected successive overrelaxation [8] are not suitable, since their rate of convergence depends on N . The wavelet-based solution algorithm suggested in [19] relies on a fixed point iteration where in each iteration step a V -projection P_{K_g} onto the convex cone K_g has to be realized. Owing to norm equivalences of the wavelet basis, the outer fixed point iteration converges at a rate independent of the dimension N of the space V^L . The projection P_{K_g} is based on a wavelet generalization of the classical Cryer algorithm [8].

Sensitivities and Greeks

As a PDE-based pricing method, wavelet methods are well suited for the fast and accurate calculation

of sensitivities of market models with respect to model parameters. Classical examples are variations of option prices with respect to the spot price or with respect to time to maturity, the so-called “Greeks” of the model.

There are two classes of sensitivities: the sensitivity of the solution u to variation of a model parameter, like the Greek Vega ($\partial_\sigma u$), and the sensitivity of the solution u to a variation of the state space such as the Greek Delta ($\partial_x u$).

Suppose that the infinitesimal generator $\mathcal{A}$ of X depends on a parameter η . We write $u(\eta_0)$ for a fixed parameter η_0 to emphasize the dependence of u on η_0 . Then, the derivative of u with respect to η

$$\tilde{u}(\delta\eta) := \lim_{s \rightarrow 0^+} \frac{1}{s} (u(\eta_0 + s\delta\eta) - u(\eta_0)) \quad (13)$$

is the solution of the PIDE (see [15])

$$\begin{aligned} \partial_t \tilde{u}(\delta\eta) + \mathcal{A}(\eta_0) \tilde{u}(\delta\eta) &= -D_\eta \mathcal{A} u(\eta_0) \\ \tilde{u}(\delta\eta)(0, \cdot) &= 0 \quad \text{in } \mathbb{R}^d \end{aligned} \quad (14)$$

where $D_\eta \mathcal{A}$ is the derivative of $\mathcal{A}$ with respect to η . Therefore, the derivative of u with respect to η can be obtained as a solution of the same pricing PIDE with a right-hand side depending on u , cf. [15].

For sensitivities with respect to a variation of the state space, a finite difference like differentiation procedure is presented in [15], which allows to obtain the sensitivities from the finite element forward price without additional forward solver.

Numerical Examples

In this section, we illustrate the use of wavelet-based finite element methods by a number of numerical examples.

Multidimensional Lévy Models

We consider a two-dimensional basket with payoff $g = (\frac{1}{2}(S_1 + S_2) - K)^+$, strike $K = 1$, and maturity $T = 1$. The price process is a pure jump process, which is given by the Clayton copula [16] and tempered stable margins [5]. The parameters are $C = (1, 1)$, $G = (10, 10)$, $M = (10, 10)$, and $Y = (0.5, 1.5)$. The copula depends on a parameter $\theta > 0$ parameterizing the dependence among jumps.

Different values for θ are used to analyze the different dependence structures. In Figure 3, we compare the model with a Black–Scholes model having the same marginal variances and the same correlation.

American-type Options in Lévy Models

We consider the finite horizon multiple stopping time problem as in [4] arising from swing options with maturity $T = 1$ and interest rate $r = 0.05$. The holder has $p = 5$ exercise rights and there is a refracting time $\delta = 0.1$ after each exercise. For computational details, see [27]. The computed prices and the exercise boundary are shown in Figure 4 where we use a tempered stable/CGMY model [5] and computed a swing put option with up

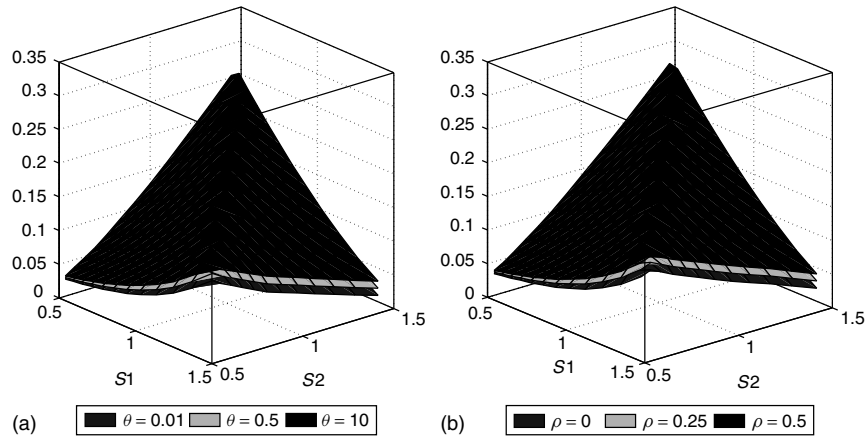

Figure 3 Time value for basket options using a Lévy model (a) and Black–Scholes model (b)

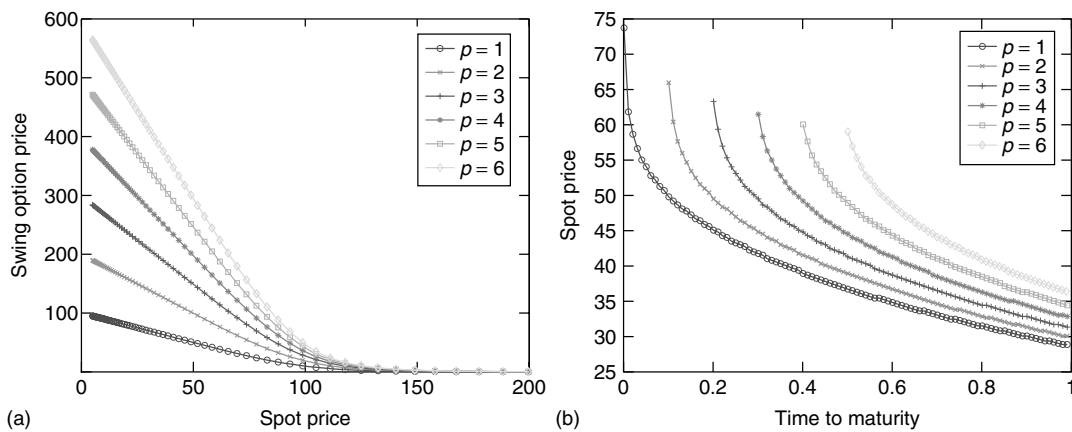

Figure 4 Swing option price (a) and exercise boundary (b) of a put option with up to six exercise rights

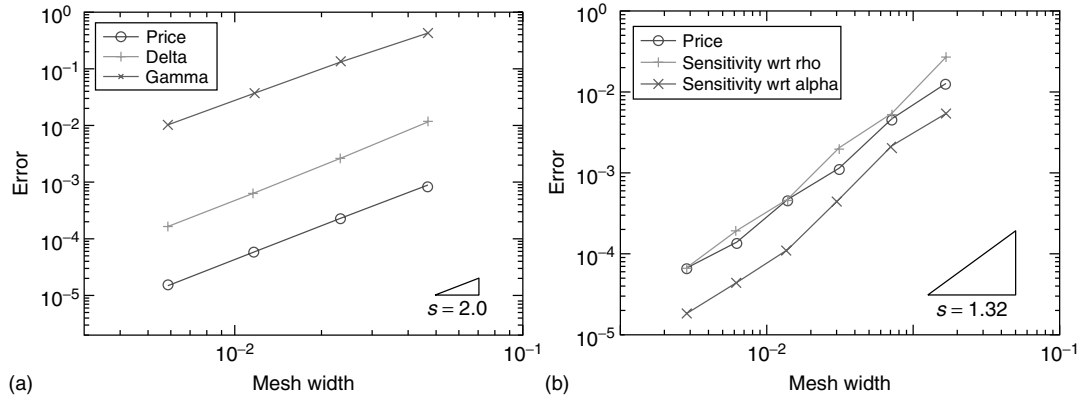

Figure 5 Convergence rates of sensitivities for a European call in the variance Gamma (a) and Heston (b) model

to five exercise rights and strike $K = 100$. The model parameters are $C = 1$, $G = 10$, $M = 10$, and $Y = 0.5$. In contrast to the result in the Black–Scholes model, the exercise boundary values in a Lévy model never reach the option’s strike price, which is well known for American options [17, 19].

Sensitivities

We compute various sensitivities for the variance Gamma [18] and the Heston model [13] where the price is known in closed form such that we are able to compute the errors between the exact price/sensitivities and their finite element approximations.

We consider a European call with strike $K = 1$ and maturity $T = 0.5$. For the variance Gamma model, we calculate the Greeks Delta, $\Delta = \partial u / \partial S$, and Gamma, $\Gamma = \partial^2 u / \partial S^2$, and use the parameters $\sigma = 0.4$, $\nu = 0.04$, and $\vartheta = -0.2$. For the Heston model, we calculate the sensitivities $\tilde{u}(\delta\rho)$ and $\tilde{u}(\delta\alpha)$ with respect to correlation ρ of the Brownian motions that drive the underlying and the volatility and the rate of mean reversion α . The model parameters are $\lambda = 0$, $\sigma = 0.5$, $m = 0.06$, $\rho = -0.5$, and $\alpha = 2.5$.

The convergence rates are shown in Figure 5. All sensitivities convergence with the same rate as the price u itself [15].

Integral Equation Methods for Free Boundaries

Free boundary problems (FBPs) are ubiquitous in modern mathematical finance. They arise as early exercise boundaries for American style options (arguably the first example in finance, introduced by McKean [15] in 1965), as default barriers in structural (value-of-firm) models of credit default [7], as the optimal strategies for refinancing mortgages [13, 21], exercising employee stock options [14] (*see Employee Stock Options*) and callable convertible bonds [20], and so on. There are many methods for treating the FBPs that arise as mathematical models of these finance problems, including variational inequalities [11], viscosity solutions [8], and the classical partial differential equations (PDE) approach [10, 16]. In this article, we focus on an integral equation (IE) approach that is particularly suited for the types of FBPs that arise in finance.

In the section Free Boundary Problems as Integral Equations, we sketch the method in the context of the American put option, perhaps the most widely known and best understood FBP in finance. After deriving an IE problem mathematically equivalent to the original Black, Scholes, and Merton (BSM) PDE FBP for the American put, we outline how the IE problem can be used to prove existence and uniqueness for the original problem and to derive analytical and numerical estimates for the location of the early exercise boundary [4, 5]. In the section Application of the IE Method to Other FBPs, we sketch how this IE approach can be carried over to other FBPs in finance [7, 21] with the goal of indicating that this is a unified approach to a diverse collection of problems.

Free Boundary Problems as Integral Equations

In this section, we outline the IE approach in the context of an American put option on a geometric Brownian motion underlier (*see American Options*). The BSM risk-neutral pricing theory says that the

option value, $p(S, t)$, satisfies the FBP

$$p_t + \frac{\sigma^2 S^2}{2} p_{SS} + rSp_S - rp = 0, \quad S_f(t) < S < \infty, 0 < t < T \quad (1)$$

$$p(S, t) = K - S \text{ on } S = S_f(t), \quad 0 < t < T \quad (2)$$

$$p_S(S, t) = -1 \text{ on } S = S_f(t), \quad 0 < t < T \quad (3)$$

$$p(S, t) \rightarrow 0 \text{ as } S \rightarrow \infty \quad (4)$$

$$p(S, T) = \max(K - S, 0), \quad K = S_f(T) < S < \infty \quad (5)$$

where r, σ, K, T have the conventional meanings and $S_f(t)$ is the location of the early exercise, free boundary to be determined along with $p(S, t)$.

Letting $\tau = \frac{\sigma^2}{2}(T - t)$ (the scaled time to expiry) and $x = \ln(S/K)$, then the scaled option price

$$P_{\text{new}} = \begin{cases} 1 - S/K & S < S_f(t) \\ p/K & S > S_f(t) \end{cases} \quad (6)$$

satisfies the transformed problem (dropping the subscript) in $-\infty < x < \infty, 0 < \tau < \sigma^2 T/2$

$$p_\tau - \{p_{xx} + (k - 1)p_x - kp\} = kH(x_f(\tau) - x) \quad (7)$$

$$p(x, 0) = \max(1 - e^x, 0) \quad (8)$$

where $k = 2r/\sigma^2$, H is the Heaviside function, $x_f(\tau) = \ln(S_f/S)$, and the coefficient k appears on the right-hand side (rhs) of equation (7) because the intrinsic payoff, $p_0(x) = 1 - e^x$ satisfies

$$p_{0\tau} - \{p_{0xx} + (k - 1)p_{0x} - kp_0\} = k \quad (9)$$

The solution to problems (7) and (8) can be written in terms of the free boundary, $x_f(\tau)$, using the fundamental solution of the pdo on the left-hand side (lhs) of equation (7),

$$\Gamma(x, \tau) = \frac{e^{-k\tau}}{2\sqrt{\pi\tau}} e^{-(x+(k-1)\tau)^2/4\tau} \quad (10)$$

in the form

$$p(x, \tau) = \int_{-\infty}^0 (1 - e^y) \Gamma(x - y, \tau) dy + k \int_0^\tau \int_{-\infty}^{x_f(u)} \Gamma(x - y, \tau - u) dy du \quad (11)$$

The first term is the price of the European style put while the second is the premium for the American optionality. Integral representations of this sort have been discussed in the finance literature for some time (see, e.g., [3]).

For the representation (11) to be useful, one must first determine the unknown location of the boundary, $x_f(\tau)$, which appears in the second integral on the rhs of equation (11). The usual approach in the free boundary literature proceeds by starting with equation (11) and evaluating the lhs at $x = x_f(\tau)$ using one or other of the conditions

$$p(x_f(\tau), \tau) = 1 - e^{x_f(\tau)} \quad (12)$$

$$p_x(x_f(\tau), \tau) = -e^{x_f(\tau)} \quad (13)$$

which are the transformed versions of the smooth pasting conditions (2) and (3). Instead, we use a trick here, based on financial considerations, to notice that $p_\tau(x_f(\tau), \tau) = 0$. Thus, from equation (11),

$$p_\tau(x, \tau) = \Gamma(x, \tau) + k \int_0^\tau \Gamma(x - x_f(u), \tau - u) \times \dot{x}_f(u) du \quad (14)$$

which, upon evaluation on the early exercise boundary, provides the following nonlinear IE for $x_f(\tau)$:

$$\Gamma(x_f(\tau), \tau) = -k \int_0^\tau \Gamma(x_f(\tau) - x_f(u), \tau - u) \times \dot{x}_f(u) du \quad (15)$$

This equation has proved, in our experience, to be much more effective in the mathematical analysis of this problem than the versions obtainable from equations (12) and (13). In addition, we have obtained still other versions, also derivable from the representation

(11), whose particular forms have proven useful in various situations [5]:

$$\int_0^\tau \{\Gamma_x(x_f(\tau), u) + k\Gamma(x_f(\tau), u)\} du = k \int_0^\tau \Gamma(x_f(\tau) - x_f(u), \tau - u) du \quad (16)$$

$$\Gamma(x_f(\tau), \tau) = \frac{k}{2} + k \int_0^\tau \{\Gamma(x_f(\tau) - x_f(u), \tau - u) - \Gamma_x(x_f(\tau) - x_f(u), \tau - u)\} du \quad (17)$$

$$\dot{x}_f(\tau) = \frac{-2\Gamma_x(x_f(\tau), \tau)}{k} + 2 \int_0^\tau \Gamma_x(x_f(\tau) - x_f(u), \tau - u) \times \dot{x}_f(u) du \quad (18)$$

Using the representation (11) to compute p_x , p_{xx} and $p_{x\tau}$, the above IEs for $x_f(\tau)$ follow (after some rearrangement of terms) by evaluation on the boundary.

The underlying theoretical rationale for using this IE approach to treat the original FBPs (1)–(5) or (7), (8), is summarized in the following result.

Theorem 1 (Theorem 3.2 and Sections 4, 5, 6 of [5]). *Suppose that $x_f \in C^1((0, \infty)) \cap C^0([0, \infty))$ and $\alpha(\tau) = x_f(\tau)^2/4\tau$. Assume that as $\tau \searrow 0$, $\alpha(\tau) = [-1 + o(1)]\ln\sqrt{\tau}$, and $\tau\dot{\alpha}(\tau) = o(1)$. Then x_f , together with p defined by equation (11), solves the (equivalent) FBPs (1–5) or (7, 8), if and only if x_f satisfies any of the equivalent integro-differential equations (IODEs) (15–18). Finally, equation (18) has a unique solution with the properties listed above.*

The equivalence of the IODEs (15–18) is established in Lemma 3.1 of [6] and the required estimates on α are rigorously derived from equation (15). The proof that equation (18) has a solution with the required properties is a highly technical analysis [6] based on Schauder's fixed point theorem. Peskir [18] used the IE obtained from equation (11) with equation (12), along with local time—space arguments, to prove uniqueness in the class of continuous boundaries.

Analytical and numerical estimates for the location of the early exercise boundary, that might be useful to practitioners, can also be obtained from the IODEs (15–18). For example, if we make the change of variables $\eta = (x_f(\tau) - x_f(u))/2\sqrt{\tau - u}$ in equation (15), the rhs for small τ (near expiry) behaves like

$$-k \int_0^{\alpha(\tau)} \left[1 - \frac{x_f(\tau) - x_f(u)}{2\dot{x}_f(u)(\tau - u)} \right]^{-1} \frac{e^{-\eta^2}}{\sqrt{\pi}} d\eta \quad (19)$$

which tends to k because $\alpha(\tau) \rightarrow -\infty$ (from the above theorem) and $[\cdot \cdot \cdot]^{-1} \rightarrow 1/2$ uniformly in u because of the convexity of x_f (proved separately in [6] using the method of Friedman and Jensen [12]); an independent proof of convexity was obtained by Ekstrom [9]. Thus, from equation (15) with small τ ,

$$\begin{aligned} \Gamma(x_f(\tau), \tau) &= \frac{e^{-k\tau}}{2\sqrt{\pi\tau}} e^{-(x_f(\tau) + (k-1)\tau)^2/4\tau} \cong \\ &= \frac{e^{-x_f(\tau)^2/4\tau}}{2\sqrt{\pi}} \cong k \end{aligned} \quad (20)$$

which leads to

$$x_f(\tau) \approx 2\sqrt{\tau} \sqrt{-\ln(4\pi k^2 \tau)^{1/2}} \text{ as } \tau \rightarrow 0 \quad (21)$$

This implies the first rigorous estimate for the near-expiry behavior of the early exercise boundary obtained by Barles *et al.* [2]

$$S_f(t) \simeq k \left[1 - \sigma \sqrt{-(T-t)\ln(T-t)} \right], t \sim T \quad (22)$$

In addition, it provides the first estimate for $\alpha(\tau)$ in the above existence theorem. Specifically,

$$\alpha(\tau) = x_f(\tau)^2 4\tau \approx -\ln(4\pi k^2 \tau)^{1/2} = -\frac{\xi}{2} \quad (23)$$

where $\xi = \ln(4\pi k^2 \tau)$.

More precise analytical and numerical estimates can be obtained for $\alpha(\tau)$ (equivalently $x_f(\tau)$ and $S_f(t)$), valid for intermediate and large times as well [5], by using Mathematica to iterate equation (23) through equation (15). Perhaps even more importantly, a very fast, accurate numerical scheme can be obtained from the IODE (18), which can be written in the equivalent form

$$\dot{x}_f(\tau) = \frac{x_f(\tau)}{2k\tau} \Gamma(x_f(\tau), \tau) [1 + m(\tau)] \quad (24)$$

where

$$\begin{aligned} m(\tau) &= k \int_0^\tau \left[\frac{2\tau}{x_f(\tau)} \left(\frac{x_f(\tau) - x_f(u)}{\tau - u} \right) - 1 \right] \\ &\quad \times \frac{\Gamma(x_f(\tau) - x_f(u), \tau - u)}{\Gamma(x_f(\tau), \tau)} \dot{x}_f(u) du \end{aligned} \quad (25)$$

that is to be solved with initial data $x_f(0) = 0$. Solving this iteratively with $m(\tau) = m_0(\tau) \equiv 0$ initially provides the fastest and most accurate approximation among all our estimates [5].

The above IE formalism can be carried over to the American put with a continuous dividend rate, d . The analog of equations (24) and (25) was used to show numerically that for a small interval of dividend rates, $r < d < (1 + \epsilon)r$, the early exercise boundary loses convexity near maturity (see Figure 1). This agrees qualitatively with the folklore on this problem generally attributed to M. Broadie.

Application of the IE Method to Other FBPs

In the previous section, we described how to formulate the American put FBP in terms of IODEs for the early exercise boundary and how to use this

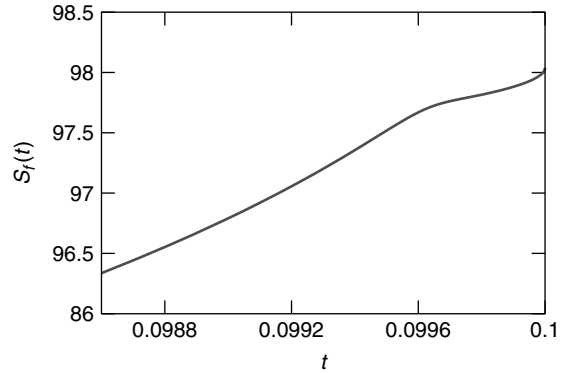

Figure 1 Graph of the early exercise boundary, $S_f(t)$, near expiry for a dividend paying stock with $r = 0.05$, $d = 0.51$, $K = 100$, $T = 0.1$. A numerical scheme based on the analog of equation (26) was used with $x_f(0) = \ln(r/d)$ and the first time step computed from the well-known $\sqrt{T-t}$ behavior near expiry

formulation to establish theoretical results (existence, uniqueness) as well as analytical and numerical estimates for the original problem. In this section, we indicate the wider applicability of the method by briefly discussing several other problems arising from finance.

Jump-diffusion Processes

These IE methods can be extended to jump-diffusion models (see **Lévy Processes**; **Poisson Process**). Specifically, letting $x = \ln(S/K)$, we now assume that the transformed asset price follows the process

$$X(t) = (\mu - \sigma^2/2)t + \sigma W(t) + N(t) \quad (26)$$

where $N(t)$ is a Poisson process with rate λt and has jumps of size $\pm\epsilon$ with equal probability. In this case, the transformed PDEs analogous to equations (7) and (8) are

$$\mathcal{L}p = \mathcal{L}(1 - e^x)H(x_f(\tau) - x) \quad (27)$$

$$p(x, 0) = \max(1 - e^x, 0) \quad (28)$$

where $\mathcal{L}$ is the nonlocal pdo

$$\begin{aligned} \mathcal{L}p = & p_\tau - \{p_{xx} + (k - 1)p_x - kp\} \\ & + \lambda\{p(x + \epsilon, \tau) - 2p + p(x - \epsilon, \tau)\} \end{aligned} \quad (29)$$

This problem is amenable by the methods outlined above because the fundamental solution can be explicitly calculated. Specifically,

$$\begin{aligned} \Gamma(x, \tau) = & \sum_{u=0}^{\infty} \frac{(\lambda\tau)^u}{2^u u!} e^{-\lambda\tau} \\ & \times \left(\sum_{j=0}^n \binom{n}{j} \Gamma_{BS}((2j - u)\epsilon + x, \tau) \right) \end{aligned} \quad (30)$$

where Γ_{BS} is the BSM fundamental solution in equation (10). Proceeding as in the section Free Boundary

Problems as Integral Equations, one obtains the analog to equation (15) in the form

$$\begin{aligned} \Gamma(x_f(\tau), \tau) = & - \int_0^\tau [k + \lambda\{2 - e^\epsilon - e^{-\epsilon}\}e^{x_f(u)} \\ & \times \Gamma(x_f(\tau) - x_f(u), \tau - u) \\ & \times \dot{x}_f(u)] du + \lambda \int_0^\epsilon (1 - e^{y-\epsilon}) \\ & \times \Gamma(x_f(\tau) - y, \tau) dy \end{aligned} \quad (31)$$

from which we obtain the near-expiry estimate for $\alpha(\tau) = x_f(\tau)^2/4\tau$ (see analog (23) with no jumps)

$$\sqrt{\tau}e^\alpha \approx 1/\sqrt{4\pi\tilde{k}^2} \text{ as } \tau \rightarrow 0 \quad (32)$$

where $\tilde{k} = k + \lambda(1 - e^{-\epsilon})$, agreeing with the result of Pham [19] using other methods.

Interest Rate Processes

These IE methods can also be used to study American style contracts on other underliers. For example, a mortgage prepayment option provides the holder with the right to prepay the outstanding balance of a fixed-rate mortgage

$$M(t) = \frac{m}{c}(1 - e^{-c(T-t)}) \quad (33)$$

where T is the maturity, c is the (continuous) fixed mortgage rate, and m is the (continuous) rate of payment of the mortgage (i.e., $m dt$ is the premium paid in any time interval dt). Clearly, the value of the prepayment option depends on $M(t)$ and also on the rate of return, $r(t)$, that the mortgage holder (borrower) can obtain by investing $M(t)$. If this short-term rate is assumed to follow the Vasicek model (see **Term Structure Models**)

$$dr = (\eta - \theta r) dt + \sigma dW \quad (34)$$

in a risk-neutral world, then the value of the prepayment option, $V(r, t)$, satisfies [13, 21]

$$\begin{aligned} V_t + \frac{\sigma^2}{2} V_{rr} + (\eta - \theta r) V_r + m - rV \\ = 0, R(t) < r < \infty, 0 < t < T \end{aligned} \quad (35)$$

$$V(r, t) = M(t), \quad r = R(t), \quad 0 < t < T \quad (36)$$

$$V_r(r, t) = 0, \quad r = R(t), \quad 0 < t < T \quad (37)$$

$$V(r, t) \rightarrow 0, \quad \text{as } r \rightarrow \infty, \quad 0 < t < T \quad (38)$$

$$V(r, T) = 0, \quad c = R(0) < r < \infty \quad (39)$$

The optimal strategy for the mortgage holder is to exercise the option to pay off the mortgage the first time that the rate r falls below $R(t)$ at time t . Existence and uniqueness for this FBP was proved using variational methods [13].

Because the fundamental solution for the Vasicek “bond pricing equation”—equation (35)—can be explicitly calculated, its form suggests a sequence of changes of dependent and independent variables (not relevant for this summary) that reduces the FBPs (35–39) to the following analog of equations (7) and (8) in $-\infty < x < \infty, s > 1$

$$u_s - \frac{1}{4}u_{xx} = f(x, s)H(x - x_f(s)) \quad (40)$$

$$u(x, 1) = 0 \quad (41)$$

where $f(x, s)$ is a specific function resulting from the transformations and $x_f(s)$ is the transformed free boundary with $u(x_f(s), s) = 0 = u_x(x_f(s), s)$.

In this form, the procedure outlined in the previous section can be followed to obtain

$$u(x, s) = \int_1^s \left[\int_{x_f(u)}^{\infty} \Gamma(x - y, s - u) f(y, u) dy \right] du \quad (42)$$

where Γ is the fundamental solution of the heat operator $\partial_s - \frac{1}{4}\partial_{xx}$, and the free boundary can be obtained by solving the IE

$$\int_1^s \left[\int_{x_f(u)}^{\infty} \Gamma(x_f(s) - y, s - u) f(y, u) dy \right] du = 0 \quad (43)$$

In [21], Dejun Xie used the integral representations (42) and (43) to obtain near-expiry estimates for the critical rate as well as to obtain a numerical scheme to determine $x_f(s)$ globally. Specifically, if $Q(x, s)$ denotes the integral on the rhs of equation

(42), he showed that the Newton–Raphson iterative scheme to solve equation (43), $Q(x_f(s), s) = 0$, can be written as

$$x_f(s)^{\text{new}} = x_f(s)^{\text{old}} + \frac{Q(x_f(s)^{\text{old}}, s)}{2f(x_f(s)^{\text{old}}, s)} \quad (44)$$

where, in the denominator, $Q_x(x_f(s), s)$ is approximated by

$$\begin{aligned} & \frac{1}{2} \{ Q_x(x_f(s)+, s) + Q_x(x_f(s)-, s) \} \\ &= \frac{1}{2} u_{xx}(x_f(s), s) = -2f(x_f(s), s) \end{aligned} \quad (45)$$

Default Barrier Models

As a final example, we outline how these methods can be used to obtain an IE formulation for the inverse first-crossing problem in a value-of-firm (structural) model for credit default (*see Structural Default Risk Models*). Suppose the default index of a company, $X(t)$, is a Brownian motion with drift following

$$dX(t) = a dt + \sigma dW(t), \quad X(0) = x_0 \quad (46)$$

(equivalently, the log of such an index that originally satisfied a geometric Brownian motion). Default of the firm is said to occur the first time τ that $X(t)$ falls below a preassigned value, $b(t)$. The survival pdf, $u(x, t)$ defined by

$$u(x, t) dx = Pr[x < x(t) < x + dx | t < \tau]$$

is known to satisfy the following problem for the forward Kolmogorov equation:

$$u_t = \frac{\sigma^2}{2} u_{xx} - a u_x, \quad b(t) < x < \infty, \quad 0 < t < T \quad (47)$$

$$u(x, t) = 0, \quad x = b(t), \quad 0 < t < T \quad (48)$$

$$u(x, t) \rightarrow 0 \quad x \rightarrow \infty, \quad 0 < t < T \quad (49)$$

$$u(x, 0) = \delta(x - x_0), \quad b(0) < x < \infty \quad (50)$$

and the resulting survival probability is given, in terms of the solution $u(x, t)$, by

$$Pr(\tau > t) = P(t) = \int_{b(t)}^{\infty} u(x, t) dx \quad (51)$$

Motivated by the work of Avellaneda and Zhu [1], Lan Cheng, studied the inverse first-crossing problem [7]: given the survival probability $P(t)$ for $0 < t < T$, find the time-dependent absorbing boundary $b(t)$ in equation (48), including $b(0)$, such that equations (47)–(51) are satisfied. The more usual extra Neumann boundary condition appearing in FBP's can be obtained by differentiating equation (51):

$$\begin{aligned} P'(t) &= -u(b(t), t)b'(t) + \int_{b(t)}^{\infty} u_x(x, t) dx \\ &= \frac{-\sigma^2}{2} u_x(b(t), t) \end{aligned} \quad (52)$$

using the PDE (47) and the boundary conditions. With $-P'(t) = (1 - P(t))' = Q'(t) = q(t)$ denoting the default pdf, the extra boundary condition becomes

$$u_x(x, t) = \frac{2}{\sigma^2} q(t), x = b(t), 0 < t < T \quad (53)$$

Following the outline in the section Free Boundary Problems as Integral Equations, one can derive IEs for $b(t)$ in the form

$$\Gamma(b(t), t) = \int_0^t \Gamma(b(t) - b(s), t - s) q(s) ds \quad (54)$$

$$\begin{aligned} \frac{1}{2} q(t) &= \Gamma_x(b(t), t) \\ &\quad - \int_0^t \Gamma_x(b(t) - b(s), t - s) q(s) ds \end{aligned} \quad (55)$$

where Γ is the fundamental solution of the pdo in equation (47). A fast and accurate numerical scheme for solving

$$\begin{aligned} F(x, t) &= \Gamma(x, t) - \int_0^t \Gamma(x - b(s), t - s) q(s) ds = 0 \end{aligned} \quad (56)$$

for $x = b(t)$ (i.e., solving equation (54)) is the Newton—Raphson iteration

$$b(t)^{\text{new}} = b(t)^{\text{old}} - \frac{F(b(t)^{\text{old}}, t)}{q(t)/2} \quad (57)$$

where, in computing F_x in the denominator, we have used

$$\begin{aligned} \frac{1}{2} q(t) &= F_x(b(t), t) \simeq F_x(b(t)^{\text{old}}, t) \\ &= \simeq \Gamma_x(b(t)^{\text{old}}, t) - \int_0^t \Gamma_x(b(t)^{\text{old}} \\ &\quad - b(s)^{\text{old}}, t - s) q(s) ds \end{aligned} \quad (58)$$

Finally, we mention that an IEs formulation of the first passage problem for Brownian motion was given by Peskir [17] but the inverse problem described here was not treated. In [7], the proof of existence and uniqueness used viscosity solution methods. A proof using integral equations is still an open question for this problem as well as the two others listed in this section.

Tikhonov Regularization

An important issue in quantitative finance is *model calibration*. The calibration problem is the *inverse* of the pricing problem. Instead of computing prices in a model with given values for its parameters, one wishes to compute the values of the model parameters that are consistent with observed prices (up to the bid–ask spread).

Many examples of such inverse problems are ill-posed. Recall that a problem is *well posed* (as defined by Hadamard) if its solution exists, is unique, and depends continuously on its input data. Thus there are three reasons for which a problem might be ill posed:

- It admits no solution.
- It admits more than one solution.
- The solution/solutions to the inverse problem does/do not depend on the input data in a continuous way.

In the case of calibration problems in finance, except for trivial situations, there exists typically *no instance* of a given class of models that is *exactly* consistent with a full calibration data set, including a number of option prices, a zero-coupons curve, an expected dividend yield curve on the underlying, and so on. However, there are often *various* instances of a given class of models that fit the data *within the bid–ask spread*. In such cases, if one perturbs the data (e.g., if the observed prices change by some small amount between today and tomorrow), it is quite typical that a numerically determined best fit solution of the calibration problem switches from one “basin of attraction” to the other, and thus the numerically determined solution is *not stable* either.

To get a well-posed problem, we need to introduce some *regularization*. The most widely known and applicable regularization method is the *Tikhonov* (–*Phillips*) regularization method [9, 14, 16].

Tikhonov Regularization of Nonlinear Inverse Problems

We consider a Hilbert space $\mathcal{H}$, a closed convex nonvoid subset $\mathcal{A}$ of $\mathcal{H}$, a direct operator (“pricing functional”)

$$\mathcal{H} \supseteq \mathcal{A} \ni a \xrightarrow{\Pi} \Pi(a) \in \mathbb{R}^d \quad (1)$$

(so a corresponds to the set of model parameters), noisy data (“observed prices”) π^δ , and a *prior* $a_0 \in \mathcal{H}$ (a priori guess for a). The Tikhonov regularization method for *inverting* Π at π^δ , or estimating the model parameter a given the observation π^δ , consists in

- reformulating the inverse problem as the following *nonlinear least squares problem*:

$$\min_{a \in \mathcal{A}} \|\Pi(a) - \pi^\delta\|^2 \quad (2)$$

- to ensure *existence* of a solution;
- selecting the solutions of the previous nonlinear least squares problem that minimize $\|a - a_0\|^2$ over the set of all solutions; and
- introducing a trade-off between accuracy and regularity, parameterized by a level of regularization $\alpha > 0$, to ensure *stability*.

More precisely, we introduce the following *cost criterion*:

$$J_\alpha^\delta(a) \equiv \|\Pi(a) - \pi^\delta\|^2 + \alpha \|a - a_0\|^2 \quad (3)$$

Given α , δ , and a further parameter η , where η represents an error tolerance on the minimization, we define a *regularized solution to the inverse problem* for Π at π^δ as any model parameter $a_\alpha^{\delta, \eta} \in \mathcal{A}$ such that

$$J_\alpha^\delta(a_\alpha^{\delta, \eta}) \leq J_\alpha^\delta(a) + \eta, \quad a \in \mathcal{A} \quad (4)$$

Under suitable assumptions, one can show that the regularized inverse problem is well posed, as follows. We first postulate that the direct operator Π satisfies the following regularity assumption.

Assumption 1 (Compactness) $\Pi(a_n)$ converges to $\Pi(a)$ in $\mathbb{R}^d$ if a_n weakly converges to a in $\mathcal{H}$.

We then have the following *stability* result.

Theorem 1 (Stability) Let $\pi^{\delta_n} \rightarrow \pi^\delta$, $\eta_n \rightarrow 0$ when $n \rightarrow \infty$. Then any sequence of regularized solutions $a_n^{\delta_n, \eta_n}$ admits a subsequence that converges toward a regularized solution $a_\alpha^{\delta, \eta=0}$.

Assuming further that the data lie in the range of the model leads to *convergence* properties of

regularized solutions to (unregularized) solutions of the inverse problem as $midi \rightarrow 0$. Let us then make the following additional assumption on Π .

Assumption 2 (Range Property) $\pi \in \Pi(\mathcal{A})$.

Definition 1 By an a_0 -solution to the inverse problem for Π at π , we mean any $a \in \underset{\{\Pi(a)=\pi\}}{\text{Argmin}} \|a - a_0\|$. Note that the set of a_0 -solutions is non-empty, by Assumption 2.

Theorem 2 (Convergence; see, for instance, Theorem 2.3 of Engl et al [10]) Let the perturbed parameters $\alpha_n, \delta_n, \eta_n$ and the perturbed data $\pi_n \in \mathbb{R}^d$ satisfy

$$\begin{aligned} (n \in \mathbb{N}) \quad & \|\pi - \pi_n\| \leq \delta_n \\ (n \rightarrow \infty) \quad & \alpha_n, \quad \delta_n^2/\alpha_n, \quad \eta_n/\alpha_n \longrightarrow 0 \end{aligned} \quad (5)$$

Then any sequence of regularized solutions $a_{\alpha_n, \eta_n}^{\delta_n}$ admits a subsequence that converges toward an a_0 -solution a of the inverse problem for Π at π . In particular, in the case when this problem admits a unique a_0 -solution a , $a_{\alpha_n, \eta_n}^{\delta_n}$ converges to a .

Remark 1 In the special case where the direct operator Π is linear, Tikhonov regularization thus appears as an approximating scheme for the pseudoinverse of Π .

Finally, assuming further regularity of Π , one can get *convergence rates* estimates, uniform over all data $\pi \in \Pi(\mathcal{A})$ sufficiently close and smooth with respect to the prior a_0 (so that the additional *source condition* 12 is satisfied). Let us thus make the following additional assumption on Π .

Assumption 3 (Twice Gateaux Differentiability)

There exist linear and bilinear forms $d\Pi(a)$ on $\mathcal{H}$ and $d^2\Pi(a)$ on $\mathcal{H}^2$ such that

$$\begin{aligned} \Pi(a + \varepsilon h) &= \Pi(a) + \varepsilon d\Pi(a) \cdot h \\ &+ \frac{\varepsilon^2}{2} d^2\Pi(a) \cdot (h, h) + o(\varepsilon^2); \\ a, a + h &\in \mathcal{A} \end{aligned} \quad (6)$$

$$\begin{aligned} \|d\Pi(a) \cdot h\| &\leq C \|h\|, \\ \|d^2\Pi(a) \cdot (h, h')\| &\leq C \|h\| \|h'\|; \\ a \in \mathcal{A}, \quad h, h' &\in \mathcal{H} \end{aligned} \quad (7)$$

where C is a constant independent of $a \in \mathcal{A}$.

In the following theorem, the operator

$$d\Pi(a)^* : \mathbb{R}^d \ni \lambda \mapsto d\Pi(a)^* \lambda \in \mathcal{H}^1 \quad (8)$$

denotes the adjoint of

$$d\Pi(a) : \mathcal{H}^1 \ni h \mapsto d\Pi(a) h \in \mathbb{R}^d \quad (9)$$

in the sense that (see [9])

$$\langle h, d\Pi(a)^* \lambda \rangle_{\mathcal{H}^1} = \lambda' d\Pi(a) \cdot h; \quad (h, \lambda) \in \mathcal{H}^1 \times \mathbb{R}^d \quad (10)$$

Theorem 3 (Convergence Rates; see, for instance, Theorem 10.4 of Engl et al [9]) Assume

$$\begin{aligned} (n \in \mathbb{N}) \quad & \|\pi - \pi_n\| \leq \delta_n, \\ (n \rightarrow \infty) \quad & \alpha_n \longrightarrow 0, \quad \alpha_n \sim \delta_n, \quad \eta_n = O(\delta_n^2) \end{aligned} \quad (11)$$

Then $\|a_{\alpha_n, \eta_n}^{\delta_n} - a\| = O(\sqrt{\delta_n})$, for any a_0 -solution a of the inverse problem for Π at π such that

$$a - a_0 = d\Pi(a)^* \lambda \quad (12)$$

for some λ sufficiently small in $\mathbb{R}^d$ (in particular, there exists at most one such a_0 -solution a).

Remark 2 An interesting feature of Tikhonov regularization is that the data set π does not need to belong to the range of the direct operator for applicability of the method—even if Assumption 2 is the simplest assumption for the previous results regarding convergence and convergence rates (in fact, a minimal assumption for such results is the existence of a least squares solution to the inverse problem; see Proposition 3.2 of Binder et al [2]).

An important issue, in practice, is the choice of the *regularization parameter* α that determines the trade-off between accuracy and regularity in the method. To set α , the two main approaches are

- *a priori* methods, in which the choice of α only depends on δ , the level of noise on the data (such as the size of the bid–ask spread, in the case of market prices data in finance);
- more general *a posteriori* methods, in which α may depend on the data in a less specific way.

In applications to calibration problems in finance, the most commonly used method for choosing α is the *a posteriori* method based on the so-called *discrepancy principle*, which consists in choosing the greatest level of α for which the “distance” $\|\Pi(a_{\alpha}^{\delta,\eta}) - \pi^{\delta}\|$ (for given δ, η) does not exceed the level of noise δ on the observations (as measured by the bid–ask spread).

Implementation

For implementation purposes, the minimization problem 3 is discretized, and thus it effectively becomes a *nonlinear minimization problem* on (some subset of) $\mathbb{R}^k$ (see, e.g., [13]), where k is the number of model parameters to be estimated.

In the case of a *strictly convex* cost criterion $J = J_{\alpha}^{\delta}$ in equation 3, and if, additionally, J is differentiable, one can prove the convergence to the (unique) minimum of various *gradient descent algorithms*. These consist, at each iteration, in making a step of a certain length (fixed-step descent vs. optimal step descent) in a direction defined by the gradient ∇J in the current step of the algorithm, in combination with, in some variants of the method (*conjugate gradient method, quasi-Newton algorithms, etc.*), the gradient(s) ∇J in the previous step(s).

In the *nonstrictly convex* case, (actually, in the context of calibration problems in finance, J is typically not even convex with respect to α), or if the cost criterion is only almost everywhere differentiable (as in the *American calibration problem*, see Remark 3 (i)), such algorithms can still be used, in which case, they typically converge to one among many *local minima* of J .

When there are no constraints (the case when $\mathcal{A} = \mathcal{H}$), the minimization problem is, in practice, much easier, and many implementations of the related gradient descent algorithms are available (e.g., in [15]). As for constrained problems, a state-of-the-art open-source implementation of the quasi-Newton method for minimizing a function in a box, the L-BFGS algorithm, is available on www.ece.northwestern.edu/~nosedal/lbfgsb.html.

When the gradient ∇J is neither computable in closed form nor computable numerically with the required accuracy, an alternative to gradient descent methods is to use the *nonlinear simplex method* (not to be confused with the simplex algorithm for solving linear programming problems, see [15]). As

opposed to gradient descent methods, the nonlinear simplex algorithm only uses the *values* (and not the *gradient*) of J , but the convergence of the algorithm is not proved in general, and there are known counterexamples in which it does not converge.

Application: Extracting Local Volatility

In the case of *parametric* models in finance, namely, models with a small number of *scalar* parameters, such as Heston’s stochastic volatility model or Merton’s jump-diffusion model (as opposed to models with *functional*, e.g., time-dependent, parameters), the choice of a suitable regularization term is generally not obvious. In this case, the calibration industry standard rather consists in solving the unregularized nonlinear least squares problem 2. So Tikhonov regularization is rather used for calibrating *nonparametric* financial models.

In this section, we consider the problem of inferring a *local volatility function* $\sigma(t, S)$ (see [7]) from observed option prices, namely, European vanilla calls and/or puts with various strikes and maturities on the underlying S . The local volatility function thus inferred may then be used to price exotic options and/or compute Greeks, consistently with the market (e.g., [5]).

The Ill-posed Local Volatility Calibration Problem

The local volatility calibration problem, however, is underdetermined (since the set of observed prices is finite whereas the nonparametric function σ has an infinite degrees of freedom) and ill posed. So a naive approach based on numerical differentiation using the so-called *Dupire’s formula* [7] gives a local volatility that is highly oscillatory (Figure 1), and thus unstable, for instance when performing a day-to-day calibration.

To address this issue, the first idea that comes to mind is to seek for σ within a parameterized family of functions. However, finding classes of functions with all the flexibility required for fitting implied volatility surfaces with several hundred implied volatility points and a variety of shapes turns out to be a very challenging task (unless a large family of splines is considered, see Coleman *et al.* [3], in which case, the ill-posedness of the problem shows up again).

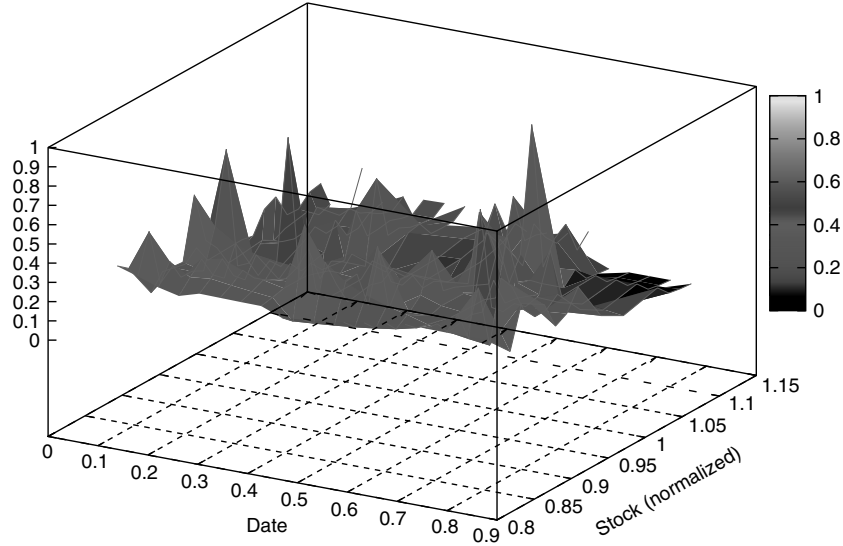

Figure 1 Local Variance $\sigma(t, S)^2$ obtained by application of Dupire's formula on the DAX index, May 2, 2001

The best way to proceed is to stay nonparametric, and to use regularization methods to stabilize the calibration procedure. Since we use a nonparametric local volatility, the model contains sufficient number of degrees of freedom to provide a perfect fit to virtually any market smile. Furthermore, the regularization method guarantees that the local volatility thus calibrated is nice and smooth.

Approach by Tikhonov Regularization

Among the various regularization methods at hand, the most popular one is the Tikhonov regularization method described in the section Tikhonov Regularization of Nonlinear Inverse Problems. One thus rewrites the local volatility calibration problem as the following nonlinear minimization problem:

$$\begin{aligned} \min_{\{\sigma \equiv \sigma(t, S); \underline{\sigma} \leq \sigma \leq \bar{\sigma}\}} J(\sigma) \\ = \|\Pi(\sigma) - \pi\|^2 + \alpha \|\sigma - \sigma_0\|_{\mathcal{H}^1}^2 \end{aligned} \quad (13)$$

where

- the bounds $\underline{\sigma}$ and $\bar{\sigma}$ are given positive constants specifying the abstract set $\mathcal{A}$ in the section Tikhonov Regularization of Nonlinear Inverse Problems ;

- π is the vector of market prices observed at the calibration time; $\Pi(\sigma)$ is the related vector of prices in the Dupire model with volatility function σ ;
- σ_0 is a suitable prior (*a priori* guess on σ), and for $u \equiv u(t, S)$,

$$\begin{aligned} \|u\|_{\mathcal{H}^1}^2 = \int_{t_0}^{\infty} \int_0^{\infty} [u(t, S)^2 + (\partial_t u(t, S))^2 \\ + (\partial_S u(t, S))^2] dt dS \end{aligned} \quad (14)$$

Problem 13 and a related gradient descent approach to solve it numerically (cf. the section Implementation) were introduced in [12]. Crépey [6] (see also [8]) further showed that the general conditions of the section Tikhonov Regularization of Nonlinear Inverse Problems are satisfied in this case. Stability and convergence of the method follow.

In [5] an efficient trinomial tree implementation of this approach was presented, based on an exact computation of the gradient of the (discretized) cost criterion J in equation 13. Figure 2 displays the local variance surface $\sigma(t, S)^2$ (to be compared with that of Figure 1), the corresponding implied volatility surface, and the accuracy of the calibration, obtained by running this algorithm on the DAX index European options data set of May 2, 2001 (consisting

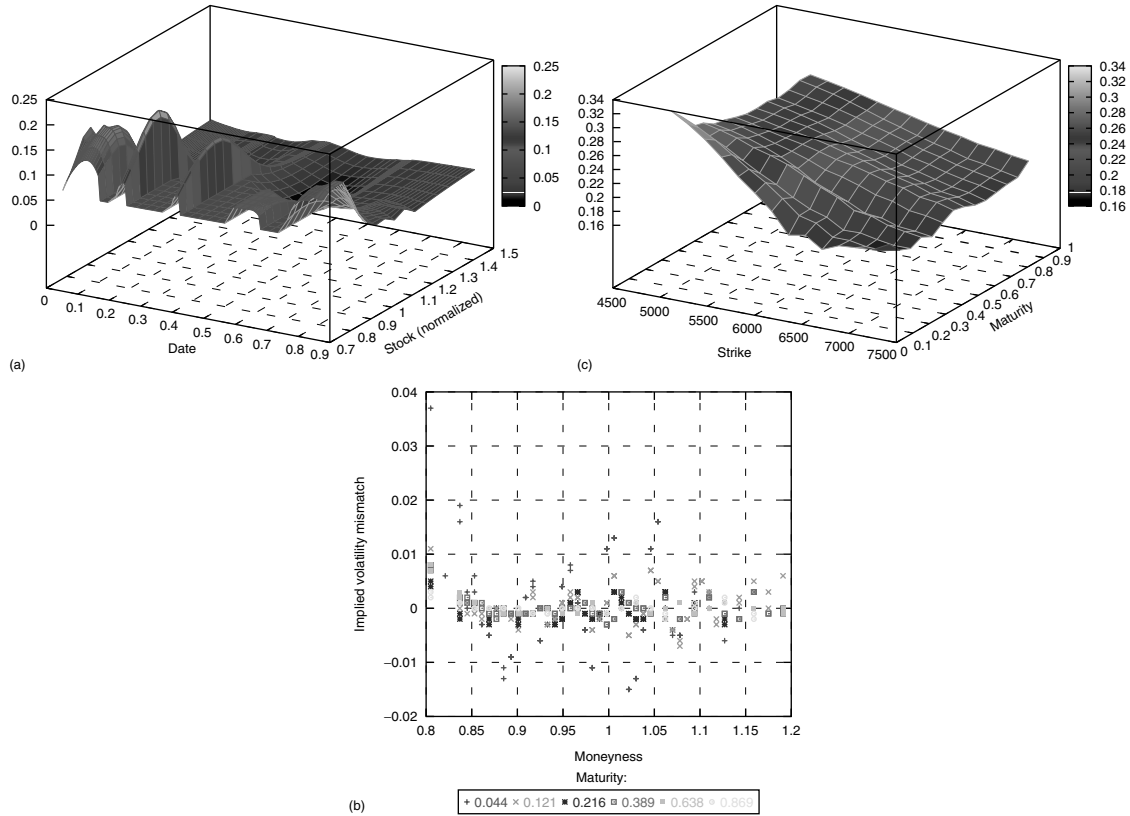

Figure 2 (a) Local variance, (b) implied volatility, and (c) calibration accuracy obtained by application of the Tikhonov regularization method on the DAX index, May 2, 2001

of about 300 European vanilla option prices distributed throughout six maturities with moneyness $K/S_0 \in [0.8, 1.2]$. At the initiation of the algorithm, the norm of the gradient of the cost criterion J in equation 13 was equal to $5.73\text{E} - 02$, and upon convergence after 65 iterations of the gradient descent algorithm, a local minimum of the cost criterion was found, with related value of the norm of the gradient of the cost criterion equal to $6.83\text{E} - 07$. In the accuracy graph, implied volatility mismatch refers to the difference between the Black–Scholes implied volatility corresponding to the market price of an option and its price in the calibrated local volatility model, for each option in the calibration data set.

Such calibration procedures are typically computationally intensive; however, it is possible to make them faster by resorting to *parallel computing* (see Table 1 and [5]).

Table 1 Calibration CPU times on a cluster of $nproc$ 1.3-GHz processors connected on a fast Myrinet network, using a calibration tree with n time steps (thus $n^2/2$ nodes in the tree)

$n \times nproc$	1	3	6
54	25s	9s	10s
101	4m30s	1m57s	1m36s

Remark 3 (1) This approach by Tikhonov regularization can be extended to the problem of calibrating a local volatility function using *American* observed option prices as input data [5], or to the problem of calibrating a *Lévy model with local jump measure* (see [4] and [11]).

(2) An alternative approach for this problem is to use *entropic regularization*, rewriting the local volatility calibration problem as a related *stochastic control problem* [1].

Tree Methods

Tree methods are among the most popular numerical methods to price financial derivatives. Mathematically speaking, they are easy to understand and do not require severe implementation skills to obtain algorithms to price financial derivatives. Tree methods basically consist in approximating the diffusion process modeling the underlying asset price by a discrete random walk.

In fact, the price of a European option of maturity T can always be written as an expectation either of the form

$$\mathbb{E}(e^{-rT} \psi(S_T))$$

in the case of vanilla options or of the form

$$\mathbb{E}(e^{-rT} \psi(S_t, 0 \leq t \leq T))$$

in the case of exotic options, where $(S_t, t \geq 0)$ is a stochastic process describing the evolution of the stock price, ψ is the payoff function, and r is the instantaneous interest rate. The basic idea of tree methods is to approximate the stochastic process $(S_t, t \geq 0)$ by a discrete Markov chain $(\tilde{S}_n^N, n \geq 0)$, such that

$$\begin{aligned} \mathbb{E}(e^{-rT} \psi(S_t, 0 \leq t \leq T)) \\ \approx \mathbb{E}(e^{-rT} \psi(\tilde{S}_n^N, 0 \leq n \leq N)) \end{aligned} \quad (1)$$

for N large enough ($\approx$ is used to remind the reader that the equality is only guaranteed for $N = \infty$). To ensure the quality of the approximation, we are interested in a particular notion of convergence called *convergence in distribution* (weak convergence) of discrete Markov chains to continuous stochastic processes. It is interesting to note that tree methods can also be regarded as a particular case of explicit finite difference algorithms.

Tree methods provide natural algorithms to price both European and American options when the risky asset is modeled by a geometric Brownian motion (see [27], for an introduction on how to use tree methods in financial problems). When considering more complex models—such as models with jumps or stochastic volatility models—the use of tree methods

is much more difficult; analytic approaches like finite difference (see **Partial Differential Equations**; **Partial Integro-differential Equations (PIDEs)**) or finite element (see **Finite Element Methods**) methods are usually preferred, and Monte Carlo methods are also widely used for complex models. Binomial (see **Binomial Tree**) and trinomial trees may also be constructed to approximate the stochastic differential equation governing the short rate [21, 26] or the intensity of default [32], permitting hereby to obtain the price of, respectively, interest rate derivatives or credit derivatives. Implied binomial trees, which enable us to construct trees consistent with the market prices of plain vanilla options, are a generalization of the standard tree methods used to price more exotic options (see [11, 14]).

For the sake of simplicity, consider a market model where the evolution of the risky asset is driven by the Black–Scholes stochastic differential equation

$$dS_t = S_t(r \, dt + \sigma \, dW_t), \quad S_0 = s_0 \quad (2)$$

in which $(W_t)_{0 \leq t \leq T}$ is a standard Brownian motion (under the so-called risk neutral probability measure) and the positive constant σ is the volatility of the risky asset.

The seminal work of Cox–Ross–Rubinstein (CRR) [10] initiated the use of tree methods and many variants have been introduced to improve the quality of the approximation when pricing plain vanilla or exotic options.

Plain Vanilla Options

The multiplicative binomial CRR model [10] is interesting on its own as a basic discrete-time model for the underlying asset of a financial derivative, since it converges to a log-normal diffusion process under appropriate conditions. One of its most attractive features is the ease of implementation to price plain vanilla options by backward induction.

Let N denote the number of steps of the tree and $\Delta T = T/N$ the corresponding time step. The log-normal diffusion process $(S_{n\Delta T})_{0 \leq n \leq N}$ is approximated by the CRR binomial process $(\tilde{S}_n^N = s_0 \prod_{j=1}^n Y_j)_{0 \leq n \leq N}$ where the random variables $Y_1, \dots, Y_N$ are independent and identically distributed with values in $\{d, u\}$ (u is called the *up factor* and d the *down factor*) with $p_u = \mathbb{P}(Y_n = u)$

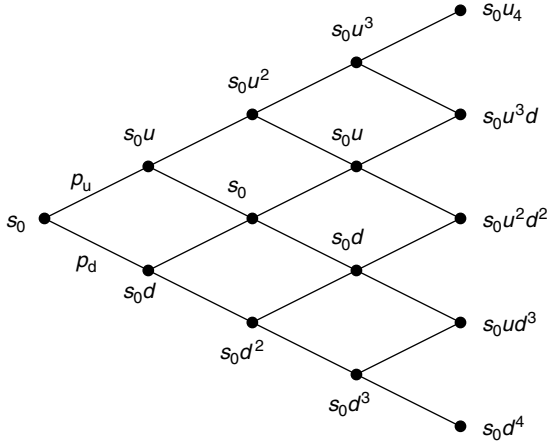

Figure 1 CRR tree

and $p_d = \mathbb{P}(Y_n = d)$. The dynamics of the binomial tree (see Figure 1) is given by the following Markov chain:

$$\bar{S}_{n+1}^N = \begin{cases} \bar{S}_n^N u & \text{with probability } p_u \\ \bar{S}_n^N d & \text{with probability } p_d \end{cases} \quad (3)$$

Kushner and Dupuis [23] proved that the local consistency conditions given by equation (4)—that is, the matching at the first order in ΔT of the first and second moments of the logarithmic increments of the approximating chain with those of the continuous-time limit—grant the convergence in distribution:

$$\begin{cases} \mathbb{E} \log \frac{\bar{S}_{n+1}^N}{\bar{S}_n^N} = \mathbb{E} \log \frac{S_{(n+1)\Delta T}}{S_{n\Delta T}} + o(\Delta T) \\ \mathbb{E} \log^2 \frac{\bar{S}_{n+1}^N}{\bar{S}_n^N} = \mathbb{E} \log^2 \frac{S_{(n+1)\Delta T}}{S_{n\Delta T}} + o(\Delta T) \end{cases} \quad (4)$$

This first-order matching condition rewrites

$$\begin{cases} p_u \log u + (1 - p_u) \log d = (r - \frac{\sigma^2}{2})\Delta T \\ p_u \log^2 u + (1 - p_u) \log^2 d = \sigma^2 \Delta T \end{cases} \quad (5)$$

The usual CRR tree corresponds to the choice $u = 1/d = e^{\sigma\sqrt{\Delta T}}$, which leads to $p_u = e^{r\Delta T} - e^{-\sigma\sqrt{\Delta T}} / (e^{\sigma\sqrt{\Delta T}} - e^{-\sigma\sqrt{\Delta T}}) = 1/2 + r - \sigma^2/2/2\sigma\sqrt{\Delta T} + \mathcal{O}(\Delta T^{3/2})$. When ΔT is small enough (i.e., for N large), the above value of p_u belongs to $[0,1]$. For this choice of u , d , and p_u , the difference between both sides of each equality in equation (5) is of order $(\Delta T)^2$. This is sufficient to ensure the convergence to the Black–Scholes model when N tends to infinity.

As $(\bar{S}_n)_n$ defined by the CRR model is Markovian, the price at time $n \in \{0, \dots, N\}$ of an American put option (see **American Options**) in the CRR model with maturity T and strike K can be written as $v(n, \bar{S}_n)$ where the function $v(n, x)$ can be computed by the following backward dynamic programming equations:

$$\begin{cases} v_N(N, x) = (K - x)^+ \\ v_N(n, x) = \max(\psi(x), \\ e^{-r\Delta T} [p_u v_N(n+1, xu) \\ v_N(n+1, xd)]) \end{cases} \quad (6)$$

where $\psi(x) = (K - x)^+$. Note that the algorithm requires the comparison between the intrinsic value and the continuation value. When considering European options, $\psi \equiv 0$.

The initial price of a put option in the Black–Scholes model can be approximated by $v_N(0, s_0)$. The initial delta, which is the quantity of risky asset in the replicating portfolio on the first time step in the CRR model, is approximated by $v_N(1, s_0u) - v_N(1, s_0d)/s_0(u - d)$. Note that to obtain the approximated price and delta, one only needs to compute $(v_N(n, s_0u^k d^{n-k}), 0 \leq k \leq n)$ by backward induction on n from N to 0. Figure 2 gives an example of backward computation of the price of an American put option using $N = 4$ time steps. The complexity of the algorithm is of order N^2 , more precisely the function v_N has to be evaluated at $(N + 1)(N + 2)/2$ nodes.

For the computation of the delta, Pelsser and Vorst [28] suggested to enlarge the original tree by adding two new initial nodes generated by an extended two-period back tree (dashed lines in Figure 2). To achieve the convergence in distribution, many other choices for u , d , p_u , and p_d can be made, leading to as many other Markov chains. We may choose other two-point schemes, such as a random walk approximation of the Brownian motion, three-point schemes (trinomial trees), or more general p -point schemes. The random walk approximation of the Brownian motion $(Z_{n+1} = Z_n + U_{n+1})$ with $(U_i)_i$ independent and identically distributed with $\mathbb{P}(U_i = 1) = \mathbb{P}(U_i = -1) = 1/2$ can be used as long as S_T is given by

$$S_T = s_0 e^{(r - \sigma^2/2)T + \sigma W_T} \quad (7)$$

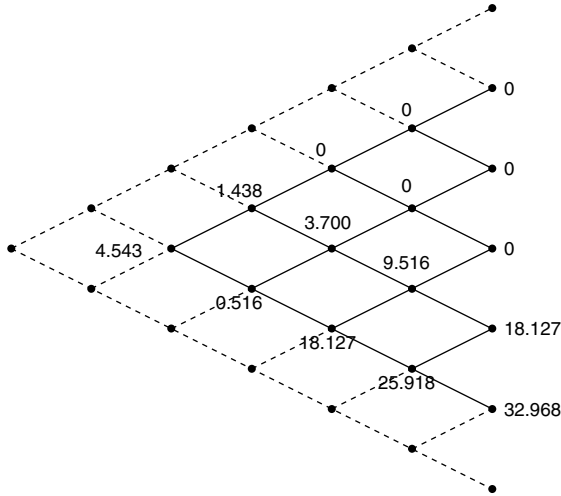

Figure 2 Backward induction for a CRR tree with $N = 4$ for an American put option with parameters $s_0 = K = 100$, $r = 0.1$, $\sigma = 0.2$, $T = 1$

This leads to $p_u = 1/2$ and

$$\begin{aligned} u &= e^{(r-\sigma^2/2)\Delta T + \sigma\sqrt{\Delta T}} \\ d &= e^{(r-\sigma^2/2)\Delta T - \sigma\sqrt{\Delta T}} \end{aligned} \quad (8)$$

The most popular trinomial tree has been introduced by Kamrad and Ritchken [22] who have chosen to approximate $(S_{n\Delta T})_{0\leq n\leq N}$ by a symmetric three-point Markov chain $(\tilde{S}_n)_{0\leq n\leq N}$

$$\bar{s}_{n+1} = \begin{cases} \bar{s}_n u & \text{with probability } p_u \\ \bar{s}_n & \text{with probability } p_m \\ \bar{s}_n d & \text{with probability } p_d \end{cases} \quad (9)$$

The convergence is ensured as soon as the first two moment matching condition on $\log(S_{\Delta T}/s_0)$ is satisfied. With $u = e^{\lambda\sigma\sqrt{\Delta T}}$ and $d = 1/u$, this condition leads to

$$\begin{aligned} p_u &= \frac{1}{2\lambda^2} + \frac{(r - \sigma^2/2)\sqrt{\Delta T}}{2\lambda\sigma}, & p_m &= 1 - \frac{1}{\lambda^2} \\ p_d &= \frac{1}{2\lambda^2} - \frac{(r - \sigma^2/2)\sqrt{\Delta T}}{2\lambda\sigma} \end{aligned} \quad (10)$$

The parameter λ —the stretch parameter—appears as a free parameter of the geometry of the tree, which can be tuned to improve the convergence. The value $\lambda \approx 1.22474$ corresponding to $p_m = 1/3$

is reported to be a good choice for at-the-money plain vanilla options. Note that choosing $u = 1/d$ is essential to avoid a complexity explosion. In this case, the complexity is still of order N^2 , but this time $(N + 1)(N + 3)$ evaluations of the function v_N are required. The value $\lambda = 1$ corresponds to the CRR tree.

Note that complexity is intimately related to the quality of the approximation. Therefore, one should always try to balance the additional computational cost with the improvement of the convergence it brings out.

Convergence Issues

Over the last years, significant advances have been made in understanding the convergence behavior of tree methods for option pricing and hedging (see [13, 24, 25, 33]). As noted in [12, 15], there are two sources of error in tree methods for call (**Call Options**) or put option: the first one (*the distribution error*) ensues from the approximation of a continuous distribution by a discrete one, whereas the second one (*the nonlinearity error*) stems from the interplay between the strike and the grid nodes at the final time step. Because of the nonlinearity error, the convergence is slow except for at-the-money options. Let P_N^{CRR} and P^{BS} denote the initial price of the European put option with maturity T and strike K , respectively, in the CRR tree (with N steps) and in the Black–Scholes model. Using the call–put parity relationship in both the models and the results given for the call option in [13], one finds

$$P_N^{\text{CRR}} = P^{\text{BS}} - \frac{Ke^{-rT}}{N} e^{-d_2^2/2} \sqrt{\frac{2}{\pi}} \\ \times [\kappa_N(\kappa_N - 1)\sigma\sqrt{T} + D_1] + \mathcal{O}\left(\frac{1}{N^{3/2}}\right) \quad (11)$$

where $d_2 = (\log(s_0/K) + (r - (\sigma^2/2)T)/\sigma\sqrt{T})$, κ_N denotes the fractional part of $\log(K/s_0)/2\sigma\sqrt{N/T} - N/2$ and D_1 is a constant. For at-the-money options (i.e., $K = s_0$), $\kappa_N = 0$ for N even and $\kappa = 1/2$ for N odd; hence, the difference $(P_N^{\text{CRR}} - P^{\text{BS}})_N$ is an alternating sequence. Figure^a 3 shows that for N even P_N^{CRR} gives an upper estimate of P^{BS} , whereas for N odd P_N^{CRR} gives a lower estimate. The monotonicity of $(P_{2N+1})_N$ and $(P_{2N})_N$ for at-the-money

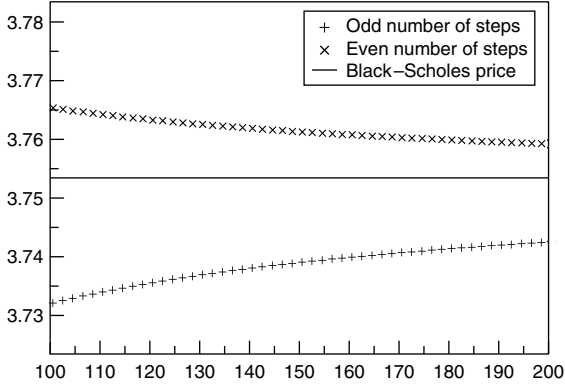

Figure 3 Convergence for an at-the-money put option with parameters $s_0 = K = 100$, $r = 0.1$, $\sigma = 0.2$, $T = 1$

options enables us to use a Richardson extrapolation (i.e., consider $2P_{4N}^{\text{CRR}} - P_{2N}^{\text{CRR}}$ or $2P_{4N+1}^{\text{CRR}} - P_{2N+1}^{\text{CRR}}$) to make the terms of order $1/N$ disappear. For not at-the-money options, Figure 4 shows that the sequences $(P_{2N+1}^{\text{CRR}})_N$ and $(P_{2N}^{\text{CRR}})_N$ are not monotonic and present an oscillating behavior. In this context, a naive Richardson extrapolation performs badly.

Several tree methods [6, 15, 18] try to deal with the nonlinearity error at maturity reproducing in some sense an at-the-money situation. The binomial Black-Scholes (BBS) method introduced by Broadie and Detemple [6] replaces at each node of the last but one time step before maturity, the continuation value with the Black-Scholes European one [3]. A two-point Richardson extrapolation aiming

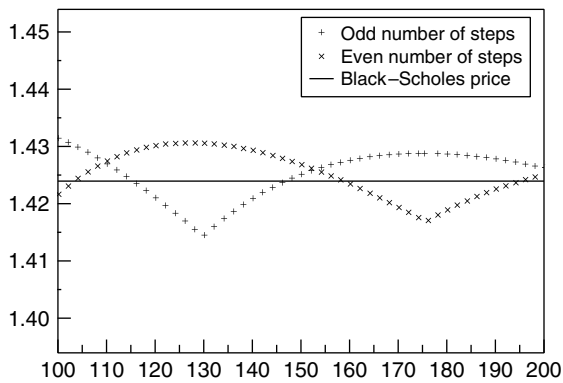

Figure 4 Convergence for a not at-the-money put option with parameters $s_0 = 100$, $K = 90$, $r = 0.1$, $\sigma = 0.2$, $T = 1$

at improving the convergence leads to the binomial Black-Scholes-Richardson (BBSR) method.

Adaptive mesh model (AMM) is a trinomial-based method introduced by Figlewski and Gao [15]. By taking into account that the nonlinearity error at maturity only affects the node nearest to the strike, AMM resorts to thickening the trinomial grid only around the strike and only at maturity time.

The binomial interpolated (with Richardson extrapolation) method (BI(R)) introduced by Gaudenzi and Pressacco [18] tries to recover the regularity of the sequences giving the CRR price of the European at-the-money options. The logic of the BI approach is to create a set of computational options, each one with a computational strike lying exactly on a final node of the tree. The value of the option with the contractual strike is then obtained by interpolating the values of the computational options.

Let us finally remark that similar techniques have been developed in numerical analysis for PDEs associated to option pricing problems (see [19]). In the case of nonsmooth initial conditions, to get good convergence of finite element and finite difference methods, there should always be a node at the strike and the payoff may have to be smoothed (see [30] for a classical reference).

In the American option case, a new source of error arises compared to the European case: the loss of opportunity to early exercise in any interval between two discrete times of the tree.

Exotic Options

The classical CRR approach may be troublesome when applied to barrier options (see **Barrier Options**) because the convergence is very slow in comparison with plain vanilla options. The reason is quite obvious: let L be the barrier and n_L denote the index such that

$$s_0 d^{n_L} \geq L > s_0 d^{n_L+1}$$

Then, the binomial algorithm yields the same result for any value of the barrier between $s_0 d^{n_L}$ and $s_0 d^{n_L+1}$, while the limiting value changes for every barrier L .

Several different approaches have been proposed to overcome this problem.

Boyle and Lau [5] choose the number of time steps in order to have a layer of nodes of the tree as close

as possible to the barrier. Ritchken [31] noted that the trinomial method is more suitable than the binomial one. The main idea is to choose the stretch parameter λ such that the barrier is exactly hit. Later, Cheuk and Vorst [9] presented a modification of the trinomial tree (based on a change of the geometry of the tree), which enables to set a layer of the nodes exactly on the barrier for any choice of the number of time steps. Numerical interpolation techniques have also been provided by Derman *et al.* [12].

In the case of Asian options (*see Asian Options; Lattice Methods for Path-dependent Options*) with arithmetic average, the CRR method is not efficient since the number of possible averages increases exponentially with the number of the steps of the tree. For this reason, Hull and White [20] and in a similar way Barraquand and Pudet [2] proposed more feasible approaches. The main idea of their procedure is to restrict the possible arithmetic averages to a set of representative values. These values are selected in order to cover all the possible values of the averages reachable at each node of the tree. The price is then computed by a backward induction procedure, whereas the prices associated to the averages outside of representative value set are obtained by some suitable interpolation methods.

These techniques drastically reduce the computation time compared to the pure binomial tree; however, they present some drawbacks (convergence and numerical accuracy) as observed by Forsyth *et al.* [16]. Chalasani *et al.* [7, 8] proposed a completely different approach to obtain precise upper and lower bounds on the pure binomial price of Asian options. This algorithm significantly increases the precision of the estimates but induces a different problem: the implementation requires a lot of memory compared to the previous methods.

In the case of lookback options (*see Lookback Options*), the complexity of the pure binomial algorithm is of order $O(N^3)$ and the methods proposed in [2, 20] do not improve the efficiency. Babbs [1] gave a very efficient and accurate solution to the problem for American floating strike lookback options by using a procedure of complexity of order $O(N^2)$. He proposed a change of “numeraire” approach, which cannot be applied in the fixed strike case.

Gaudenzi *et al.* [17] introduced the singular point method to price American path-dependent options. The main idea is to give a continuous representation

of the option price function as a piecewise linear convex function of the path-dependent variable. These functions are characterized only by a set of points named *singular points*. Such functions can be evaluated by backward induction in a straightforward manner. Hence, this method provides an alternative and more efficient approach to evaluate the pure binomial prices associated with the path-dependent options. Moreover, because the piecewise linear function representing the price is convex, it is easy to obtain upper and lower bounds of the price.

For the rainbow options, extensions of the binomial approach for pricing American options on two or more stocks have been made by Boyle *et al.* [4] and Kamrad and Ritchken [22]. In higher dimensional problems (say, dimension greater than three), the straightforward application of tree methods fails because of the so-called curse of dimension: the computational cost and the memory requirement increase exponentially with the dimension of the problem.

Quadrature Methods

Beyond the Black–Scholes equations [6] for European style options and certain other cases, generally with no early exercise, “numerical” techniques involving repetitive calculations are required in order to extract approximate solutions, which can be refined by further calculation to make them comparable in accuracy with analytic solutions. The numerical techniques are then classified as trees [18], various finite-difference methods following from the most basic explicit method [8], Monte Carlo simulation [7], and—introduced only recently—QUAD [4], each of which has been subject of modification and refinement.

Quadrature *via* the QUAD method was first presented as a flexible, robust option pricing tool of wide applicability *via* cross-disciplinary work by the research group of Duck (mathematics) and Newton (finance), then at Manchester University [4]. Just as the mathematics of tree, finite-difference and Monte Carlo approaches were known and used in other areas, such as engineering and natural sciences, long before their introduction into finance; basic quadrature goes back centuries and is, in simple conversational terms, the calculation of an area under a graph *via* an approximation. Pictorially, this can be the splitting of an area into a series of shapes, such as rectangles, that approximate the total area and summing their individual areas. Taking smaller shapes produces more accurate results, converging on the correct one. For doing this, the well-known methods are the trapezium rule, Simpson’s method, and Gaussian quadrature, and there are others as well. Each has differing properties and is more or less easy to program, but of particular interest is the rate of convergence to a correct solution as the number of calculations is increased in finer and finer approximations.

A key concept in financial quadrature—sometimes not appreciated—is that the mathematical quadrature component is merely a computational engine to be chosen appropriately to fit into the wider calculations of the particular options problem [4, 5]. Thus, even the very simple trapezium rule can be adequate when elements in wider calculation are less refined. Similarly, Gaussian quadrature only provides useful extra speed over Simpson’s rule in pricing problems where unusually heavy calculational

demands on the “engine” are requisite. Details of quadrature schemes can be found in [1].

It was well known for many years that the majority of options could be written as either a finite or an infinite set of nested (multiple) integrals. Geske and Johnson [20] valued the American put option using a set of multivariate integrals, and Huang *et al.* [25] and Sullivan [33] valued them using univariate integration at discrete observation points followed by Richardson extrapolation. The Geske and Johnson method, however, is computationally very time consuming when more than four nested (i.e., multiple) integrals have to be evaluated. Huang *et al.* used univariate integrals to achieve the same effect, but not more than three observation times were used due to computational complexity. Sullivan [33] also used univariate integrals using a Gaussian quadrature scheme. The first flexible, robust, and widely applicable option pricing tool in quadrature came with QUAD [4]. Its range has been extended to cover the most difficult problems in combination: path dependency, early exercise, and multiple underlyings [5]. In a parallel work, Broadie and Yamamoto [11, 12] have adapted the fast Gauss transform (FGT) technique of Greengard and Strain [21], which, like QUAD, omits time steps between exercise dates, thus vastly reducing the computational load.

As with trees and finite-difference methods, QUAD works backward in time from the maturity of the option, in contrast to Monte Carlo that calculates forward. In the past, this tended to make the backward-working techniques the methods of choice when there could be early (American-style) exercise but favored Monte Carlo both for path-dependent options and for those with several underlyings, since although Monte Carlo starts by requiring a higher computational load than the other techniques (from averaging a large number of simulations), unlike the other techniques it does not suffer from the “curse of dimensionality”, which raises their loads exponentially rather than linearly as dimensions are added. This lack of immediate ability to handle American-style options with Monte Carlo and a desire to tackle problems with both forward and backward elements lead to improvements in all the techniques, with the result that they now compete as alternatives across the spectrum of options types. Since the work of Longstaff and Schwartz [28], in particular, Monte Carlo has been able to handle early exercise (*see Bermudan Options*). In mathematics,

where “high dimension” can mean that a large number of dimensions are of interest, Monte Carlo may become the only technique of concern; however, in finance five dimensions can be considered large. Moreover, quadrature-based methods are so fast to converge that they may only be overtaken in speed by Monte Carlo in dimensions above five (clearly depending on which two quadrature and Monte Carlo techniques are compared; see below for more on this).

QUAD is a particularly effective tool because of the way it deals with the two fundamental causes of error in the numerical methods for finance: distribution error and nonlinearity error. The distribution error arises from approximating a continuous distribution with a discrete one and in other methods can be reduced by adding more steps to a lattice or grid to improve the approximation. This, however, adds to the computational load, whereas with QUAD no calculations are needed at time steps between exercise dates which, combined with the well-known high accuracy of quadrature methods in approximating integrals of functions, results in a huge advantage (measured in orders of magnitude). An extreme example is a plain European option which, if valued numerically not analytically, would require just one set of QUAD calculations in moving from maturity to valuation, with no intermediate steps.

Nonlinearity error is dealt with by the flexibility in placing calculational nodes so as not to miss non-smooth changes (the simplest example being the kink in payoff for a plain European option). Nonlinearity error is observed when valuing options using lattice methods (such as binomial and trinomial trees) or grid methods (notably finite-difference techniques). The familiar saw tooth shape observed in plots of the error with varying time steps when pricing options with binomial trees is directly the result of a nonlinearity in the option price for certain values of the underlying [9, 14, 15, 19, 27, 31, 36]. Extrapolation procedures are possible only when nonlinearity error has been removed. For products such as European vanilla and continuous barrier options, the lattice or the grid can be adapted to remove this nonlinearity error, the main advantage of which is to provide smooth, monotonically converging results that can be improved significantly by standard extrapolation procedures. For options containing more and more exotic features, it becomes increasingly difficult, if not impossible, to adjust the lattice or the grid to

remove new sources of nonlinearity error: for example, options in which the source of nonlinearity moves with time as in barrier or American-style options.

The QUAD method improves on lattice and grid methods in two important ways: superior convergence and, most important, far greater flexibility. The convergence of the method is dependent on which underlying quadrature scheme is used; with Simpson’s rule the convergence is with $1/N^4$, where N is the number of steps, that is, $N = 1/h$, with h being the quadrature mesh size of steps (contrast $1/N^{1/2}$ for the Monte Carlo method). This, combined with its flexibility, makes the improvement offered significant for many types of options. Using the QUAD method with one underlying and either one or two discontinuities at any time, the grid can be maneuvered so as to remove all nonlinearity error, leaving only distribution error and providing monotonic, smooth, fast convergence. These results can then be extrapolated, providing remarkably accurate results rapidly.

One significant problem with lattice and grid methods is what is dubbed the curse of dimensionality; as more underlying assets are introduced, computation time increases exponentially. The usual alternative is to solve by means of Monte Carlo methods, for which the computational effort increases only linearly as more underlying assets are added. For a single underlying asset, Monte Carlo methods are inferior to lattice and grid methods because of slow convergence, but as more underlying assets are considered, Monte Carlo methods can take over as the preferred technique; however, as we shall see, this is not the case with QUAD, which retains its considerable speed/accuracy advantage across the gamut of practical options problems.

To quantify the trade-off between dimensions and convergence, Broadie and Glasserman [10] express convergence as a function of computational effort or work. Under this measure, for an n -underlying asset option pricing problem, lattice or explicit finite-difference methods (*see Finite Difference Methods for Barrier Options*) have convergence rates of $O(\text{work}^{-1/(n+1)})$, the Crank–Nicolson finite-difference method (*see Crank–Nicolson Scheme*) has $O(\text{work}^{-2/(n+1)})$, whereas Monte Carlo methods (*see Monte Carlo Simulation*), because of the linear increase in effort, exhibit $O(\text{work}^{-1/2})$ convergence. Where time stepping is required (e.g., for Bermudan options), under this metric, the QUAD method when using

unextrapolated Simpson's rule has $O(\text{work}^{-4/(n+1)})$ convergence, increasing to $O(\text{work}^{-8/(n+1)})$ when extrapolation is employed. Andricopoulos *et al.* [5] have compared QUAD in a deliberately unfavorable circumstance with [28] Monte Carlo on multiple underlyings for American options (where QUAD is naturally slowed by more exercise times, Bermudan-style, followed by extrapolation) and found that QUAD still has an advantage with five underlyings, thus covering most cases in practical finance.

Extending the Method

The fast convergence of QUAD is partly due to the careful placing of nodes in the calculations. For example, the payoff conditions at an option's maturity show a break in the direction, and nodes are correctly placed so as not to calculate across the break, which would lead to propagation of errors. This does mean that some appreciation of the "geometry" of solution is necessary in each problem in order to attain the highest accuracy. This is, perhaps, not a great difficulty (and careful placement of nodes for improved accuracy is a general feature of all the lattice and grid methods); nevertheless, it is useful that the degradation of results through programming roughly, without care for node placement, can still give adequate results in a quickly programmed exploratory setup [13]. For convenience, a hybrid QUAD finite-difference approach was used by Law [26] for the case of "arithmetic Asian tail" options—a reminder that methods can be mixed.

The foundation work for QUAD was presented in the Black–Scholes framework but this method applies whenever the conditional probability density function is known. This restricts the immediate use of the QUAD technique to the Black–Scholes setup, to Merton's jump-diffusion model (*see* **Jump-diffusion Models**), and to certain interest-rate models such as those of Vasicek [34] and Cox *et al.* [17] (*see* **Term Structure Models**). Extending the technique to Merton's process is straightforward, but the interest-rate models are more subtle and Heap [23] has successfully extended the coverage to interest-rate derivatives including these mean-reverting underlying processes.

A notable advance was made by O'Sullivan [30], who used the observation that many useful processes that do not have a well-known density function

do nonetheless have a well-understood characteristic function. The density function, as the inverse Fourier transform of the characteristic function, can be computed using fast Fourier transform and the output may then be inserted in the QUAD scheme to price derivatives. We refer to this method as *FFT-QUAD*. O'Sullivan's method applies in particular to exponential Levy processes. This made FFT-QUAD an important advance, but it does suffer from drawbacks [22]. First, it requires two integrations even for a derivative on a single underlying process. This brings the complexity of the algorithm to at least $O(N^2)$, where N is the number of grid points used in the numerical integrations; by comparison, the original QUAD had a much better complexity of just $O(N)$ for vanilla options. Second, FFT-QUAD cannot be used to price heavily path-dependent options in stochastic volatility frameworks, since it does not keep track of the evolution of the volatility process in moving from one observation point to the next.

O'Sullivan's FFT-QUAD was considerably improved by the CONV technique of Lord *et al.* [29] (*see also* **Fourier Methods in Options Pricing**). We refer to this method as *CONV-QUAD* [32]. This excellent method uses the observation that the basic pricing integral may usually be regarded as the convolution (strictly speaking, the cross correlation) of the payoff and the density function. The beauty of this insight is that the two integrals of FFT-QUAD may then be replaced by two fast Fourier transforms. This brings the complexity of the algorithm down to $O(N \log(N))$ and, for example, for Bermudan options (on M observation points), the complexity remains at $O(MN \log(N))$, which beats even QUAD's $O(MN^2)$. The CONV method applies in particular to exponential Levy processes (*see* **Exponential Lévy Models**) and hence in particular to CGMY processes (*see* **Tempered Stable Process**). Owing to its nearly linear speed, it is clearly the method of choice for a great many processes. CONV-QUAD, however, suffers from the same difficulty of application to stochastic volatility processes: the volatility process is ignored again. Moreover, there is no possibility of treating, say, Heston's processes [24] (*see also* **Heston Model**) by a two-dimensional CONV-QUAD; the volatility component is simply not sufficiently well behaved.

In summary thus far, we have, in various forms of QUAD, a remarkably accurate (fast-converging) technique that covers complex combinations of option

characteristics in multiple dimensions. It outperforms other methods in most circumstances, making it the method of choice in situations when this power is needed and is a convenient alternative to trees, finite-difference grids, and Monte Carlo among others. There remains, however, some further development underway in order to complete the universality of QUAD: full coverage of underlying processes, particularly stochastic volatility and Heston's framework [24]. This appears possible *via* the basic QUAD scheme, reducing complexity *via* CONV-QUAD techniques when possible. When pricing, say, Bermudan options, complexity will grow linearly, not exponentially, with the number of observation points, that is, with B observation points, the overall complexity will be $O(BM^2N \log(N))$. This complexity is worse than what CONV can produce in other cases, but it is necessary to keep track of an extra process, and some extra penalty is to be expected as CONV-QUAD techniques cannot be used on the volatility component [22].

QUAD Mathematics

We now proceed to a demonstration of the basic technique for QUAD. The original description of the QUAD method can be found in detail in [3] and in overview in [5]. Starting with the well-known [6] partial differential equation for an option with an underlying asset following geometric Brownian motion (*see Black–Scholes Formula*):

$$\frac{\partial V}{\partial t} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + (r - D_c)S \frac{\partial V}{\partial S} - rV = 0 \quad (1)$$

where V is the price of the derivative product and is a function of S , the value of the underlying asset and time, t . The risk-free interest rate is r , the volatility of the underlying asset is σ , and the exercise price is X . D_c is a continuous dividend yield. A convenient log transform may be made:

$$x = \log(S) \quad (2)$$

Then suppose that y is the corresponding value of the transform of the underlying at time $t + \Delta t$, where Δt is a time step. It is important to note that Δt is not restricted to small time periods; for example, were QUAD has to be applied to a plain European call option (this is not required since we have the

Black–Scholes analytic solution), then the complete time to expiry would be taken in a single time step, Δt . At expiry, the final condition (payoff) becomes $\max(e^y - X, 0)$. The solution for the value of the option at time t on an underlying asset S is then

$$V(x, t) = A(x) \int_{-\infty}^{\infty} B(x, y) V(y, t + \Delta t) dy \quad (3)$$

where

$$A(x) = \frac{1}{\sqrt{2\sigma^2\pi\Delta t}} e^{-(kx/2) - (\sigma^2 k^2 \Delta t/8) - r\Delta t} \quad (4)$$

$$B(x, y) = e^{-((x-y)^2/(2\sigma^2\Delta t)) + (ky/2)} \quad (5)$$

$$k = \frac{2(r - D)}{\sigma^2} - 1 \quad (6)$$

for a plain vanilla call, for example, the integrand becomes

$$f(x, y) = B(x, y) \times \max(e^y - 1, 0) \quad (7)$$

This integral is the key. Next, any of the many quadrature methods can be employed as a valuation “engine” for what is a European option with known payoff. The integration covers a single time step, Δt . As already noted, this is not of any special use for a plain European option; the (considerable) advantage comes from treating more complex and interesting options problems as equivalent to series of European options. Regions where there is no boundary condition to deal with can be jumped in a single step. Contrast this with other techniques, such as finite difference or trees, in which many intermediate calculations are employed (though there are techniques for thinning the grids/trees). Once more complex option features are incorporated, the choice of quadrature “engine” becomes more important. The speed of convergence comes from a combination of the calculations required for the quadrature “engine” and the calculations arising from particular option features (boundary conditions). A faster engine is needed only in some cases in order to attain the required speed and accuracy. Andricopoulos [3] originally considered the trapezium rule, Simpson's method, and Gaussian quadrature. From the exceedingly simple technique of the trapezium rule, familiar in schoolrooms, through to Gaussian Quadrature, these three are progressively more accurate (fast converging). At the extreme end of fast “engines”, the superior convergence of the Gauss–Legendre method of Sullivan [33] used within

QUAD has been subject to detailed examination by Chung *et al.* [16].

Note that the range of integration is infinite, but this is not a practical problem; the range can be truncated, provided the integrand outside the truncated range is suitably small. Highly accurate calculations are then possible to any level required. A vanilla call option has a discontinuity in the first derivative at expiry, where $S = X$ or $y = \log(X)$. Integration is needed from $\log(X)$ and above, with a frequency of quadrature points and a cutoff to suit the desired accuracy. Extension to options observed discretely M times ($T_1; \dots; T_M$ with the current time T_0 and expiry T_M) is made possible by splitting the option into M separate options, V_m . Each option, V_m , runs from T_{m-1} to T_m . The values at expiry (time T_M) are simply the option payoff. The values of the option at T_{m-1} can be found for all values of y required by the quadrature routine at T_m . American exercise is readily handled by a combination of extra observation times and extrapolation. Any additional operations, such as the imposition of a barrier, can be performed on these values and then these can be used to value the option at time T_{m-2} . The process is continued until the option value is found at the present time, T_0 .

Regarding truncation, for the logarithm of an underlying asset, $\log(S)$, the probability of moving more than five standard deviations in any time period is negligible and truncation to this range typically affects, at worst, only the fifth significant figure of the option price. The probability of moving more than 10 standard deviations is so small that truncating to this range is comparable to machine accuracy on a computer (note that this is important in attaining machine accuracy rather than specifically the choice of quadrature technique supposed in [16]). The choice of range, ξ (the number of standard deviations of the range of integration), is left to the practitioner, but it should be somewhere between these bounds, 5 and 10. The value 7.5 is generally good because it is accurate enough, yet it does not affect extrapolation and does not render the computational effort prohibitively high. For an option valued at time T_m , the range in y , $[y^{\min}; y^{\max}]$ used is

$$y^{\min} = x - \xi \sqrt{T_m - T_{m-1}} \quad (8)$$

and

$$y^{\max} = x + \xi \sqrt{T_m - T_{m-1}} \quad (9)$$

If the QUAD grid is constructed to coincide with the discontinuities such as a strike price, barrier, or exercise boundary, then convergence is perfectly smooth and suitable for improvement through extrapolation because only distribution error remains. It is useful because it is so smooth that extrapolated results can often be further extrapolated themselves. This extrapolation is applicable in all cases, including those with early exercise (but see [5], for adaptive quadrature). Extrapolation is straightforward, *via* a simple Richardson-type procedure. If results converge at a known rate $(\delta y)^d$, then consider two calculations undertaken with step sizes, δy_1 and δy_2 , producing option values V_1 and V_2 , respectively. An improved value V_{ext} is given as

$$V_{\text{ext}} = \frac{(\delta y_1)^d V_2 - (\delta y_2)^d V_1}{(\delta y_1)^d - (\delta y_2)^d} \quad (10)$$

Assuming that the discontinuities are correctly located, the extrapolated trapezium rule results converge as $(\delta y)^4$, which is $1/N^4$. For Simpson's rule, the extrapolated results converge as $(\delta y)^8$, which is $1/N^8$, a remarkable rate of convergence compared with other methods. For comparison, a trinomial tree converges merely with N^{-1} or in some cases only with $N^{-1/2}$. Even the more sophisticated finite-difference methods at best converge at the rate of $(\Delta S^2, \Delta t^2)$, where ΔS and Δt are the step sizes in the S and the t directions, respectively.

Simpson's rule remains one of the most accurate and popular methods for approximating integrals. For a function of y , $f(y)$, plotted against t , y divides the desired range, $[a_1, a_2]$ into n intervals of a fixed length δy such that $n\delta y = a_2 - a_1$. Then approximate the area under the curve by summing the area of the individual regions. This yields the following expression:

$$\begin{aligned} \int_{a_1}^{a_2} f(y) dy \approx & \frac{\delta y}{6} \left\{ f(a_1) + 4f\left(a_1 + \frac{1}{2}\delta y\right) \right. \\ & + 2f(a_1 + \delta y) + 4f\left(a_1 + \frac{3}{2}\delta y\right) \\ & + 2f(a_1 + 2\delta y) + \dots + 2f(a_2 - \delta y) \\ & \left. + 4f\left(a_2 - \frac{1}{2}\delta y\right) + f(a_2) \right\} \quad (11) \end{aligned}$$

It is easily shown that, for smooth functions, the error term associated with this method decreases

at a rate of order $(\delta y)^4$ and so a doubling of the number of steps reduces the error by a factor of 16. Here, it is useful to reiterate the analogy of quadrature techniques as merely “engines” to be fitted into the bodywork of QUAD. When pricing options for which the overall valuation technique puts other, more stringent, limitations on convergence, very basic quadrature may be appropriate. For example, the trapezium rule is an even simpler quadrature method, slower to converge than Simpson’s rule, at a rate of $(\delta y)^2$, but in rare cases its use can save computational time, as in the case of lookback options priced in three dimensions, where the use of more accurate quadrature schemes would be superfluous. QUAD benchmarks may be found in [3, 35].

Speed and Accuracy

For once-only calculations under no research or business time constraint, options valuations are now usually accessible *via* more than one technique; however, there remain some difficult or high-volume repetitive requirements for fast and accurate answers and for these QUAD competes across all option types. For a once-only calculation, it does not probably matter at all whether the chosen technique delivers acceptable accuracy in 10 ms or 10 min for a moderately simple problem, but this difference becomes compounded with the hardest problems and with large numbers of repeat calculations. Thus, speed and convergence results quoting such differences in research papers are of particular interest; a doubling of computer speed, say, since publication, is of less interest than the relative benchmarking. The original QUAD results were computed on a Pentium III 550 MHz system, using the NAG Fortran 95 v4.0 compiler with optimization [4], later on a 2.4 GHz Pentium computer, approximately four times faster [5]. Even given the current faster computers and projected speed increases for the next several years, the practical convergence/accuracy gains for many options problems remain exceptional, generally measurable in several orders of magnitude. Pricing to penny accuracy with a trinomial tree (mathematically similar to an explicit finite difference) takes hours, if not days, for some options (e.g., a lookback barrier) but they are priced correct to four decimal places in seconds with QUAD on the outdated Pentium III. In the valuation of a three-underlying American call option, QUAD

achieves penny accuracy in just over a minute, which is a level of accuracy not achieved by the explicit finite-difference method in over 85 min. For European options on two and three underlyings, QUAD exhibits a huge improvement upon Monte Carlo and finite-difference schemes. For two underlyings, the accuracy after 0.01 s is an order of magnitude better than that with Monte Carlo (the next best method) after 21 s. For three underlyings, QUAD is more accurate after 0.04 s than Monte Carlo is after 35 s. By five underlyings, the results start to become comparable, although QUAD still has the edge in accuracy. The new and popular technique introduced by Figlewski’s group at NYU [2, 19], the adaptive mesh model (AMM), bears comparison. This improves lattice and grid methods by setting up more concentrated areas of lattice in areas of greater importance for errors, such as at payoff and on barriers. Another way of thinking of this is as a heavy pruning dense lattices everywhere except in the areas of the greatest importance. Levels of AMM calculation (not explained here) are expressed as AMM1, AMM2, and so on. As an example, for moving barrier options (on a Pentium III), AMM8 with 80 time steps between observations gives root-mean-squared errors of 0.00034 and takes an average time of 8.65 s, and extrapolated QUAD achieves better accuracy in 0.28 s.

Acknowledgments

I thank Dr Hannu Härkönen for his mathematical insights into FFT-QUAD and CONV-QUAD.

Partial Integro-differential Equations (PIDEs)

Partial integro-differential equations (PIDEs) appear in finance in the context of option pricing in discontinuous models. They generalize the Black–Scholes partial differential equation (PDE) when the continuous Black–Scholes dynamics for the underlying price is replaced by a Markov process with jumps.

The jump models proposed for option pricing are mostly based on Lévy processes (see **Exponential Lévy Models**). The jumps of a Lévy process are characterized by a positive measure $\nu(dx)$ on $\mathbb{R} \setminus \{0\}$, called *Lévy measure*, which satisfies the following integrability condition:

$$\int_{\mathbb{R} \setminus \{0\}} \min(1, x^2) \nu(dx) < \infty \quad (1)$$

In particular, it may be singular at the origin.

Consider an asset whose risk-neutral dynamics are described by an exponential Lévy model $S_t = S_0 \exp X_t$, where X_t is a Lévy process with coefficient σ and Lévy measure ν (the drift is determined by the martingale condition on $e^{-rt} S_t$). The value $V_t = V(t, S_t)$ at time $t \leq T$ of a European option on this underlying with maturity T and payoff $H(S_T)$ is then given by the solution of the following PIDE:

$$\begin{aligned} V_t + \frac{1}{2} \sigma^2 S^2 V_{SS} + r S V_S - r V \\ + \int [V(t, S e^y) - V(t, S) \\ - S(e^y - 1) V_S(t, S)] \nu(dy) = 0 \end{aligned} \quad (2)$$

The subscripts indicate partial derivatives and r is the continuously compounded risk-free interest rate. We can see that this equation contains the same terms as the Black–Scholes PDE and an integral term with respect to the Lévy measure ν . In particular, if ν is equal to 0, the integral term disappears and equation (2) reduces to the Black–Scholes equation. This is compatible with the fact that an exponential Lévy model without jumps is simply the Black–Scholes model.

Similar to the diffusion case, the PIDE formulation can be used for other types of options, such as barrier or American options, leading to

boundary-value problems or variational inequalities with the same integro-differential operator. The PIDE approach can also be generalized to more complicated cases: for example, stochastic volatility with jumps, nonhomogeneous jump measure $\nu_{t,x}(dx)$, multiasset derivatives (see **Jump Processes; Exponential Lévy Models**). Finally, one can obtain a *forward PIDE*—in maturity and strike variables—for call options, analogous to the Dupire equation (see [6, 14]) in one-factor Markovian models with jumps.

We first present the specific features of the integro-differential equations compared with the PDEs. In particular, we highlight the difficulties that arise for the numerical solution of these equations. We see that the use of standard techniques, such as finite differences or finite elements, is not straightforward. We then survey the existing approaches to adapt numerical methods developed for PDEs to the solution of partial integro-differential equations.

General Remarks

To solve the PIDE (2), it is convenient to make the change of variables $x = \log(S/S_0)$ and $\tau = T - t$. Denote $v(\tau, x) = e^{r(T-t)} V(t, S) = e^{r\tau} V(T - \tau, S_0 e^x)$. This leads to the following equation:

$$\begin{aligned} v_\tau = \frac{1}{2} \sigma^2 v_{xx} + \left(r - \frac{1}{2} \sigma^2 \right) v_x \\ + \int [v(\tau, x + y) - v(\tau, x) \\ - (e^y - 1) v_x(\tau, x)] \nu(dy) \end{aligned} \quad (3)$$

The payoff function provides a terminal condition for (2): $V(T, S) = H(S)$ and an initial condition for equation (3):

$$v(0, x) = H(S_0 e^x) \equiv h(x), \quad x \in \mathbb{R} \quad (4)$$

The main sources of difficulties with the PIDEs of type (2) or (3) are the following:

- nonlocal character of the operator;
- possible lack of regularity of the solution, especially in the pure jump case ($\sigma = 0$); and
- possible singularity of the Lévy measure at 0.

Let us get a closer look at these issues. Observe that the operator in equation (3) is nonlocal in space: that is, to evaluate it at a given point (τ, x_*) , we need

the values $v(\tau, x)$ for all $x \in \mathbb{R}$. This has multiple implications. First of all, if we consider equation (3) on a bounded domain in x , which is always the case if we solve it numerically, the boundary conditions must be specified not only *at* the boundary but also *beyond* the boundary:

$$v(\tau, x) = g(\tau, x) \quad \forall x \notin (x_{\min}, x_{\max}) \quad (5)$$

where g is a given function. Second, a finite difference or finite element discretization of equation (3) gives rise to a dense matrix, in contrast with the PDE case where the discretized operator is a sparse (usually tridiagonal) matrix easy to invert. The direct solution of a nonsparse linear system of N equations requires, in general, $O(N^3)$ operations, which makes the direct application of these methods inefficient. Finally, the integral operator propagates possible irregularities of the solution. For instance, the price of a barrier option is usually discontinuous at the barrier. While in the PDE case this discontinuity influences only the neighborhood of the boundary, a PIDE will propagate it inside the domain. It is worth mentioning that the regularity of the solution is not only a theoretical issue but also has a direct impact on the efficiency (stability and order of convergence) of numerical methods.

If the volatility σ is strictly positive (jump diffusion case), the integro-differential operator has the same regularizing property as the differential Black–Scholes operator: the solution is smooth for all $t < T$ even for discontinuous payoffs. The same is true in the pure jump case (without diffusion component) if there are “sufficiently many” jumps. More precisely, we have the following result [15, 16]:

Proposition 1 *Let H be a measurable function with a finite set of discontinuities. Suppose that $h(x) \equiv H(S_0 e^x)$ has at most polynomial growth: $\exists p \geq 0, |h(x)| \leq C(1 + |x|^p)$. Let X be a Lévy process with characteristic triplet (σ, ν, γ) satisfying $\int_{|y|>1} |y|^{2p} \nu(dy) < \infty$ and*

$$\begin{aligned} &\sigma > 0 \quad \text{or} \quad \exists \beta \in (0, 2), \\ &\liminf_{\varepsilon \downarrow 0} \frac{1}{\varepsilon^{2-\beta}} \int_{-\varepsilon}^{\varepsilon} |y|^2 \nu(dy) > 0 \end{aligned} \quad (6)$$

Then the forward European option price $v(\tau, x) = E[h(x + X_\tau)]$ belongs to the class $C^\infty((0, T] \times \mathbb{R})$ with $|\partial^{n+m} v / \partial x^n \partial t^m(x)| \leq C(1 + |x|^p)$, for all

$n, m \geq 0$. Moreover, $v(\tau, x)$ is a solution of the PIDE (3) with the initial condition (4).

The main idea of the proof is to apply the Itô formula to the discounted option price, which is a martingale, identify the drift term, and put it to 0: this gives the corresponding PIDE (see also **Partial Differential Equations**). The condition (6) ensures the regularity of the option price, so that we can apply the Itô formula. While the condition (6) is satisfied by most of the exponential Lévy models in the literature, there are some exceptions such as the popular Variance Gamma model (see **Variance-gamma Model**). When equation (6) is not satisfied, the irregularities in the payoff are not smoothened immediately and the option price may not be sufficiently regular to apply the Itô formula (see the examples in [16]). In the case of barrier options, the option price may be irregular even if $\sigma > 0$. This is due to the fact that the irregularity at the barrier is propagated inside the domain by the integral operator.

The possible lack of regularity of option prices led to consider them as different kinds of weak solutions of the PIDEs. Existence and uniqueness of solutions of integro-differential equations in Sobolev spaces has been studied in [10] and more recently in [25, 26, 33]. This approach provides the necessary framework for the solution of PIDEs by finite element methods. Another type of weak solution is the viscosity solution (see **Monotone Schemes**). Viscosity solutions of PIDEs are studied in [4, 5, 7, 9, 23, 27–29]. This approach is naturally linked to the probabilistic interpretation of the solution [16]. Moreover, it can be shown that any monotone scheme converges to the viscosity solution of the equation (see **Monotone Schemes**). This property is exploited in [11, 17].

We stress that Proposition 1 gives the PIDE satisfied by a *European* option price in the relatively simple *exponential Lévy models*. Although a rigorous proof of similar results for more complicated jump models or option types is often not available, the formal derivation of the pricing PIDEs is very easy and is regularly used for numerical valuation of option prices in models with jumps. However, we should be aware that, in many cases, the PIDE approach remains to be justified.

Finally, let us comment on the singularity of the Lévy measure. In pure jump models, such as Variance Gamma or CGMY (see **Tempered Stable Process**), the jumps are of infinite activity in order to

compensate the absence of diffusion component. This implies that the jump measure ν is not integrable at 0, which brings an additional difficulty for the discretization of equation (3). For finite element discretization, this is not really a problem because we do not need to discretize ν separately but only to evaluate the integral on some basis functions. To solve the PIDE using finite differences, we can approximate small jumps of the Lévy process by a Brownian motion with appropriately chosen volatility. This approximation is based on the results obtained in [8], and its impact on the option price is estimated in [17]. In the case of jumps of finite variation, as in the Variance Gamma model, it is also possible to replace small jumps by a drift rather than a diffusion term, as done in [24].

Numerical Solution

To illustrate the issues discussed above, we describe a simple finite difference scheme for equation (3) proposed in [17]. We consider here the case of nonzero diffusion and finite jump measure. As noted above, the general case may be reduced to this one by approximating small jumps.

European Vanilla and Barrier Options

To solve numerically the integro-differential problem (3)–(4), we first need to localize it to a bounded computational domain in x and truncate the integration domain in the integral part.

Truncation of the integration domain. Since we cannot calculate numerically an integral on the infinite range $(-\infty, \infty)$, the domain is truncated to a bounded interval (B_l, B_r) . In terms of the Lévy process, this corresponds to removing large jumps. Usually, the tails of ν decrease exponentially, so the probability of large jumps is small and the impact on the solution of the truncation is exponentially small in the domain size (see [17] for pointwise estimates).

Localization. Similarly, for the computational purposes, the domain of definition of the equation has to be bounded. For barrier options, the barriers are the natural limits for this domain and the rebate is the natural boundary condition. In the absence of barriers, we have to choose artificial bounds $(x_{\min}, x_{\max})$ and impose artificial boundary conditions. Recall that “boundary” conditions in this case must extend the

solution beyond the bounds as well (cf. equation (5)). It can be shown that any bounded function $g(\tau, x)$ leads to an exponentially decreasing localization error when the size of the domain increases. However, from the numerical point of view, it is better to take into account the asymptotic behavior of the solution. For instance, a good choice for a put option is $g(\tau, x) = (K - S_0 e^{x+r\tau})^+$. Of course, in the case of one barrier option, we need this condition only on one side of the domain: the other is zero or given by the rebate.

Remark In [25, 26], the authors subtract the payoff from the option price and solve a PIDE with zero boundary conditions on the excess to payoff. This leads to a source term in the equation which is, in the case of a put option, a Dirac delta-function. This is easily handled in the finite element framework but makes problem for finite difference discretization.

Discretization. We consider now the localized problem on $(x_{\min}, x_{\max})$:

$$v_\tau = Lv \quad \text{on } (0, T] \times (x_{\min}, x_{\max}) \quad (7)$$

$$v(0, x) = h(x), \quad x \in (x_{\min}, x_{\max}) \quad (8)$$

$$v(\tau, x) = g(\tau, x), \quad x \notin (x_{\min}, x_{\max}) \quad (9)$$

where L is the following integro-differential operator:

$$Lv = \frac{1}{2}\sigma^2 v_{xx} - \left(\frac{1}{2}\sigma^2 - r\right)v_x + \int_{B_l}^{B_r} \nu(dy)v(\tau, x+y) - \lambda v - \alpha v_x \quad (10)$$

with $\lambda = \int_{B_l}^{B_r} \nu(dy)$, $\alpha = \int_{B_l}^{B_r} (e^y - 1)\nu(dy)$. We introduce a uniform grid on $[0, T] \times \mathbb{R}$:

$$\begin{aligned} \tau_n &= n\Delta t, \quad n = 0, \dots, M, \\ x_i &= x_{\min} + i\Delta x, \quad i \in \mathbb{Z} \end{aligned} \quad (11)$$

with $\Delta t = T/M$, $\Delta x = (x_{\max} - x_{\min})/N$. The values of v on this grid are denoted by $\{v_i^n\}$. The space derivatives of v are approximated by finite differences:

$$(v_{xx})_i \approx \frac{v_{i+1} - 2v_i + v_{i-1}}{(\Delta x)^2} \quad (12)$$

$$(v_x)_i \approx \frac{v_{i+1} - v_i}{\Delta x} \quad \text{or} \quad (v_x)_i \approx \frac{v_i - v_{i-1}}{\Delta x} \quad (13)$$

The choice of the approximation of the first-order derivative—forward or backward difference—depends on the parameters σ , r , and α .

To approximate the integral term, we use the trapezoidal rule with the same discretization step Δx . Choose integers K_l , K_r such that $[B_l, B_r]$ is contained in $[(K_l - 1/2)\Delta x, (K_r + 1/2)\Delta x]$. Then,

$$\int_{B_l}^{B_r} v(dy)v(\tau, x_i + y) \approx \sum_{j=K_l}^{K_r} v_j v_{i+j} \quad \text{where} \quad v_j = \int_{(j-1/2)\Delta x}^{(j+1/2)\Delta x} v(dy) \quad (14)$$

Using equations (12)–(14), we obtain an approximation for $Lv \approx D_\Delta v + J_\Delta v$, where $D_\Delta v$ and $J_\Delta v$ are chosen as follows:

Explicit–implicit Scheme. Without loss of generality, suppose that $\sigma^2/2 - r < 0$. Then

$$(D_\Delta v)_i = \frac{\sigma^2}{2} \frac{v_{i+1} - 2v_i + v_{i-1}}{(\Delta x)^2} - \left(\frac{\sigma^2}{2} - r \right) \frac{v_{i+1} - v_i}{\Delta x}$$

If $\sigma^2/2 - r > 0$, to ensure the stability of the algorithm, we must change the discretization of v_x by choosing the backward difference instead of the forward one. Similarly, if $\alpha < 0$ we discretize J as follows:

$$(J_\Delta v)_i = \sum_{j=K_l}^{K_r} v_j v_{i+j} - \lambda v_i - \alpha \frac{v_{i+1} - v_i}{\Delta x} \quad (15)$$

Otherwise, we change the approximation of the first derivative. Finally, we replace the problem (7)–(9) with the following semiimplicit scheme:

Initialization:

$$v_i^0 = h(x_i) \quad \text{if } i \in \{0, \dots, N-1\} \quad (16)$$

$$v_i^0 = g(0, x_i) \quad \text{otherwise} \quad (17)$$

For $n = 0, \dots, M-1$:

$$\frac{v_i^{n+1} - v_i^n}{\Delta t} = (D_\Delta v^{n+1})_i + (J_\Delta v^n)_i \quad \text{if } i \in \{0, \dots, N-1\} \quad (18)$$

$$v_i^{n+1} = g((n+1)\Delta t, x_i) \quad \text{otherwise} \quad (19)$$

Here, the nonlocal operator J is treated explicitly to avoid the inversion of the fully populated matrix J_Δ , while the differential part D is treated implicitly. At each time step, we first evaluate vector $J_\Delta v^n$ where v^n is known from the previous iteration, and then solve the tridiagonal system (18) for $v^{n+1} = (v_0^{n+1}, \dots, v_{N-1}^{n+1})$.

Remark A direct computation of the term $J_\Delta v^n$ would require $O(N^2)$ operations and would be the most expensive step of the method. Fortunately, the particular form of the sum—discrete convolution of two vectors—allows to compute it efficiently and simultaneously for all i using fast Fourier transform (FFT) (see [21]). Note, however, that this is only possible in the case of a translation invariant jump measure. Another way to solve the problem of the dense matrix, valid also for nonhomogeneous jump models, is proposed in [26]. The authors use a finite element method with a special basis of wavelet functions (see also **Wavelet Galerkin Method**). In this basis, most of the entries in the matrix operator are very small, so that they can be replaced by zeros without affecting the solution much. The efficiency of the wavelet compression depends on the degree of singularity of the jump measure. Although it does not appear explicitly, this is also the case for the finite difference scheme, because of the trade-off that has to be done between the parameter ε of truncation of small jumps and discretization step Δx (see [17]). Finally, let us mention [31] where the integral is evaluated in linear complexity using a recursive formula in the particular case of the Kou model (see **Kou Model**).

Stability. The scheme (16)–(19) is stable if

$$\Delta t < \frac{\Delta x}{|\alpha| + \lambda \Delta x} \quad (20)$$

It is possible to make it unconditionally stable by moving the local terms in equation (15) in the implicit part. However, numerical experiments show that this leads to large errors for infinite activity Lévy measures.

Remark

- In [21, 26, 30–32], fully implicit or Crank–Nicolson finite difference schemes are used, which are unconditionally stable. To solve the resulting dense linear systems, the authors use

iterative methods that require only matrix-vector multiplication performed using FFT.

- Equation (2) can be solved directly in the original variables. We can also choose a nonuniform grid with, for example, more nodes near the strike and maturity [2, 31]. In this case, an interpolation at each time step is needed in order to apply FFT [21].
- Similar semiimplicit scheme in the finite activity case is used in [11]. In [6], the operator is also split into differential and integral parts, and then an alternating direction implicit (ADI) time stepping is used.
- The situation is more challenging for PIDEs in more than one dimension. The main idea here is to devise an operator-splitting scheme as above where each component only acts on one of the variables, thus reducing the dimension in each step of the computation [12, 13, 18].

American Options

Pricing American options in jump models leads to integro-differential variational inequalities [10, 27]. Equivalently, option price may be represented as solution of a linear complementarity problem (LCP) of the following form (see also **Finite Difference Methods for Early Exercise Options**):

$$V_\tau - \mathcal{L}V \geq 0 \quad (21)$$

$$V - V^* \geq 0 \quad (22)$$

$$(V_\tau - \mathcal{L}V)(V - V^*) = 0 \quad (23)$$

For example, in exponential Lévy models, $\mathcal{L}$ is the same integro-differential operator as in the PIDE (2) and V^* is the payoff received upon exercise. Pricing American options in Lévy driven models based on equations (21)–(23) is considered in [1–3, 19–22, 24, 25, 32, 33]. Numerical solution of the integro-differential problem (21)–(23) faces globally the same difficulties as that of PIDEs. The dense and nonsymmetric matrix of the operator makes unfeasible or inefficient standard methods for solving LCPs. The solutions proposed rely on similar ideas as in the European case: splitting the operator [1, 33], wavelet compression [25], using iterative methods with suitable preconditioning. In [19, 21, 32], the LCP is replaced by an equation with a nonlinear penalty term. We refer to the references cited above for the details on these methods.

Method of Lines

The complexity of a partial differential equation (PDE) grows with the number of independent variables. In applied mathematics, the *method of lines* (MoL) is frequently used to reduce the number of independent variables by one. For this reduction, one has to pay a price, which is twofold:

1. A *system* of several dependent variables arises.
2. The system is an approximation—that is, a discretization error is introduced.

In finance, the method of lines is applied to the Black–Scholes PDE, which involves two independent variables, namely, time t and price S of the underlying asset. The continuous domain is the *half strip* $0 \leq t \leq T$, $S > 0$, where T denotes the time to maturity. Introducing the backward running time $\tau := T - t$, the Black–Scholes equation is

$$-\frac{\partial V(S, \tau)}{\partial \tau} + \mathcal{L}_{\text{BS}}(V(S, \tau)) = 0 \quad \text{with} \quad (1)$$

$$\mathcal{L}_{\text{BS}}(V(S, \tau)) := \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + (r - \delta)S \frac{\partial V}{\partial S} - rV$$

Here, the dependent variable $V(S, \tau)$ denotes the value function of a vanilla American put option, r is the risk-free interest rate, δ denotes a constant dividend yield, and σ the volatility (*see Options: Basic Definitions*). According to the Black–Scholes model, r, σ, δ are taken as constants. For a put option of the American style with strike K , the payoff at time T is

$$(K - S)^+ := \max(K - S, 0) \quad (2)$$

The initially unknown early exercise curve S_f separates the half strip into two parts: stopping region $S \leq S_f$, where V equals the payoff, and the continuation region, where V solves the Black–Scholes equation:

$$V = (K - S)^+ \quad \text{for } S \leq S_f \quad (3)$$

$$V \text{ solves equation (1) for } S > S_f$$

The geometry of the domain is illustrated in Figure 1.

Since equation (1) depends on two independent variables, MoL leads to a system with only one independent variable—that is, to a system of ordinary differential equations (ODEs). For introducing “lines” in our context, we have two possibilities: either we set up lines parallel to the t -axis or we work with lines parallel to the S -axis. The former approach leads to a fully numerical method; it is described in Exercise 4.10 of [6]. Our focus is on the latter MoL approach, with lines parallel to the S -axis. This approach (which goes back to [3]) is attractive because the resulting ODEs can be solved analytically.

Semidiscretization

The method of lines replaces the half strip by a set of equidistant lines, each line defined by a constant value of τ . To this end, the interval $0 \leq \tau \leq T$ is discretized into n subintervals by

$$\tau_v := v\Delta\tau, \quad \Delta\tau := T/n, \quad v = 1, \dots, n-1 \quad (4)$$

(Figure 1). On this discrete set of lines, the partial derivative $\partial V / \partial \tau$ is approximated by the difference quotient

$$\frac{V(S, \tau) - V(S, \tau - \Delta\tau)}{\Delta\tau} \quad (5)$$

This gives a semidiscretized version of equation (1), namely, for each τ_v the ODE

$$w(S, \tau - \Delta\tau) - w(S, \tau) + \Delta\tau \mathcal{L}_{\text{BS}}(w(S, \tau)) = 0 \quad (6)$$

which holds for $S \geq S_f$. Here, we use the notation w rather than V to indicate that a discretization error is involved. As this semidiscretized version of equation (6) is applied for each of the parallel lines, $\tau = \tau_v$, $v = 1, \dots, n-1$, a coupled system of ODEs is derived.

Analytic Solution

Substituting equation (1) into equation (6) gives the equation to be solved for each line τ_v

$$\frac{1}{2}\Delta\tau \sigma^2 S^2 \frac{\partial^2 w}{\partial S^2} + \Delta\tau (r - \delta)S \frac{\partial w}{\partial S} - (1 + r\Delta\tau)w = -w(S, \tau_{v-1}) \quad (7)$$

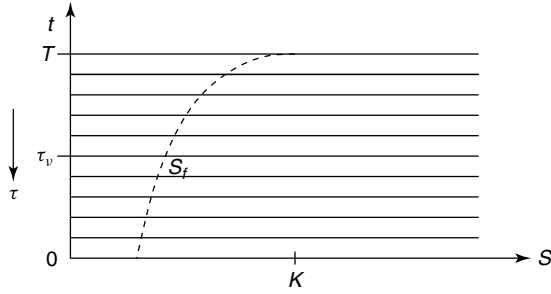

Figure 1 Method of lines applied to an American-style vanilla put

where the argument of w on the left-hand side is (S, τ_v) . This is a second-order ODE for $w(S, \tau_v)$, with boundary conditions for $S_f(\tau_v)$ and $S \rightarrow \infty$. For any line $\tau = \tau_v$, the function $w(S, \tau_{v-1})$ of the right-hand side is known from the previous line, starting from the known payoff for $\tau = 0$. The right-hand function $q(S) := -w(S, \tau_{v-1})$ is an inhomogeneous term of the ODE.

The analytic solution exploits that the equation (7) is linear in w and of the simple type of an inhomogeneous Euler equation

$$\begin{aligned} \alpha S^2 w'' + \beta S w' + \gamma w &= q(S) \\ \text{with } \alpha &= \frac{1}{2} \Delta \tau \sigma^2, \quad \beta = (r - \delta) \Delta \tau, \quad (8) \\ \gamma &= -(1 + r \Delta \tau) \end{aligned}$$

where the prime denotes differentiation with respect to S . The solution method for such a simple type of ODE is standard and found in any ODE text book. It is based on substituting S^λ into the homogeneous ODE ($q \equiv 0$). This yields a quadratic equation with

zeros

$$\begin{aligned} \lambda_{1,2} &:= \frac{1}{2} - \frac{r - \delta}{\sigma^2} \\ &\pm \sqrt{\left(\frac{1}{2} - \frac{r - \delta}{\sigma^2}\right)^2 + \frac{2(1 + r \Delta \tau)}{\sigma^2 \Delta \tau}} \quad (9) \end{aligned}$$

Solutions to the homogeneous ODE are obtained by linear combinations of the S^λ ,

$$aS^{\lambda_1} + bS^{\lambda_2} \quad (10)$$

for suitable constants a and b . A solution of the inhomogeneous equation is added. Note that this analytical solution avoids a truncation error in S -direction.

Matching Solution Parts

In our context, we need (at least) two such solutions for every line, because the inhomogeneous terms change. The early exercise curve S_f separates each of the parallel lines into two parts (Figure 2). As for the previous line τ_{v-1} , the separation point lies more “on the right” (recall that for a put the curve $S_f(\tau)$ is monotonically decreasing for growing τ), the inhomogeneous term $w(\cdot, \tau_{v-1})$ consists of (at least) two parts as well, but separated differently. Neglecting for a moment the previous history of lines $\tau_{v-2}, \tau_{v-3}, \dots$, the analytic solution of equation (7) for τ_v consists of three parts, defined on the three subintervals

$$\begin{aligned} \text{A: } & 0 < S \leq S_f(\tau_v) \\ \text{B: } & S_f(\tau_v) < S \leq S_f(\tau_{v-1}) \\ \text{C: } & S_f(\tau_{v-1}) < S \end{aligned} \quad (11)$$

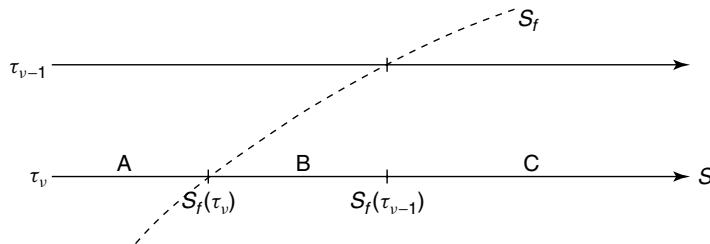

Figure 2 Detail of Figure 1, situation along line τ_v : A: solution is given by payoff; B: inhomogeneous term of differential equation given by payoff; and C: inhomogeneous term given by $-w(\cdot, \tau_{v-1})$

On the left-hand interval A, w equals the payoff; nothing needs to be calculated. For the middle interval B, the inhomogeneous term $-w(., \tau_{v-1})$ is given by the payoff, $q(S) = -(K - S)$. As we need solutions for both subintervals B and C, a second pair of constants is required for C. In this subinterval, the value of a put vanishes for $S \rightarrow \infty$, which contradicts $\lambda_1 > 0$; the root λ_1 drops out for the solution part in C. Hence, this solution is of the type cS^{λ_2} for a constant c . When we consider the dependence on previous lines, then we realize that there are recursively several B-type subintervals, and only one C-type interval for $S > S_f(\tau_0) = K$. To illustrate this, merge Figures 1 and 2. For $S_f(\tau_0) = K$ to hold, assume in addition $\delta \leq r$ for a put ($\delta \geq r$ for a call).

First Line

Let us discuss for the first line $v = 1$ how the solution is setup. For this exposition, we take specifically $\delta = 0$. For $v = 1$, we have $S_f(\tau_{v-1}) = K$ and $q = w(S, \tau_{v-1}) = 0$ for $S > K$. Hence, in subinterval C the inhomogeneous solution is 0. And $q = S - K$ for $S_f(\tau_1) < S < K$, hence

$$\frac{K}{1 + r \Delta \tau} - S \quad (12)$$

solves the inhomogeneous equation for subinterval B. This leads to the three parts of the solution along the first line $\tau = \tau_1$

$$\begin{aligned} w(S; \tau_1) &= K - S \quad \text{for A} \\ w(S; \tau_1) &= \frac{K}{1 + r \Delta \tau} - S + a^{(1)} S^{\lambda_1} \\ &\quad + b^{(1)} S^{\lambda_2} \quad \text{for B} \end{aligned} \quad (13)$$

$$w(S; \tau_1) = c^{(1)} S^{\lambda_2} \quad \text{for C}$$

The value of $S_f(\tau_1)$ is still undetermined as well as the three constants $a^{(1)}$, $b^{(1)}$ and $c^{(1)}$. To determine these four parameters, we require four equations.

The unknown separation point $S_f(\tau_v)$ is fixed by the high-contact conditions

$$V(S_f, \tau) = K - S_f, \quad \frac{\partial V(S_f, \tau)}{\partial S} = -1 \quad (14)$$

This is applied to the approximation w as well. Two remaining conditions are given by the requirement

that both w and dw/dS are continuous at the matching point $S_f(\tau_{v-1})$. This fixes all variables. For the first line, the four equations for the parameters are (with $E := S_f(\tau_1)$)

$$\frac{K}{1 + r \Delta \tau} - E + a^{(1)} E^{\lambda_1} + b^{(1)} E^{\lambda_2} = K - E \quad (15)$$

$$-1 + \lambda_1 a^{(1)} E^{\lambda_1-1} + \lambda_2 b^{(1)} E^{\lambda_2-1} = -1 \quad (16)$$

$$\frac{K}{1 + r \Delta \tau} - K + a^{(1)} K^{\lambda_1} + b^{(1)} K^{\lambda_2} = c^{(1)} K^{\lambda_2} \quad (17)$$

$$-1 + \lambda_1 a^{(1)} K^{\lambda_1-1} + \lambda_2 b^{(1)} K^{\lambda_2-1} = \lambda_2 c^{(1)} K^{\lambda_2-1} \quad (18)$$

which has made use of $S_f(\tau_0) = K$. The solution of this system is tedious, we skip the derivation. This explains the analytic solution of equation (13) along the first line.

General Case

The following lines ($v \geq 2$) lead to even more involved equations, because in subinterval C the inhomogeneous solution is nontrivial, and additional subintervals B are inserted for each new line. The general structure of the solutions of the ODE is the same in the subintervals B, but the coefficients differ. And, of course, the points $S_f(\tau_v)$ vary. The resulting analytic method of lines is quite involved. The final formulas from [3] for a put with $\delta \leq r$ are the following:

Notations

$$\gamma = \frac{1}{2} - \frac{r - \delta}{\sigma^2}$$

$$R = \frac{1}{1 + r \Delta \tau} \quad (\text{single-period discount factor})$$

$$D = \frac{1}{1 + \delta \Delta \tau}$$

$$\varepsilon = \sqrt{\gamma^2 + \frac{2}{R\sigma^2\Delta\tau}}$$

$$p = \frac{\varepsilon - \gamma}{2\varepsilon}, \quad q = 1 - p$$

$$\hat{p} = \frac{\varepsilon - \gamma + 1}{2\varepsilon}, \quad \hat{q} = 1 - \hat{p}$$

$$S_{f,v} := S_f(\tau_v)$$

$V^{(n)}(S)$ = approximation of the American put for
 $t = 0$

After n lines, the solutions consist of $n + 2$ pieces,

$$V^{(n)}(S) = \begin{cases} K - S & \text{for } S \leq S_{f,n} \\ v_v^{(n)}(S) + b_v^{(n)}(S) + A_v^{(n)}(S; 1) & \text{for } S_{f,v} < S \leq S_{f,v-1}, v = 1, \dots, n \\ p_0^{(n)}(S) + b_1^{(n)}(S) & \text{for } S > S_{f,0} \equiv K \end{cases} \quad (19)$$

This piecewise defined function represents $w(S, \tau_n)$ and corresponds to $V(S, 0)$. The coefficients are

$$p_0^{(n)}(S) = \left(\frac{S}{K}\right)^{\gamma-\varepsilon} \sum_{k=0}^{n-1} \frac{(2\varepsilon \ln(S/K))^k}{k!} \times \sum_{l=0}^{n-k-1} \binom{n-1+l}{n-1} \times [K R^n q^n p^{l+k} - K D^n \hat{q}^n \hat{p}^{l+k}] \quad (20)$$

$$v_v^{(n)}(S) = K R^{n-v+1} - S D^{n-v+1} \quad (21)$$

$$b_v^{(n)}(S) = \sum_{j=1}^{n-v+1} \left(\frac{S}{S_{f,n-j+1}}\right)^{\gamma-\varepsilon} \times \sum_{k=0}^{j-1} \frac{(2\varepsilon \ln(S/S_{f,n-j+1}))^k}{k!} \times \sum_{l=0}^{j-k-1} \binom{j-1+l}{j-1} \times [q^j p^{k+l} R^j K r - \hat{q}^j \hat{p}^{k+l} D^j S_{f,n-j+1} \delta] \Delta \tau \quad (22)$$

$$A_v^{(n)}(S; i) = \sum_{j=i}^{n-v+1} \left(\frac{S}{S_{f,n-j+1}}\right)^{\gamma+\varepsilon} \times \sum_{k=0}^{j-1} \frac{(2\varepsilon \ln(S_{f,n-j+1}/S))^k}{k!}$$

$$\times \sum_{l=0}^{j-k-1} \binom{j-1+l}{j-1} \times [p^j q^{k+l} R^j K r - \hat{p}^j \hat{q}^{k+l} D^j S_{f,n-j+1} \delta] \Delta \tau \quad (23)$$

The approximation of the optimal exercise prices $S_{f,m}$ are solutions of the equations

$$c_1^{(m)}(K) - A_1^{(m)}(K; 2) = \left(\frac{K}{S_{f,m}}\right)^{\gamma+\varepsilon} [p R K r - \hat{p} D S_{f,m} \delta] \Delta \tau \quad (24)$$

for $m = 1, \dots, n$, where

$$c_1^{(m)}(K) = \sum_{l=0}^{m-1} \binom{m-1+l}{m-1} \times [K D^m \hat{p}^m \hat{q}^l - K R^m p^m q^l] \quad (25)$$

This equation is solved iteratively with Newton's method. In case no dividend is paid ($\delta = 0$, $D = 1$), no iteration is needed, and the solution is

$$S_{f,m} = K \left(\frac{p R K r \Delta \tau}{c_1^{(m)}(K) - A_1^{(m)}(K; 2)} \right)^{1/(\gamma+\varepsilon)} \quad (26)$$

This value would serve as initial guess for the Newton iteration in case $\delta > 0$. The formulas of these triple sums are also collected in [2]. The corresponding formulas for a call are available too. Instead, the put-call symmetry relation from [4] can be used as well.

Extrapolation

For small values of n , the method does not provide high accuracy in its basic state. To enhance the quality of the approximation, Richardson extrapolation is applied. Let $\bar{V}_n$ denote the result of the above MoL with n lines, evaluating equation (19) for a given value of S . Assume that three approximations $\bar{V}_1$, $\bar{V}_2$, and $\bar{V}_3$ are calculated. Note that $\bar{V}_1$ means that only a single timestep of size $\Delta \tau = T$ is used. Then the extrapolated value

$$\bar{V}^{1:3} := \frac{1}{2}(9\bar{V}_3 - 8\bar{V}_2 + \bar{V}_1) \quad (27)$$

Table 1 Test results of the tuned $\bar{V}^{1:3}$ for $K = 100$

S	T	σ	r	δ	$V(S, 0)$
80	0.5	0.4	0.06	0.00	21.6257
100	0.5	0.4	0.02	0.00	10.7899
80	3.0	0.4	0.06	0.02	29.2323

gives an accurate result with order $(\Delta\tau)^3$. As shown in [1], the obtainable accuracy of the combined MoL/extrapolation approach compares well to the other methods. Reference [3] applies a fine tuning to the three-point formula $\bar{V}^{1:3}$ replacing the coefficient 8 in the above formula by $8(1 - 0.0002(5 - T)^+)$. Even with only two approximations, $\bar{V}_1, \bar{V}_2$, extrapolation enhances the accuracy significantly. The formula

$$\bar{V}^{1:2} := -\bar{V}^1 + 2\bar{V}^2 \quad (28)$$

is of the order $(\Delta\tau)^2$. The justification of Richardson extrapolation in this context does not yet appear fully explored; smoothness in time is assumed. This is not a disadvantage since equations (27) or (28) serve as analytic-approximation formulas.

Further Remarks

For comparison, we provide in Table 1, three test values of the tuned version of the three-line extrapolation

equation (27). To check the accuracy, an independent computation with a highly accurate version of a finite-difference approach was run. This has revealed relative errors of about 10^{-3} in the three examples reported in Table 1—that is, three digits are correct. For testing purposes, the MoL method with the tuned version of the formula $\bar{V}^{1:3}$ of equation (27) is installed in the option-calculator of the website www.compfin.de. Note that the above describes the analytic method of [3]; the MoL approach of [5] solves equation (7) numerically.

Fourier Methods in Options Pricing

Pricing European Options

There are various ways to price European options *via* Fourier inversion. Before we consider such methods, it is worth mentioning why Fourier option pricing methods can be useful. First recall that the risk-neutral valuation theorem states that the forward price of a European call option on a single asset S can be written as

$$C(S(t), K, T) = \mathbb{E}[(S(T) - K)^+] \quad (1)$$

where C denotes the value, T the maturity, and K the strike price of the call. The expectation is taken under the T -forward probability measure. As equation (1) is an expectation, it can be calculated *via* numerical integration, provided we know the density in closed form. For many models the density is either not known in closed form, or is quite cumbersome, whereas its characteristic function is often much easier to obtain. A good example in finance is the variance gamma model, introduced by Madan and Seneta [15]. Its density involves a Bessel function of the third kind, whereas its characteristic function only consists of elementary functions.

Heston [8] was among the first to utilize Fourier methods to price European options within his stochastic volatility model. Since Heston's seminal paper, the pricing of European options by means of Fourier inversion has become more and more commonplace. Heston's approach starts from the observation that equation (1) can be recast as

$$C(S(t), K, T) = F(t, T) \cdot \mathbb{S}(S(T) > K) - K \cdot \mathbb{P}(S(T) > K) \quad (2)$$

with $F(t, T)$ the forward price of the asset and $\mathbb{P}$ and $\mathbb{S}$ respectively the T -forward probability measure and the measure induced by taking the asset price as the numeraire. The cumulative probabilities in equation (2) can subsequently be found by Fourier inversion, an approach dating back to [6, 7, 11]. As this approach necessitates the evaluation of two Fourier inversions, and is inaccurate for out-of-the-money options, due to cancellation, we do not discuss

it here in further detail. Instead we focus on more recent approaches due to [3, 16], and [12].

Carr and Madan's approach was to consider the Fourier transform of the damped European call price with respect to the logarithm of the strike price:

$$\begin{aligned} \psi(v, \alpha) &\equiv \int_{-\infty}^{\infty} e^{ivk} e^{\alpha k} C(k) dk \\ &= \frac{\phi(v - i(\alpha + 1))}{-(v - i\alpha)(v - i(\alpha + 1))} \end{aligned} \quad (3)$$

and subsequently invert this to arrive at the desired call price:

$$\begin{aligned} C(S(t), K, T) &= \frac{e^{-\alpha k}}{2\pi} \int_{-\infty}^{\infty} e^{-ivk} \psi(v, \alpha) dv \\ &= \frac{e^{-\alpha k}}{\pi} \int_0^{\infty} \text{Re}(e^{-ivk} \psi(v, \alpha)) dv \end{aligned} \quad (4)$$

In equations (3) and (4), $\phi(u)$ is the characteristic function; $\phi(u) = \mathbb{E}[\exp(iu \ln S(T))]$. Sufficient conditions for equation (4) to exist are that the damping factor $\alpha > 1$, and that the $(\alpha + 1)$ st moment of the asset, $\phi(-(\alpha + 1)i)$, is finite. The first condition is required to make the damped call price an L^1 -integrable function, which is a sufficient condition for the existence of its Fourier transform.

Whereas Carr and Madan took the Fourier transform with respect to the strike price of the call option, Raible [16] and Lewis [12] used an approach that is slightly more general in that it does not require the existence of a strike in a payoff. Raible took the transform with respect to the log-forward price, Lewis used the log-spot price. Note that for all three methods, the Fourier transform of the option price can be decoupled into two parts, a payoff-dependent part, the payoff transform, and a model-dependent part, the characteristic function.

One of the restrictions on the damping factor α for a call price is that it must be larger than 1. However, as Lewis [12] and Lee [9] point out, this is not a real restriction if we recast equation (4) as a contour integral in the complex plane. Shifting the contour, equivalent to varying α in equation (4), and carefully applying Cauchy's residue theorem leads to the following option pricing equation:

$$\begin{aligned} C(S(t), K, T, \alpha) \\ = R(F(t, T), K, \alpha) \end{aligned}$$

$$+ \frac{e^{-\alpha k}}{\pi} \int_0^\infty \operatorname{Re}(e^{-ivk} \psi(v, \alpha)) dv \quad (5)$$

where the residue term $R(F, K, \alpha)$ equals 0 for $\alpha > 0$, $1/2F$ for $\alpha = 0$, F for $\alpha \in (-1, 0)$, $F - 1/2K$ for $\alpha = -1$, and $F - K$ for $\alpha < -1$. For values of $\alpha < -1$, for example, this means that the integral in equation (5) yields the value of a put, from which we obtain the price of a call *via* put–call parity.

As far as the numerical implementation of equation (5) goes, the appropriate numerical algorithm depends, as always, on the user’s demands. If one is interested in the option price at a great many strike prices, equation (5) can be discretized in such a way that it is amenable to use of the fast Fourier transform (FFT), as detailed in [3] and in the article **Fourier Transform**. If one is calibrating a model to a volatility surface, one often only needs to evaluate option prices at a handful of strikes, at which point a direct integration of equation (5) becomes computationally advantageous. Important points to consider in approximating the semi-infinite integral in equation (5) are the discretization error, the truncation error, and the choice of contour or damping factor α . Lee [9] extensively analyzes these choices when equation (5) is discretized using the discrete Fourier transform (DFT), and proposes a minimization algorithm to determine the parameters of the discretization.

Lord and Kahl [14] propose a different approach. If an appropriate transformation function is available that maps the semi-infinite interval into a finite one, the truncation error can be avoided altogether. This leaves the discretization error, which can be

controlled by using adaptive integration methods. Finally, the speed and accuracy of the integration algorithm can be controlled by choosing an appropriate value of α . A good proxy for the optimal value of α , the value that minimizes the approximation error given a fixed computational budget, is

$$\begin{aligned} \alpha^* &= \arg \min_{\alpha \in (\alpha_{\min}, \alpha_{\max})} |e^{-\alpha k} \psi(0, \alpha)| \\ &= \arg \min_{\alpha \in (\alpha_{\min}, \alpha_{\max})} -\alpha k + \frac{1}{2} \ln(\psi(0, \alpha)^2) \quad (6) \end{aligned}$$

where $(\alpha_{\min}, \alpha_{\max})$ is the allowed range of α , corresponding to $\phi(-(\alpha + 1)i) < \infty$. This choice of contour is closely linked to how the optimal contour is chosen in saddlepoint approximations. That α really can have a significant impact on the accuracy should become clear from the following example.

Example 1—Impact of α on the Numerical Approximation in Heston’s Model

As an example, we look at the impact of α in Heston’s stochastic volatility model (*see Heston Model*). The parameters we pick are $\kappa = \omega = 1$, $\rho = -0.7$, $\theta = v(0) = 0.1$, $F = 1$, $K = 1.5$ and the time to expiry is 0.1 years. Figure 1 shows the impact of α on the approximation error when two different ways are used to discretize equation (5).

If one plots the function that is minimized in equation (6), one obtains a very similar pattern, suggesting that α^* is indeed close to optimal.

Finally, Andersen and Andreasen [2] and Cont and Tankov [4] have suggested that the Black–Scholes

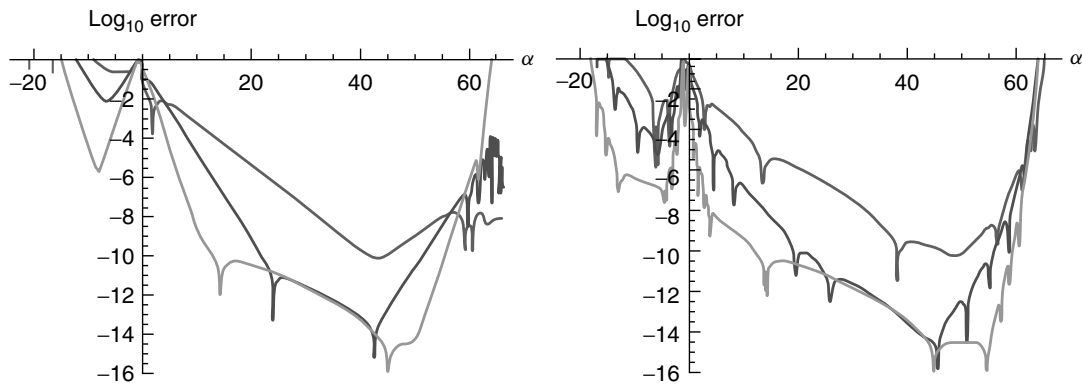

Figure 1 Impact of α using (a) Lee [9] DFT discretization, or (b) Gauss–Legendre quadratures. The various lines represent the number of abscissae used (8, 16, or 32)

option price could be used as a control variate in the evaluation of equation (5), that is, we could subtract the Black–Scholes integrand from the integrand, and subsequently add the Black–Scholes price back to the equation. While this could work for some models, the approach does require a good correspondence between both characteristic functions, and also requires an educated guess as to which Black–Scholes volatility should be used.

Pricing Bermudan and American Options

Now that we can price European options using Fourier methods, the next question is whether options with early exercise features can be priced in a similar framework. The answer is in the affirmative. The first paper to attempt this in the framework of Carr and Madan was by O’Sullivan [18], who extended the QUAD method of [1] (see **Quadrature Methods**) to allow for models where the density is not known in closed form, but has to be approximated *via* Fourier inversion. This method has complexity $O(MN^2)$, where M is the number of time steps and N is the number of discretization points used in a one-dimensional model.

Building upon a presentation by Reiner [17], Lord *et al.* [13] noticed that the key to extending Carr and Madan’s approach to early exercise options was to abandon the idea of working with an analytical Fourier transform of the option payoff and to numerically approximate it. If at time t_m we have an expression for the value of the option contract, then its continuation value at t_{m-1} can be obtained by calculating its convolution with the transition density. As we know the Fourier transform of a convolution is the product of the individual Fourier transforms, all we need to do is numerically calculate the Fourier transform of the continuation value. Having calculated the continuation value, we obtain the value at time t_{m-1} simply by comparison with the exercise value. The CONV method of Lord *et al.* [13] utilizes the FFT to approximate the convolutions. As such, the algorithm is $O(MN \log N)$. For Bermudan options, the algorithm is certainly competitive with the fastest partial integro-differential differential equation (PIDE) methods (see **Partial Integro-differential Equations (PIDEs)**); see the numerical comparison in [13]. The prices of American options can be obtained *via* Richardson extrapolation. It is

here that PIDE methods have an advantage. Another area where PIDE methods are advantageous is at the choice of gridpoints—as the CONV method employs the FFT, the grid for the logarithm of the asset price needs to be uniform. This makes it harder to place discontinuities on the grid, something which is much easier to achieve in, for example, the QUAD or PIDE methods. Extensions of the CONV method to multiple dimensions can be found in [10].

Finally, we mention a recent paper by Fang and Oosterlee [5], in which Bermudan options are efficiently priced *via* Fourier cosine series expansions. While this method is also $O(MN \log N)$ and has some similarities with the CONV method, a great advantage is that the exercise boundary is directly solved, as in the QUAD method. Hence, the cosine series coefficients can be calculated exactly, instead of being approximated, which is the case in the CONV method. Whereas the convergence of the CONV method is dictated by the chosen Newton–Cotes rule, the convergence of the COS method is dictated by the rate of decay of the characteristic function.

Quantization Methods

The origin of optimal vector quantization goes back to the early 1950s as a way to discretize a (stationary) signal so that it could be transmitted for a given cost with the lowest possible degradation. The starting idea is to consider the best approximation in the mean quadratic sense—or, more generally, in an L^p -sense—of an $\mathbb{R}^d$ -valued random vector X by a random variable $q(X)$ taking at most N values (with respect to a given norm on $\mathbb{R}^d$, usually the canonical Euclidean norm).

More recently (in the late 1990s), it has been introduced as an efficient tool in numerical probability—first, for numerical integration in medium dimensions [15, 16], and soon as a method for the computation of conditional expectations. The main motivation was the pricing and hedging of multias-set American-style options [2, 4] and more generally to devise some realistic numerical schemes for the reflected backward stochastic differential equations (SDEs) (see **Backward Stochastic Differential Equations** and [1, 3]). Presently, this ability to compute conditional expectations has led to tackling other nonlinear problems like stochastic control (portfolio management [18], pricing of swing options [5, 6]), nonlinear filtering with some applications to stochastic volatility models [20], and some classes of stochastic partial differential equations (PDEs) like stochastic Zakai and McKean–Vlasov equations [8]. In all these problems, quantization is used to produce a space discretization of the underlying (Markov) dynamics at the time discretization instants (see also [19]).

Optimal Vector Quantization: A Short Background

Assume $\mathbb{R}^d$ is equipped with the Euclidean norm $|\cdot|$. Let $X : (\Omega, \mathcal{A}, \mathbb{P}) \rightarrow \mathbb{R}^d$ be a random vector. For a given set $\Gamma = \{x_1, \dots, x_N\} \subset \mathbb{R}^d$, $N \geq 1$, any (Borel) projection $\widehat{X}^\Gamma$ of X on Γ following the *nearest neighbor rule* provides an optimal solution

$$|X - \widehat{X}^\Gamma| = d(X, \Gamma) = \min_{1 \leq i \leq N} |X - x_i| \quad (1)$$

The projection is essentially unique if all hyperplanes have 0-mass for the distribution of X . If $X \in L^2(\mathbb{P})$,

the induced mean quadratic error $\|X - \widehat{X}^\Gamma\|_2$ reaches a minimum as Γ runs over all subsets of $\mathbb{R}^d$ of size at most N . Any such minimizer $\Gamma^{N,*}$ is called an *optimal quadratic N -quantizer* of X and $\widehat{X}^{\Gamma^{N,*}}$ is called an *optimal quadratic N -quantization* of X . Using the property that conditional expectation given a σ -field $\mathcal{B}$ is the best $\mathcal{B}$ -measurable quadratic approximation, one derives the result that an optimal quantizer satisfies the so-called *stationary property*:

$$\mathbb{E}(X|\widehat{X}) = \widehat{X} \quad \text{with} \quad \widehat{X} := \widehat{X}^{\Gamma^{N,*}} \quad (2)$$

It is easy to show that the minimal mean quantization error $\|X - \widehat{X}^{\Gamma^{N,*}}\|_2$ is nonincreasing and goes to zero as $N \rightarrow \infty$ (decreasing if the support of X is infinite). Optimal quantizers also exist with respect to the $L^r(\mathbb{P})$ -norm, $r \neq 2$. The rate of convergence is ruled by the Zador Theorem.

Theorem 1 (a) Sharp rate [9]. Let $X \in L^{r+\eta}(\mathbb{P})$ for some $r, \eta > 0$. Let $\mathbb{P}_x(d\xi) = \varphi(\xi)d\xi + \nu(d\xi)$ be the canonical decomposition of the distribution of X (ν and the Lebesgue measure are singular). Then there exists a real constant $\tilde{J}_{r,d} \in (0, \infty)$ such that

$$\lim_N N^{\frac{1}{d}} \min_{\Gamma \subset \mathbb{R}^d, \text{card}(\Gamma) \leq N} \|X - \widehat{X}^\Gamma\|_r \sim \tilde{J}_{r,d} \times \left(\int_{\mathbb{R}^d} \varphi^{\frac{d}{d+r}}(u) du \right)^{\frac{1}{d} + \frac{1}{r}} \quad \text{as } N \rightarrow +\infty \quad (3)$$

(b) Nonasymptotic upper bound [13]. Let $d \in \mathbb{N}$. Let $r, \eta > 0$. There exists $C_{d,r,\eta} \in (0, \infty)$ such that, for every $\mathbb{R}^d$ -valued random vector X ,

$$\forall N \geq 1,$$

$$\min_{\Gamma \subset \mathbb{R}^d, |\Gamma| \leq N} \|X - \widehat{X}^\Gamma\|_r \leq C_{d,r,\eta} \|X\|_{r+\eta} N^{-\frac{1}{d}} \quad (4)$$

The real constant $\tilde{J}_{r,d}$ (which depends on the underlying norm on $\mathbb{R}^d$) corresponds to the case of the uniform distribution over $[0, 1]^d$ for which the above “ $\lim_N$ ” also holds as an “ $\inf_N$ ” as well. When $d = 1$, $\tilde{J}_{r,1} = (r+1)^{-\frac{1}{r}}/2$. When $d = 2$, with the canonical Euclidean norm, $\tilde{J}_{2,d} = \sqrt{\frac{5}{18\sqrt{3}}}$. For $d \geq 3$ one only knows that $\tilde{J}_{2,d} \sim \sqrt{\frac{d}{2\pi e}} \approx \sqrt{\frac{d}{17.08}}$ as $d \rightarrow$

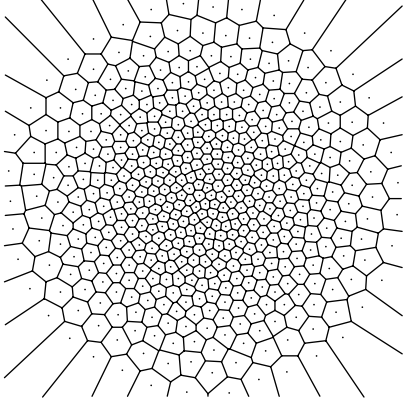

Figure 1 N -quantizer (and its Voronoi diagram) of the normal distribution $\mathcal{N}(0; I_2)$ on $\mathbb{R}^2$ with $N = 500$ (The Voronoi diagram never needs to be computed for numerics)

$+\infty$. For more results on the theoretical aspects of vector quantization we refer to [9] and the references therein. Figure 1 shows a quantization of the bivariate normal distribution of size $N = 500$.

Some Quantization-based Cubature Formulae

Let X be an $\mathbb{R}^d$ -valued random vector and Y an $\mathbb{R}^q$ -valued random vector; let $\Gamma_X = \{x_1, \dots, x_{N_X}\}$, $\Gamma_Y = \{y_1, \dots, y_{N_Y}\}$ be two quantizers of X and Y , respectively. Let $F : \mathbb{R}^d \rightarrow \mathbb{R}$ be a (continuous) function. It seems natural to approximate these quantities by their quantized version, that is,

$$\mathbb{E}(F(X)) \approx \mathbb{E}(F(\widehat{X}^{\Gamma_X})) \quad \text{and} \\ \mathbb{E}(F(X)|Y) \approx \mathbb{E}(F(\widehat{X}^{\Gamma_X})|\widehat{Y}^{\Gamma_Y})$$

$$\text{where } \mathbb{E}(F(\widehat{X}^{\Gamma_X})) = \sum_{1 \leq i \leq N_X} F(x_i) \mathbb{P}(\widehat{X}^{\Gamma_X} = x_i) \quad (5)$$

$$\mathbb{E}(F(\widehat{X}^{\Gamma_X})|\widehat{Y}^{\Gamma_Y}) \\ = \sum_{1 \leq i \leq N_X} F(x_i) \mathbb{P}(\widehat{X}^{\Gamma_X} = x_i | \widehat{Y}^{\Gamma_Y} = y_j), \\ 1 \leq j \leq N_Y \quad (6)$$

Numerical computation of $\mathbb{E}(F(\widehat{X}^{\Gamma_X}))$ and $\mathbb{E}(F(\widehat{X}^{\Gamma_X})|\widehat{Y}^{\Gamma_Y})$ is possible as soon as $F(\xi)$ is computable at any $\xi \in \mathbb{R}^d$ and both the distribution $(\mathbb{P}(\widehat{X}^{\Gamma_X} = x_i))_{1 \leq i \leq N_X}$ of $\widehat{X}^{\Gamma_X}$ and the conditional distribution of $\widehat{X}^{\Gamma_X}$ given $\widehat{Y}^{\Gamma_Y}$ are made explicit.

Likewise, one can consider *a priori* the $\sigma(\widehat{X}^{\Gamma_X})$ -measurable random variable $F(\widehat{X}^{\Gamma_X})$ as a good approximation of the conditional expectation $\mathbb{E}(F(X)|\widehat{X}^{\Gamma_X})$. One shows (see, e.g., [25]) that

$$\|X - \widehat{X}^{\Gamma_X}\|_1 = \sup_{[F]_{\text{Lip}} \leq 1} |\mathbb{E}F(X) - \mathbb{E}F(\widehat{X}^{\Gamma_X})| \quad (7)$$

where $[F]_{\text{Lip}}$ denotes the Lipschitz coefficient of F . If, furthermore, $\varphi_F : \mathbb{R}^q \rightarrow \mathbb{R}$, which is a (Borel) version of the conditional expectation, that is, satisfying $\mathbb{E}(F(X)|Y) = \varphi_F(Y)$ turns out to be Lipschitz, then

$$\|\mathbb{E}(F(X)|Y) - \mathbb{E}(F(\widehat{X}^{\Gamma_X})|\widehat{Y}^{\Gamma_Y})\|_2 \\ \leq [F]_{\text{Lip}} \|X - \widehat{X}^{\Gamma_X}\|_2 + [\varphi_F]_{\text{Lip}} \|Y - \widehat{Y}^{\Gamma_Y}\|_2 \quad (8)$$

When F is twice differentiable with a Lipschitz differential and Γ_X is a stationary quantizer, then

$$|\mathbb{E}F(X) - \mathbb{E}F(\widehat{X}^{\Gamma_X})| \leq [DF]_{\text{Lip}} \|X - \widehat{X}^{\Gamma_X}\|_2^2 \quad (9)$$

Similar cubature formulas can be established for locally Lipschitz functions such that $|F(x) - F(y)| \leq C|x - y|(1 + g(x) + g(y))$ where g is a nonnegative, nondecreasing, convex function (e.g., $g(x) = e^{|a||x|}$). Finally, when F is convex and $\widehat{X}^{\Gamma_X}$ is stationary, Jensen's inequality yields

$$\mathbb{E}(F(X)|\widehat{X}^{\Gamma_X}) \geq F(\mathbb{E}(X|\widehat{X}^{\Gamma_X})) \\ = F(\widehat{X}^{\Gamma_X}) \quad (\text{so that } \mathbb{E}(F(\widehat{X}^{\Gamma_X})) \leq \mathbb{E}(F(X))) \quad (10)$$

Example: Pricing a Bermuda Option Using a Quantization Tree

Let $(X_k)_{0 \leq k \leq n}$ be a Markov chain modeling the dynamics of d traded risky assets (interest rate is set to 0 for simplicity), assumed to be homogeneous for the sake of simplicity, with Lipschitz transition $P(x, dy) = \mathcal{L}(X_{k+1}|X_k = x)$, that is, satisfying the condition that for every Lipschitz continuous function f , $[Pf]_{\text{Lip}} \leq [P]_{\text{Lip}}[f]_{\text{Lip}}$. Let $(\widehat{X}_k)_{0 \leq k \leq n}$ be a sequence of quantizations $(\widehat{X}_k := \widehat{X}_k^{\Gamma_k})$ where the grids $\Gamma_k := \{x_1^k, \dots, x_{N_k}^k\} \subset \mathbb{R}^d$ are optimal, see the section How to Get Optimal Quantization below). These grids (and the related quantized transition probability weights defined below) are called a *quantization tree* of the chain.

Let $(h(X_k))_{0 \leq k \leq n}$ be a Bermuda (vanilla) payoff. Then, one can approximate the premium

$$\mathcal{V}_0 = \sup \{ \mathbb{E}(h(X_\tau)), \tau \mathcal{F}^X\text{-stopping time} \} \quad (11)$$

of the option by implementing a backward quantized dynamic programming formula as follows:

$$\begin{aligned} \widehat{\mathcal{V}}_n &= h(\widehat{X}_n), \\ \widehat{\mathcal{V}}_k &= \max(h(\widehat{X}_k), \mathbb{E}(\widehat{\mathcal{V}}_{k+1} | \widehat{X}_k)), \quad k = 0, \dots, n-1 \end{aligned} \quad (12)$$

in which the Markov property is “forced” since $(\widehat{X}_k)_{0 \leq k \leq n}$ has no reason to be a Markov chain. In practice, one shows that $\widehat{\mathcal{V}}_k = v_k(\widehat{X}_k)$ where the functions v_k defined on Γ_k satisfy the following backward induction:

$$v_n(x_i^n) = h(x_i^n), \quad i = 1, \dots, N_n \quad (13)$$

$$v_k(x_i^k) = \max \left(h(x_i^k), \sum_{x_j \in \Gamma_{k+1}} \widehat{p}_k^{ij} v_{k+1}(x_j^{k+1}) \right), \quad i = 1, \dots, N_k \quad (14)$$

$$\text{where } \widehat{p}_k^{ij} = \mathbb{P}(\widehat{X}_{k+1} = x_j^{k+1} | \widehat{X}_k = x_i^k) \quad (15)$$

The point is that once the transitions $\widehat{p}_k^{ij}$ have been computed (e.g., by a—possibly parallelized, see [5]—Monte Carlo simulation), the above backward induction can be applied to any (reasonable) payoff: the quantization-based approach is not payoff dependent as the regression-based simulation methods (*see Bermudan Options*) are. The resulting error bound, combining equation (8) and the Zador Theorem(b) is

$$\begin{aligned} |\mathcal{V}_0 - \mathbb{E}v_0(X_0)| &\leq C_{[P]_{\text{Lip}}, d} \sum_{k=0}^n \|X_k - \widehat{X}_k\|_2 \\ &= O\left(\frac{n}{\bar{N}^{\frac{1}{d}}}\right) \end{aligned} \quad (16)$$

where $\bar{N} := \frac{1}{n+1} \sum_{k=0}^n N_k$. First-order schemes have been devised involving the approximation $\widehat{D}v_k$ of the (space) differential of Dv_k of v_k in [3]. Other quantization-based schemes have been devised for many other problems (stochastic control, nonlinear filtering [20], etc.).

How to Get Optimal Quantization

For this aspect, which is clearly critical for applications, we mainly refer to [17, 21, 25] and the references therein. We just say that the two main procedures are both based on the stationary equation $\widehat{X}^\Gamma = \mathbb{E}(X | \widehat{X}^\Gamma)$. The randomized Lloyd’s I is the induced fixed-point procedure whereas the *competitive learning vector quantization* algorithm is a recursive stochastic gradient zero search procedure. Both are based on the massive simulation of independent and identically distributed (i.i.d.) copies of X and nearest neighbor search. Recent developments in the field of fast versions of such procedures [7, 14] clearly open new perspectives to the online implementation of quantization-based methods. Regarding the Gaussian distribution, a quantization process has been completed and some optimal grids are available on the website [23]: www.quantize.maths-fi.com.

New Directions

Although optimal quantization is an autonomous field of research at the intersection of approximation theory, information theory, and probability theory, which has its own life, it seems that it generates many ideas that can easily and efficiently be applied to numerical probability and computational finance.

One important direction, not developed here, is *functional quantization* where a stochastic process—for example, the Brownian motion, a Lévy process, or a diffusion—is quantized as a random variable taking values in its path space (see [10–12]) or [17] for a survey, and the references therein). This has been applied to the pricing of path-dependent options in [22]. See also the website [23] to download optimal quadratic functional quantizers of the Brownian motion.

Another direction is variance reduction where quantization can be used either as a control variate or a stratification method, with, in both cases, the specificity being an optimal way to proceed among Lipschitz continuous functions/functionals [22, 24, 25].

Monte Carlo Simulation for Stochastic Differential Equations

Weak Convergence Criterion

There exists a well-developed literature on classical Monte Carlo methods. We might mention, among others, Hammersley and Handscomb [3] and Fishman [1]. This literature, however, does not focus on approximating functionals of solutions of *stochastic differential equations* (SDEs). Exploiting the stochastic analytic structure of the underlying SDEs in discrete-time approximations allows to obtain deeper insight and significant benefits in a Monte Carlo simulation. One can construct more efficient methods than usually would be obtained under the classical Monte Carlo approach. Monographs on Monte Carlo methods for SDEs include [6, 7, 10]. The area of Monte Carlo methods in finance is the focus of the well-written books by Jackel [5] and Glasserman [2]. In [12], one can find a brief survey of such methods. In many circumstances, when other numerical methods fail or are difficult to implement, Monte Carlo methods can still provide a reasonable answer. This applies, in particular, to problems involving a large number of factors.

First, let us introduce a criterion that provides a classification of different simulation schemes. In Monte Carlo simulation, one concentrates on the approximation of probabilities and expectations of payoffs. Consider the process $X = \{X_t, t \in [0, T]\}$, which is the solution of the SDE

$$dX_t = a(X_t) dt + b(X_t) dW_t \quad (1)$$

for $t \in [0, T]$ with $X_0 \in \mathfrak{R}$. We shall say that a discrete-time approximation Y^Δ *converges with weak order* $\beta > 0$ to X at time T as $\Delta \rightarrow 0$ if for each polynomial $g : \mathfrak{R} \rightarrow \mathfrak{R}$ there exists a constant C_g , which does not depend on Δ , and a $\Delta_0 \in [0, 1]$ such that

$$\mu(\Delta) = |E(g(X_T)) - E(g(Y_T^\Delta))| \leq C_g \Delta^\beta \quad (2)$$

for each $\Delta \in (0, \Delta_0)$. We call this also the *weak convergence criterion*.

Systematic and Statistical Error

Under the weak convergence criterion (2) functionals of the form

$$u = E(g(X_T)) \quad (3)$$

are approximated *via weak approximations* Y^Δ of the solution of the SDE (1). One can form a *raw Monte Carlo estimate* by using the sample average

$$u_{N,\Delta} = \frac{1}{N} \sum_{k=1}^N g(Y_T^\Delta(\omega_k)) \quad (4)$$

with N independent simulated realizations $Y_T^\Delta(\omega_1), Y_T^\Delta(\omega_2), \dots, Y_T^\Delta(\omega_N)$ of a discrete-time weak approximation Y_T^Δ at time T , where $\omega_k \in \Omega$ for $k \in \{1, 2, \dots, N\}$. The corresponding *weak error* $\hat{\mu}_{N,\Delta}$ has the form

$$\hat{\mu}_{N,\Delta} = u_{N,\Delta} - E(g(X_T)) \quad (5)$$

which we decompose into a *systematic error* μ_{sys} and a *statistical error* μ_{stat} , such that

$$\hat{\mu}_{N,\Delta} = \mu_{\text{sys}} + \mu_{\text{stat}} \quad (6)$$

Here, we set

$$\begin{aligned} \mu_{\text{sys}} &= E(\hat{\mu}_{N,\Delta}) \\ &= E\left(\frac{1}{N} \sum_{k=1}^N g(Y_T^\Delta(\omega_k))\right) - E(g(X_T)) \\ &= E(g(Y_T^\Delta)) - E(g(X_T)) \end{aligned} \quad (7)$$

Thus, we have

$$\mu(\Delta) = |\mu_{\text{sys}}| \quad (8)$$

The absolute systematic error $|\mu_{\text{sys}}|$ can be interpreted as the absolute weak error and is a critical variable under the weak convergence criterion (2).

For a large number N of simulated independent realizations of Y^Δ , we can conclude from the central limit theorem that the statistical error μ_{stat} becomes asymptotically Gaussian with mean 0 and variance of the form

$$\text{Var}(\mu_{\text{stat}}) = \text{Var}(\hat{\mu}_{N,\Delta}) = \frac{1}{N} \text{Var}(g(Y_T^\Delta)) \quad (9)$$

Note that in equation (9) we used the independence of the realization for each ω_k . The expression (9) reveals a major disadvantage of the raw Monte Carlo method. One notes that the variance of the statistical error μ_{stat} decreases only with $1/N$. Consequently, the deviation

$$\text{Dev}(\mu_{\text{stat}}) = \sqrt{\text{Var}(\mu_{\text{stat}})} = \frac{1}{\sqrt{N}} \sqrt{\text{Var}(g(Y_T^\Delta))} \quad (10)$$

of the statistical error decreases at only the slow rate $1/\sqrt{N}$ as $N \rightarrow \infty$. This means that, unless one has to estimate the expectation of a random variable $g(Y_T^\Delta)$ with a small variance, one may need an extremely large number N of sample paths to achieve a reasonably small confidence interval. However, there exist various *variance reduction techniques* (see **Variance Reduction**), that deal with this problem.

We shall discuss now discrete-time approximations of solutions of SDEs that are appropriate for the Monte Carlo simulation of derivative prices or other functionals of diffusion processes. This means that we study the weak order of convergence of discrete-time approximations. By truncating appropriately the Wagner–Platen expansion (see **Stochastic Taylor Expansions**) one obtains *weak Taylor schemes*. The desired order of weak convergence determines the kind of truncation that must be used [6]. However, the truncations will be different from those required for the strong convergence of a comparable order, as described in **Stochastic Differential Equations: Scenario Simulation**. In general, weak Taylor schemes involve fewer terms compared with the strong Taylor schemes of the same order.

Euler and Simplified Weak Euler Scheme

The simplest weak Taylor scheme is the Euler scheme (see also **Stochastic Taylor Expansions**), which has the form

$$Y_{n+1} = Y_n + a \Delta + b \Delta W_n \quad (11)$$

with $\Delta W_n = W_{\tau_{n+1}} - W_{\tau_n}$ and initial value $Y_0 = X_0$, where $\tau_n = n\Delta$, $\Delta > 0$. Here and in the following, we suppress in our notation of coefficient functions, as a and b , the dependence on τ_n and Y_n .

The Euler scheme (11) corresponds to the truncated Wagner–Platen expansion that contains only the time integral and the single Itô integral with respect to the Wiener process. The Euler scheme has order of weak convergence $\beta = 1.0$ if the drift and diffusion coefficient are sufficiently smooth and regular.

For weak convergence, we only need to approximate the probability measure induced by the process X . Here, we can replace the Gaussian increments ΔW_n in (11) by other simpler random variables $\Delta \hat{W}_n$ with similar moment properties as ΔW_n . We can thus obtain a simpler scheme by choosing more easily generated random variables. This leads to the *simplified weak Euler scheme*

$$Y_{n+1} = Y_n + a \Delta + b \Delta \hat{W}_n \quad (12)$$

where the $\Delta \hat{W}_n$ are independent random variables with moments satisfying the moment-matching condition

$$\begin{aligned} & \left| E(\Delta \hat{W}_n) \right| + \left| E\left((\Delta \hat{W}_n)^3 \right) \right| \\ & + \left| E\left((\Delta \hat{W}_n)^2 \right) - \Delta \right| \leq K \Delta^2 \end{aligned} \quad (13)$$

for some constant K . The simplest example of such a simplified random variable $\Delta \hat{W}_n$ to be used in equation (12) is a two-point distributed random variable with

$$P(\Delta \hat{W}_n = \pm \sqrt{\Delta}) = 1/2 \quad (14)$$

When the drift and diffusion coefficients are only Hölder continuous, then it has been shown in [8] that the Euler scheme still converges weakly, but with some weak order $\beta < 1.0$.

Weak Order 2.0 Taylor Scheme

Now, let us consider the Taylor scheme of weak order $\beta = 2.0$. This scheme is obtained by adding all of the double stochastic integrals from the Wagner–Platen expansion to the terms of the Euler scheme, as shown in **Stochastic Taylor Expansions**. This scheme was

first proposed in [9]. The *weak order 2.0 Taylor scheme* has the form

$$\begin{aligned} Y_{n+1} = & Y_n + a \Delta + b \Delta W_n + \frac{1}{2} b b' \{(\Delta W_n)^2 - \Delta\} \\ & + a' b \Delta Z_n + \frac{1}{2} \left(a a' + \frac{1}{2} a'' b^2 \right) \Delta^2 \\ & + \left(a b' + \frac{1}{2} b'' b^2 \right) \{ \Delta W_n \Delta - \Delta Z_n \} \end{aligned} \quad (15)$$

The random variable $\Delta Z_n = \int_{\tau_n}^{\tau_{n+1}} \int_{\tau_n}^{s_2} dW_{s_1} ds_2$ represents a stochastic double integral. One can easily generate the pair of correlated Gaussian random variables ΔW_n and ΔZ_n from independent Gaussian random variables.

Under the weak convergence criterion, one has more freedom than under the strong convergence criterion (see **Stochastic Differential Equations: Scenario Simulation**) in constructing the random variables in a discrete-time weak approximation. For instance, from the above scheme, one can derive the *simplified weak order 2.0 Taylor scheme*

$$\begin{aligned} Y_{n+1} = & Y_n + a \Delta + b \Delta \hat{W}_n \\ & + 1/2 b b' \left\{ (\Delta \hat{W}_n)^2 - \Delta \right\} \\ & + 1/2 (a' b + a b' + 1/2 b'' b^2) \Delta \hat{W}_n \Delta \\ & + 1/2 (a a' + 1/2 a'' b^2) \Delta^2 \end{aligned} \quad (16)$$

Here the simplified random variable $\Delta \hat{W}_n$ must satisfy the moment-matching condition

$$\begin{aligned} & \left| E(\Delta \hat{W}_n) \right| + \left| E\left((\Delta \hat{W}_n)^3 \right) \right| \\ & + \left| E\left((\Delta \hat{W}_n)^5 \right) \right| + \left| E\left((\Delta \hat{W}_n)^2 \right) - \Delta \right| \\ & + \left| E\left((\Delta \hat{W}_n)^4 \right) - 3\Delta^2 \right| \leq K \Delta^3 \end{aligned} \quad (17)$$

for some constant K . For instance, an $N(0, \Delta)$ Gaussian distributed random variable satisfies the

condition (17). So also does a three-point distributed random variable $\Delta \hat{W}_n$ with

$$\begin{aligned} P(\Delta \hat{W}_n = \pm \sqrt{3\Delta}) &= \frac{1}{6} \quad \text{and} \\ P(\Delta \hat{W}_n = 0) &= \frac{2}{3} \end{aligned} \quad (18)$$

Under appropriate conditions on the drift and diffusion coefficients, the scheme converges with weak order 2.0 [6].

Weak Order 3.0 Taylor Scheme

As shown in [6], Taylor schemes of weak order $\beta = 3.0$ need to include from the Wagner–Platen expansion all of the multiple Itô integrals of up to multiplicity three. The following *simplified weak order 3.0 Taylor scheme* can be obtained

$$\begin{aligned} Y_{n+1} = & Y_n + a \Delta + b \Delta \tilde{W}_n + \frac{1}{2} L^1 b \left\{ (\Delta \tilde{W}_n)^2 - \Delta \right\} \\ & + L^1 a \Delta \tilde{Z}_n + \frac{1}{2} L^0 a \Delta^2 + L^0 b \\ & \times \left\{ \Delta \tilde{W}_n \Delta - \Delta \tilde{Z}_n \right\} \\ & + \frac{1}{6} (L^0 L^0 b + L^0 L^1 a + L^1 L^0 a) \Delta \tilde{W}_n \Delta^2 \\ & + \frac{1}{6} (L^1 L^1 a + L^1 L^0 b + L^0 L^1 b) \\ & \times \left\{ (\Delta \tilde{W}_n)^2 - \Delta \right\} \Delta \\ & + \frac{1}{6} L^0 L^0 a \Delta^3 + \frac{1}{6} L^1 L^1 b \\ & \times \left\{ (\Delta \tilde{W}_n)^2 - 3\Delta \right\} \Delta \tilde{W}_n \end{aligned} \quad (19)$$

Here $\Delta \tilde{W}_n$ and $\Delta \tilde{Z}_n$ are correlated Gaussian random variables with

$$\Delta \tilde{W}_n \sim N(0, \Delta), \quad \Delta \tilde{Z}_n \sim N(0, 1/3 \Delta^3) \quad (20)$$

and covariance

$$E(\Delta \tilde{W}_n \Delta \tilde{Z}_n) = 1/2 \Delta^2 \quad (21)$$

Furthermore, we use here the operators

$$L^0 = \frac{\partial}{\partial t} + a \frac{\partial}{\partial x} + \frac{1}{2} b^2 \frac{\partial^2}{\partial x^2} \quad (22)$$

and $L^1 = b \frac{\partial}{\partial x}$

Weak Order 4.0 Taylor Scheme

To construct the weak order 4.0 Taylor scheme, we also need to include all of the fourth-order multiple stochastic integrals from the Wagner–Platen expansion.

In the case of particular SDEs, for instance those with additive noise, one obtains highly accurate schemes in this manner. For accurate Monte Carlo simulation, the following *simplified weak order 4.0 Taylor scheme for additive noise* can be used:

$$\begin{aligned} Y_{n+1} = & Y_n + a \Delta + b \Delta \tilde{W}_n + \frac{1}{2} L^0 a \Delta^2 \\ & + L^1 a \Delta \tilde{Z}_n + L^0 b \left\{ \Delta \tilde{W}_n \Delta - \Delta \tilde{Z}_n \right\} \\ & + \frac{1}{3!} \left\{ L^0 L^0 b + L^0 L^1 a \right\} \Delta \tilde{W}_n \Delta^2 \\ & + L^1 L^1 a \left\{ 2 \Delta \tilde{W}_n \Delta \tilde{Z}_n - \frac{5}{6} \left(\Delta \tilde{W}_n \right)^2 \Delta \right. \\ & \quad \left. - \frac{1}{6} \Delta^2 \right\} \\ & + \frac{1}{3!} L^0 L^0 a \Delta^3 + \frac{1}{4!} L^0 L^0 L^0 a \Delta^4 \\ & + \frac{1}{4!} \left\{ L^1 L^0 L^0 a + L^0 L^1 L^0 a \right. \\ & \quad \left. + L^0 L^0 L^1 a + L^0 L^0 L^0 b \right\} \Delta \tilde{W}_n \Delta^3 \\ & + \frac{1}{4!} \left\{ L^1 L^1 L^0 a + L^0 L^1 L^1 a + L^1 L^0 L^1 a \right\} \\ & \times \left\{ \left(\Delta \tilde{W}_n \right)^2 - \Delta \right\} \Delta^2 \\ & + \frac{1}{4!} L^1 L^1 L^1 a \Delta \tilde{W}_n \left\{ \left(\Delta \tilde{W}_n \right)^2 - 3 \Delta \right\} \Delta \end{aligned} \quad (23)$$

Here $\Delta \tilde{W}_n$ and $\Delta \tilde{Z}_n$ are correlated Gaussian random variables with $\Delta \tilde{W}_n \sim N(0, \Delta)$, $\Delta \tilde{Z}_n \sim N(0, \frac{1}{3} \Delta^3)$ and $E(\Delta \tilde{W}_n \Delta \tilde{Z}_n) = \frac{1}{2} \Delta^2$. The weak order of convergence of the above schemes is derived in [6].

Explicit Weak Schemes

Higher order weak Taylor schemes require the evaluation of derivatives of various orders of the drift and diffusion coefficients. We can construct derivative-free discrete-time weak approximations, which avoid the use of such derivatives.

The following *explicit weak order 2.0 scheme* was suggested by Platen

$$\begin{aligned} Y_{n+1} = & Y_n + 1/2 \left(a \left(\tilde{\Upsilon}_n \right) + a \right) \Delta \\ & + 1/4 \left(b \left(\tilde{\Upsilon}_n^+ \right) + b \left(\tilde{\Upsilon}_n^- \right) + 2b \right) \Delta \hat{W}_n \\ & + 1/4 \left(b \left(\tilde{\Upsilon}_n^+ \right) - b \left(\tilde{\Upsilon}_n^- \right) \right) \\ & \times \left\{ \left(\Delta \hat{W}_n \right)^2 - \Delta \right\} \Delta^{1/2} \end{aligned} \quad (24)$$

with supporting values

$$\tilde{\Upsilon}_n = Y_n + a \Delta + b \Delta \hat{W}_n \quad (25)$$

and

$$\tilde{\Upsilon}_n^\pm = Y_n + a \Delta \pm b \sqrt{\Delta} \quad (26)$$

Here $\Delta \hat{W}_n$ is required to satisfy the moment condition (17). This means, $\Delta \hat{W}_n$ can be, for instance, Gaussian or three-point distributed with

$$\begin{aligned} P \left(\Delta \hat{W}_n = \pm \sqrt{3\Delta} \right) &= 1/6 \quad \text{and} \\ P \left(\Delta \hat{W}_n = 0 \right) &= 2/3 \end{aligned} \quad (27)$$

By comparing equation (24) with the corresponding simplified weak Taylor scheme (16), one notes that equation (24) avoids the derivatives that appear in equation (16) by using additional supporting values.

For *additive noise* the second-order weak scheme (24) reduces to the relatively simple algorithm

$$\begin{aligned} Y_{n+1} = & Y_n + 1/2 \left\{ a \left(Y_n + a \Delta + b \Delta \hat{W}_n^j \right) + a \right\} \Delta \\ & + b \Delta \hat{W}_n^j \end{aligned} \quad (28)$$

For the case with additive noise, one finds in [6] the *explicit weak order 3.0 scheme*

$$\begin{aligned}
 Y_{n+1} = & Y_n + a \Delta + b \Delta \hat{W}_n \\
 & + \frac{1}{2} \left(a_{\zeta_n}^+ + a_{\zeta_n}^- - \frac{3}{2} a - \frac{1}{4} (\tilde{a}_{\zeta_n}^+ + \tilde{a}_{\zeta_n}^-) \right) \Delta \\
 & + \sqrt{\frac{2}{\Delta}} \left(\frac{1}{\sqrt{2}} (a_{\zeta_n}^+ - a_{\zeta_n}^-) \right. \\
 & \left. - \frac{1}{4} (\tilde{a}_{\zeta_n}^+ - \tilde{a}_{\zeta_n}^-) \right) \zeta_n \Delta \hat{Z}_n \\
 & + \frac{1}{6} \left[a \left(Y_n + (a + a_{\zeta_n}^+) \Delta + (\zeta_n + \varrho_n) b \sqrt{\Delta} \right) \right. \\
 & \left. - a_{\zeta_n}^+ - a_{\varrho_n}^+ + a \right] \\
 & \times \left[(\zeta_n + \varrho_n) \Delta \hat{W}_n \sqrt{\Delta} + \Delta \right. \\
 & \left. + \zeta_n \varrho_n \left\{ (\Delta \hat{W}_n)^2 - \Delta \right\} \right] \quad (29)
 \end{aligned}$$

with

$$a_{\phi}^{\pm} = a \left(Y_n + a \Delta \pm b \sqrt{\Delta} \phi \right) \quad (30)$$

and

$$\tilde{a}_{\phi}^{\pm} = a \left(Y_n + 2a \Delta \pm b \sqrt{2\Delta} \phi \right) \quad (31)$$

where ϕ is either ζ_n or ϱ_n . Here, one can use two correlated Gaussian random variables $\Delta \hat{W}_n \sim N(0, \Delta)$ and $\Delta \hat{Z}_n \sim N(0, 1/3 \Delta^3)$ with $E(\Delta \hat{W}_n \Delta \hat{Z}_n) = 1/2\Delta^2$, together with two independent two-point distributed random variables ζ_n and ϱ_n with

$$P(\zeta_n = \pm 1) = P(\varrho_n = \pm 1) = 1/2 \quad (32)$$

Extrapolation Methods

Extrapolation provides an efficient, yet simple way of obtaining a higher order weak approximation when using only lower order weak schemes. Only equidistant time discretizations of the time interval $[0, T]$ with $\tau_{n_T} = T$ are used in what follows. As before, we denote the considered discrete-time approximation with time step size $\Delta > 0$ by Y^Δ , with value $Y_{\tau_n}^\Delta = Y_n^\Delta$ at the discretization time τ_n , and the corresponding approximation with twice this step size by $Y^{2\Delta}$, and so on.

Suppose that we have evaluated *via* simulation the functional

$$E(g(Y_T^\Delta))$$

of a weak order 1.0 approximation using, say, the Euler scheme (11) or the simplified Euler scheme (12) with step size Δ . Let us repeat this Monte Carlo simulation with the double step size 2Δ to obtain a Monte Carlo estimate of the functional

$$E(g(Y_T^{2\Delta}))$$

We can then combine these two functionals to obtain the *weak order 2.0 extrapolation*

$$V_{g,2}^\Delta(T) = 2E(g(Y_T^\Delta)) - E(g(Y_T^{2\Delta})) \quad (33)$$

which was proposed in [13]. It is a stochastic generalization of the well-known *Richardson extrapolation*.

As is shown in [6], if a weak method exhibits a certain representation of the leading error term, then a corresponding extrapolation method can be constructed. For instance, one can use a weak order $\beta = 2.0$ approximation Y^Δ and extrapolate it to obtain a fourth-order weak approximation of the targeted functional. A *weak order 4.0 extrapolation* has the form

$$\begin{aligned}
 V_{g,4}^\Delta(T) = & 1/21 \left[32 E(g(Y_T^\Delta)) \right. \\
 & \left. - 12 E(g(Y_T^{2\Delta})) + E(g(Y_T^{4\Delta})) \right] \quad (34)
 \end{aligned}$$

Suitable weak order 2.0 approximations include the weak order 2.0 Taylor scheme (15), the simplified weak order 2.0 Taylor scheme (16), and the explicit weak order 2.0 scheme (24).

The practical use of extrapolations of discrete time approximations depends strongly on the numerical stability of the underlying weak schemes. These weak methods need to have almost identical leading error coefficients for a wide range of step sizes and should yield numerically stable simulation results; see **Stochastic Differential Equations: Scenario Simulation**.

Implicit Methods

In Monte Carlo simulation, the numerical stability of a scheme has highest priority. Introducing some

type of implicitness into a scheme usually improves its numerical stability. The simplest implicit weak schemes can be found in the *family of drift implicit simplified Euler schemes*

$$Y_{n+1} = Y_n + \{(1 - \alpha) a(Y_n) + \alpha a(Y_{n+1})\} \Delta + b(Y_n) \Delta \hat{W}_n \quad (35)$$

where the random variables $\Delta \hat{W}_n$ are independent two-point distributed with

$$P(\Delta \hat{W}_n = \pm \sqrt{\Delta}) = 1/2 \quad (36)$$

The parameter α is the *degree of drift implicitness*. With $\alpha = 0$, the scheme (35) reduces to the simplified Euler scheme (12), whereas with $\alpha = 0.5$ it represents a stochastic generalization of the trapezoidal method. Under sufficient regularity conditions, one can show that the scheme (35) converges with weak order $\beta = 1.0$. The scheme (35) is A -stable for $\alpha \in [0.5, 1]$, whereas for $\alpha \in [0, 0.5]$ its region of A -stability, in the sense of what is discussed in **Stochastic Differential Equations: Scenario Simulation**, is the interior of the interval that begins at $-2(1 - 2\alpha)^{-1}$ and finishes at 0.

The possible use of bounded random variables in weak simplified schemes allows us to construct fully implicit weak schemes that is, algorithms where also the approximate diffusion term becomes implicit.

The *fully implicit weak Euler scheme* has the form

$$Y_{n+1} = Y_n + \bar{a}(Y_{n+1}) \Delta + b(Y_{n+1}) \Delta \hat{W}_n \quad (37)$$

where $\Delta \hat{W}_n$ is as in equation (35) and $\bar{a}$ is some adjusted drift coefficient defined by

$$\bar{a} = a - b b' \quad (38)$$

The drift adjustment is necessary, otherwise the approximation would not converge toward the correct solution of the given Itô SDE.

We also mention a *family of implicit weak Euler schemes*

$$Y_{n+1} = Y_n + \{\alpha \bar{a}_\eta(Y_{n+1}) + (1 - \alpha) \bar{a}_\eta(Y_n)\} \Delta + \{\eta b(Y_{n+1}) + (1 - \eta) b(Y_n)\} \Delta \hat{W}_n \quad (39)$$

where the random variables $\Delta \hat{W}_n$ are as in equation (35) and the corrected drift coefficient $\bar{a}_\eta$ is defined

as

$$\bar{a}_\eta = a - \eta b \frac{\partial b}{\partial x} \quad (40)$$

for $\alpha, \eta \in [0, 1]$.

One can avoid the calculation of derivatives in the above family of implicit schemes by using differences instead. The following *implicit weak order 2.0 scheme* can be found in [11], where

$$Y_{n+1} = Y_n + 1/2 (a + a(Y_{n+1})) \Delta + 1/4 (b(\tilde{Y}_n^+) + b(\tilde{Y}_n^-) + 2b) \Delta \hat{W}_n + 1/4 (b(\tilde{Y}_n^+) - b(\tilde{Y}_n^-)) \times \left\{ (\Delta \hat{W}_n)^2 - \Delta \right\} \Delta^{-1/2} \quad (41)$$

with supporting values

$$\tilde{Y}_n^\pm = Y_n + a \Delta \pm b \sqrt{\Delta} \quad (42)$$

Here, the random variable $\Delta \hat{W}_n$ can be chosen as in (18).

Note that the scheme (39) is A -stable. In [6], it is shown that the above second-order weak scheme converges under appropriate conditions with weak order $\beta = 2.0$.

Weak Predictor–Corrector Methods

In general, implicit schemes require an algebraic equation to be solved at each time step. This imposes an additional computational burden. However, without giving a weak scheme some kind of implicitness the simulation might not turn out to be of much practical use due to inherent numerical instabilities.

Predictor–corrector methods are similar to implicit methods but do not require the solution of an algebraic equation at each time step. They are used mainly because of their good numerical stability properties, which they inherit from the implicit counterparts of their corrector. The following predictor–corrector methods can be found in [11].

One has the following *family of weak order 1.0 predictor–corrector methods* with corrector

$$Y_{n+1} = Y_n + \{\alpha \bar{a}_\eta(\bar{Y}_{n+1}) + (1 - \alpha) \bar{a}_\eta(Y_n)\} \Delta + \{\eta b(\bar{Y}_{n+1}) + (1 - \eta) b(Y_n)\} \Delta \hat{W}_n \quad (43)$$

for $\alpha, \eta \in [0, 1]$, where

$$\bar{a}_\eta = a - \eta b \frac{\partial b}{\partial x} \quad (44)$$

and with predictor

$$\bar{Y}_{n+1} = Y_n + a \Delta + b \Delta \hat{W}_n \quad (45)$$

Here, the random variables $\Delta \hat{W}_n$ are as in (14). Note that the corrector (43) with $\eta > 0$ allows to include some implicitness in the diffusion terms. This scheme often provides efficient and numerically reliable methods for appropriate choices of α and η . By performing the Monte Carlo simulation with different parameter choices for α and η one can obtain useful information about the numerical stability of the scheme for the given application.

A *weak order 2.0 predictor–corrector method* is obtained by choosing as corrector

$$Y_{n+1} = Y_n + 1/2 \{a(\bar{Y}_{n+1}) + a\} \Delta + \Psi_n \quad (46)$$

with

$$\begin{aligned} \Psi_n = & b \Delta \hat{W}_n + 1/2 b b' \left\{ (\Delta \hat{W}_n)^2 - \Delta \right\} \\ & + 1/2 \left(a b' + \frac{1}{2} b^2 b'' \right) \Delta \hat{W}_n \Delta \end{aligned} \quad (47)$$

and as predictor

$$\begin{aligned} \bar{Y}_{n+1} = & Y_n + a \Delta + \Psi_n + 1/2 a' b \Delta \hat{W}_n \Delta \\ & + 1/2 (a a' + 1/2 a'' b^2) \Delta^2 \end{aligned} \quad (48)$$

Here the random variable $\Delta \hat{W}_n$ can be, for instance, $N(0, \Delta)$ Gaussian or three-point distributed as in equation (18).

Another *derivative-free weak order 2.0 predictor–corrector method* has corrector

$$Y_{n+1} = Y_n + 1/2 \{a(\bar{Y}_{n+1}) + a\} \Delta + \phi_n \quad (49)$$

where

$$\begin{aligned} \phi_n = & 1/4 (b(\bar{\Upsilon}_n^+) + b(\bar{\Upsilon}_n^-) + 2b) \Delta \hat{W}_n \\ & + 1/4 (b(\bar{\Upsilon}_n^+) - b(\bar{\Upsilon}_n^-)) \\ & \times \left\{ (\Delta \hat{W}_n)^2 - \Delta \right\} \Delta^{-1/2} \end{aligned} \quad (50)$$

with supporting values

$$\bar{\Upsilon}_n^\pm = Y_n + a \Delta \pm b \sqrt{\Delta} \quad (51)$$

and with predictor

$$\bar{Y}_{n+1} = Y_n + 1/2 \{a(\bar{\Upsilon}_n) + a\} \Delta + \phi_n \quad (52)$$

using the supporting value

$$\bar{\Upsilon}_n = Y_n + a \Delta + b \Delta \hat{W}_n \quad (53)$$

Here the random variable $\Delta \hat{W}_n$ can be chosen as in equation (18).

Predictor–corrector methods of the above kind have been successfully used in the Monte Carlo simulation of various asset price models, see, for instance, [4].

Stochastic Differential Equations: Scenario Simulation

Discrete-time Approximation

We have explicit solutions only in a few cases of *stochastic differential equation* (SDEs), including linear SDEs and their transformations. In finance, it is often helpful, and in some situations essential, to be able to simulate accurate trajectories of solutions of SDEs that model the financial quantities under consideration. These scenarios are typically generated by algorithms that use pseudorandom number generators, as introduced in **Pseudorandom Number Generators**. However, one can use also historical returns, log-returns, or increments from observed asset prices as input in a simulation that is then called a *historical simulation*. In the following, we give a basic introduction into *scenario simulation*. Here, we approximate the path of a solution of a given SDE by the path of a discrete-time approximation, simulated by using random number generators, *see Pseudorandom Number Generators*. For books on scenario simulation of solutions of SDEs we refer to [7, 8]. There exists also an increasing literature on simulation methods in finance. Important monographs that the reader can be referred to include [5, 6].

Consider a given discretization $0 = \tau_0 < \tau_1 < \dots < \tau_n < \dots < \tau_N = T$ of the time interval $[0, T]$. We shall approximate a diffusion process $X = \{X_t, t \in [0, T]\}$ satisfying the one-dimensional SDE

$$dX_t = a(t, X_t) dt + b(t, X_t) dW_t \quad (1)$$

on $t \in [0, T]$ with initial value $X_0 \in \mathbb{R}$.

Let us first introduce one of the simplest discrete-time approximations, the *Euler scheme* or *Euler-Maruyama scheme*, see [9]. An *Euler approximation* is a continuous-time stochastic process $Y^\Delta = \{Y_t^\Delta, t \in [0, T]\}$ satisfying the recursive scheme

$$Y_{n+1} = Y_n + a(\tau_n, Y_n) (\tau_{n+1} - \tau_n) + b(\tau_n, Y_n) (W_{\tau_{n+1}} - W_{\tau_n}) \quad (2)$$

for $n \in \{0, 1, \dots\}$ with initial value

$$Y_0 = Y_0^\Delta = X_0 \quad (3)$$

For convenience, we write

$$Y_n = Y_{\tau_n}^\Delta \quad (4)$$

for the value of the approximation at the discretization time τ_n . We write

$$\Delta_n = \tau_{n+1} - \tau_n \quad (5)$$

for the n th increment of the time discretization and call

$$\Delta = \max_{n \in \{0, 1, \dots, N-1\}} \Delta_n \quad (6)$$

the *maximum step size*. We consider here, for simplicity, *equidistant time discretizations* with

$$\tau_n = n \Delta \quad (7)$$

for $\Delta_n = \Delta = T/N$ and some integer N large enough so that $\Delta \in (0, 1)$.

The sequence $(Y_n)_{n \in \{0, 1, \dots, N\}}$ of values of the Euler approximation (2) at the instants of the time discretization $\tau_0, \tau_1, \dots, \tau_N$ can be recursively computed. For this purpose, we need to generate the random increments

$$\Delta W_n = W_{\tau_{n+1}} - W_{\tau_n} \quad (8)$$

for $n \in \{0, 1, \dots, N-1\}$ of the Wiener process $W = \{W_t, t \in [0, T]\}$. These increments represent independent Gaussian distributed random variables with mean

$$E(\Delta W_n) = 0 \quad (9)$$

and variance

$$E((\Delta W_n)^2) = \Delta \quad (10)$$

For the increments (8) of the Wiener process we can use a sequence of independent Gaussian pseudorandom numbers. These can be generated, for instance, as suggested in **Pseudorandom Number Generators**.

For describing a numerical scheme efficiently, we typically use the abbreviation

$$f = f(\tau_n, Y_n) \quad (11)$$

for a function f defined on $[0, T] \times \mathbb{R}^d$ and $n \in \{0, 1, \dots, N-1\}$, when no misunderstanding is possible. We can then rewrite the Euler scheme (2) in the form

$$Y_{n+1} = Y_n + a \Delta + b \Delta W_n \quad (12)$$

for $n \in \{0, 1, \dots, N-1\}$. Usually, we suppress the mentioning of the initial condition, where we typically set

$$Y_0 = X_0 \quad (13)$$

The recursive structure of the Euler scheme, which generates approximate values of the diffusion process X at the discretization times only, is the key to its implementation.

Interpolation

We emphasize that we shall consider a discrete-time approximation to be a stochastic process defined on the interval $[0, T]$. Although it will be often sufficient to generate its values at the discretization times, if required, values at the intermediate instants can be determined by an appropriate interpolation method. The simplest one is the *piecewise constant interpolation* with

$$Y_t^\Delta = Y_{n_t} \quad (14)$$

for $t \in [0, T]$. Here n_t is the integer defined by

$$n_t = \max\{n \in \{0, 1, \dots, N : \tau_n \leq t\}\} \quad (15)$$

which is the largest integer n for which τ_n does not exceed t .

Furthermore, the *linear interpolation*

$$Y_t^\Delta = Y_{n_t} + \frac{t - \tau_{n_t}}{\tau_{n_t+1} - \tau_{n_t}} (Y_{n_t+1} - Y_{n_t}) \quad (16)$$

for $t \in [0, T]$ is often used in the visualization of trajectories because it provides continuous sample paths in a convenient and realistic manner.

In general, the sample paths of a diffusion process inherit some properties of the trajectory of its driving Wiener process, in particular, its nondifferentiability. It is impossible to fully reproduce on a digital computer the microstructure of such path in a scenario simulation. Thus, we shall concentrate on simulating values of a discrete-time approximation at given discretization times and interpolate these appropriately if needed.

Simulating Geometric Brownian Motion

To illustrate various aspects of a *scenario simulation via* a discrete-time approximation of a diffusion process, it is useful to examine, in some detail, a simple

but important example with an explicit solution. In finance, one often faces growth processes. These are under the standard market model usually interpreted as geometric Brownian motions. Let us consider the geometric Brownian motion $X = \{X_t, t \in [0, T]\}$ satisfying the linear SDE

$$dX_t = a X_t dt + b X_t dW_t \quad (17)$$

for $t \in [0, T]$ with initial value $X_0 > 0$. This model is also known as the *Black–Scholes model*. The geometric Brownian motion X is a diffusion process with *drift coefficient*

$$a(t, x) = a x \quad (18)$$

and *diffusion coefficient*

$$b(t, x) = b x \quad (19)$$

Here a denotes the *appreciation rate* and $b \neq 0$ the *volatility*. It is well known that the SDE (17) has the explicit solution

$$X_t = X_0 \exp\{(a - 1/2 b^2)t + b W_t\} \quad (20)$$

for $t \in [0, T]$ and given Wiener process $W = \{W_t, t \in [0, T]\}$. The availability of an explicit solution makes the simulation an easy task because the solution of the SDE (17) is simply the exponential function (20) of the corresponding Wiener process value.

Simulation of Approximate Trajectories

Knowing the solution (20) of the SDE (17) explicitly gives us the possibility of comparing the Euler approximation Y , see equation (12), with the exact solution X . Of course, in general, this is not possible.

To simulate a trajectory of the Euler approximation for a given time discretization, we start from the initial value $Y_0 = X_0$, and proceed recursively by generating the next value

$$Y_{n+1} = Y_n + a Y_n \Delta + b Y_n \Delta W_n \quad (21)$$

for $n \in \{0, 1, \dots, N-1\}$ according to the Euler scheme (12) with drift coefficient (18) and diffusion coefficient (19). Here

$$\Delta W_n = W_{\tau_{n+1}} - W_{\tau_n} \quad (22)$$

see equation (8), is the $N(0, \Delta)$ Gaussian distributed increment of the Wiener process W over the interval $[\tau_n, \tau_n + \Delta]$, which we generate by a pseudorandom number generator, *see Pseudorandom Number Generators*.

For comparison, we can use the equation (20) for the given Black–Scholes dynamics to determine the corresponding exact values of the solution. This uses the same sample path of the Wiener process in equation (20), as employed by the Euler scheme (21), where one obtains as explicit solution at time τ_n the value

$$X_{\tau_n} = X_0 \exp \left\{ (a - 1/2 b^2) \tau_n + b \sum_{i=1}^n \Delta W_{i-1} \right\} \quad (23)$$

for $n \in \{0, 1, \dots, N-1\}$.

One needs always to be careful when using a discrete-time approximation such as the Euler scheme (21). This is clearly a different object than the exact solution of the underlying SDE. For instance, inconsistencies may arise because the increments in the noise part of the Euler scheme can take extremely large values of either sign. Even though this can occur only with small probability, large negative stochastic increments can, for instance, make the Euler approximation (21) negative. This would be not consistent with our aim of simulating positive asset prices via the Black–Scholes model. The possibility of generating negative asset prices is quite a serious defect in the Euler method when directly applied for the Black–Scholes dynamics. For extremely small step sizes, this phenomenon becomes highly unlikely; however, it is not excluded unless one designs the simulation in a way that guarantees positivity. For the above Black–Scholes dynamics, this can be achieved by simulating first the logarithm of the geometric Brownian motion by using a corresponding Euler scheme and deriving then the approximate value of X as the exponential of the approximated logarithm. In the case of constant volatility and appreciation rate, this even yields the exact solution of the SDE at the discretization points.

Order of Strong Convergence

So far we have not specified a criterion for the classification of the overall accuracy of a discrete-time

approximation with respect to vanishing time step size. Such a criterion should reflect the main goal of a scenario simulation, which applies in situations where a *pathwise approximation* is required. For instance, scenario simulation is needed for the visualization of typical trajectories of financial models, the testing of calibration methods and statistical estimators, and also in filtering hidden variables. Monte Carlo simulation is discussed in **Monte Carlo Simulation for Stochastic Differential Equations**, which is different since it focuses on *approximating probabilities* and functionals of the underlying processes.

One can estimate the error of an approximation using the following *absolute error criterion*. For a given step size Δ , it is defined as the expectation of the absolute difference between the discrete-time approximation $Y_N = Y_T^\Delta$ and the solution X_T of the SDE at the time horizon $T = N\Delta$, that is,

$$\varepsilon(\Delta) = E(|X_T - Y_T^\Delta|) \quad (24)$$

This gives some measure for the pathwise closeness at the end of the time interval $[0, T]$ as a function of the maximum step size Δ of the time discretization.

Although the Euler approximation is one of the simplest discrete-time approximations, it is, generally, not very efficient numerically. In the following we shall, therefore, derive and investigate also other discrete-time approximations.

To classify different discrete-time approximations, we introduce their *order of strong convergence*. We shall say that a discrete-time approximation Y^Δ *converges strongly with order $\gamma > 0$* at time T if there exists a positive constant C , which does not depend on Δ , and a $\delta_0 > 0$ such that

$$\varepsilon(\Delta) = E(|X_T - Y_T^\Delta|) \leq C \Delta^\gamma \quad (25)$$

for each $\Delta \in (0, \delta_0)$. We call equation (25) the strong convergence criterion.

We emphasize that this criterion has been constructed for the classification of, so called, *strong approximations*. There exist in the literature results, see for instance, [7], which provide uniform error estimates and involve also higher moments than used by the criterion (25). For instance, the supremum of the squared difference between X_t and Y_t^Δ for $t \in [0, T]$ has been estimated. The criterion (25) for the order of strong convergence appears

to be natural and sufficient for the classification of schemes.

Euler Scheme

Let us now use Wagner–Platen expansions (*see Stochastic Taylor Expansions*), to derive discrete-time approximations with respect to the criterion (25). By appropriate truncation of the expansions in each discretization step, we obtain corresponding strong Taylor schemes of given strong order of convergence. For details, we refer to [7]. Recall that we usually suppress the dependence on τ_n and Y_n in the coefficients.

Let us begin with the already mentioned *Euler scheme* (21), which represents the simplest useful strong Taylor approximation. The *Euler scheme* has the form

$$Y_{n+1} = Y_n + a \Delta + b \Delta W_n \quad (26)$$

where $\Delta = \tau_{n+1} - \tau_n$ is the length of the time discretization subinterval $[\tau_n, \tau_{n+1}]$ and $\Delta W_n = W_{\tau_{n+1}} - W_{\tau_n}$ is an $N(0, \Delta)$ independent Gaussian distributed increment of the Wiener process W on $[\tau_n, \tau_{n+1}]$.

The Euler scheme corresponds to a truncated Wagner–Platen expansion that contains only single time and Wiener integrals. Assuming Lipschitz and linear growth conditions on the coefficient functions a and b , it can be shown that the Euler approximation is of strong order $\gamma = 0.5$.

Note that in special cases, this means for specific SDEs, the Euler scheme may achieve a higher order of strong convergence. For example, if the noise is *additive*, that is when the diffusion coefficient is a differentiable, deterministic function of time of the form

$$b(t, x) = b_t \quad (27)$$

then the Euler scheme achieves the order of strong convergence $\gamma = 1.0$.

The Euler scheme gives reasonable numerical results when the drift and diffusion coefficients are almost constant and the time step size is chosen to be sufficiently small. In general, however, it is not very satisfactory. The use of higher order and numerically stable schemes is recommended, which we discuss later.

Milstein Scheme

We now introduce an important scheme, the *Milstein scheme*, which was first suggested in [10] and turns out to be of strong order $\gamma = 1.0$. It is obtained by using one additional term from the Wagner–Platen expansions, *see Stochastic Taylor Expansions*.

The Milstein scheme has the form

$$Y_{n+1} = Y_n + a \Delta + b \Delta W_n + b b' 1/2 \times \{(\Delta W_n)^2 - \Delta\} \quad (28)$$

We remark that for more general SDEs, involving several driving Wiener processes, multiple stochastic integrals

$$I_{(j_1, j_2)} = \int_{\tau_n}^{\tau_{n+1}} \int_{\tau_n}^{s_1} dW_{s_2}^{j_1} dW_{s_1}^{j_2} \quad (29)$$

with $j_1 \neq j_2$ appear in the general version of the Milstein scheme. They cannot be simply expressed in terms of the increments $\Delta W_n^{j_1}$ and $\Delta W_n^{j_2}$ of the corresponding Wiener processes. Still, approximations are possible [4, 8]. However, in the special case $j_1 = j_2$ we have

$$I_{(j_1, j_1)} = 1/2 \{(\Delta W_n^{j_1})^2 - \Delta\} \quad (30)$$

which makes this double Wiener integral easy to generate.

For the Black–Scholes model and some other important dynamics in financial modeling, the corresponding SDEs have special properties which simplify the Milstein scheme. This avoids, in some cases, the use of double Wiener integrals of the type (29) involving two different Wiener processes. For instance, in the case of an SDE with *additive noise*, that is, when the diffusion coefficients depend at most on time t and not on the state variable, the Milstein scheme (28) reduces to the Euler scheme (26). Another important special case is that of *commutative noise*, *see* [7]. For commutative noise, the coefficient functions of the double Wiener integrals $I_{(j_1, j_2)}$ and $I_{(j_2, j_1)}$ are the same and one can exploit the fact that $I_{(j_1, j_2)} + I_{(j_2, j_1)} = \Delta W_n^{j_1} \Delta W_n^{j_2}$.

Order 1.5 Strong Taylor Scheme

There exist simulation tasks that require more accurate schemes than the Milstein scheme. For

instance, if one wants to capture extreme asset price movements or simply needs to be more accurate in a scenario simulation, then one may use higher order strong schemes. In general, we obtain more accurate strong Taylor schemes by including into the scheme further multiple stochastic integrals from the Wagner–Platen expansion (see **Stochastic Taylor Expansions**). Each of these multiple stochastic integrals contains additional information about the sample path of the driving Wiener process. The necessity of the inclusion of further multiple stochastic integrals for achieving higher orders of convergence is a fundamental feature of stochastic numerical methods solving SDEs.

The *order 1.5 strong Taylor scheme* is of the form

$$\begin{aligned} Y_{n+1} = & Y_n + a \Delta + b \Delta W_n \\ & + b b' 1/2 \{(\Delta W_n)^2 - \Delta\} + a' b \Delta Z_n \\ & + 1/2 \left(a a' + \frac{1}{2} b^2 a'' \right) \Delta^2 \\ & + (a b' + 1/2 b^2 b'') \{ \Delta W_n \Delta - \Delta Z_n \} \\ & + b (b b'' + (b')^2) 1/2 \\ & \times \left\{ \frac{1}{3} (\Delta W_n)^2 - \Delta \right\} \Delta W_n \end{aligned} \quad (31)$$

Here the additional random variable ΔZ_n is required, which represents the double integral

$$\Delta Z_n = I_{(1,0)} = \int_{\tau_n}^{\tau_{n+1}} \int_{\tau_n}^{s_2} dW_{s_1} ds_2 \quad (32)$$

One can show that ΔZ_n is Gaussian distributed with mean $E(\Delta Z_n) = 0$, variance $E((\Delta Z_n)^2) = \frac{1}{3} \Delta^3$, and covariance $E(\Delta Z_n \Delta W_n) = 1/2 \Delta^2$. Note that a pair of appropriately correlated Gaussian distributed random variables $(\Delta W_n, \Delta Z_n)$ can be easily constructed by linear combination of two independent $N(0, 1)$ standard Gaussian distributed random variables. All multiple stochastic integrals that appear in equation (31) can be expressed in terms of Δ , ΔW_n , and ΔZ_n . In particular, the last term in equation (31) contains the triple Wiener integral

$$I_{(1,1,1)} = 1/2 \{ 1/3 (\Delta W_n^1)^2 - \Delta \} \Delta W_n^1 \quad (33)$$

which reflects the third-order Hermite polynomial in ΔW_n^1 . The Taylor schemes of any desired strong order are described in [7].

An Explicit Order 1.0 Strong Scheme

Let us now consider strong schemes that avoid the use of derivatives similar to Runge–Kutta schemes for ordinary differential equations. Even though the resulting schemes look similar to Runge–Kutta methods, they cannot be simply constructed as heuristic adaptations of deterministic Runge–Kutta schemes. Appropriate *strong derivative-free schemes* have been systematically designed in [1, 2, 7].

Various first-order derivative-free schemes can be obtained from the Milstein scheme (28) simply by replacing the derivatives in the Milstein scheme by corresponding differences. The inclusion of these differences requires the computation of supporting values of the coefficients at additional supporting points. An example is given by the following scheme, called the *order 1.0 Platen scheme*, see [7], which is of the form

$$\begin{aligned} Y_{n+1} = & Y_n + a \Delta + b \Delta W_n + \frac{1}{2\sqrt{\Delta}} \\ & \times \{b(\tau_n, \tilde{\gamma}_n) - b\} \{(\Delta W_n)^2 - \Delta\} \end{aligned} \quad (34)$$

and uses the supporting value

$$\tilde{\gamma}_n = Y_n + a \Delta + b \sqrt{\Delta} \quad (35)$$

Multidimensional versions of this and most other schemes exist also for the case of several driving Wiener processes.

An Explicit Order 1.5 Strong Scheme

One can construct also derivative-free schemes of strong order $\gamma = 1.5$ by replacing the derivatives in the order 1.5 strong Taylor scheme by corresponding finite differences. The following *explicit order 1.5 strong scheme*, also called *order 1.5 Platen scheme*, has the form

$$\begin{aligned} Y_{n+1} = & Y_n + b \Delta W_n + \frac{1}{2\sqrt{\Delta}} \\ & \times \{a(\tilde{\gamma}_+) - a(\tilde{\gamma}_-)\} \Delta Z_n \\ & + \frac{1}{4} \{a(\tilde{\gamma}_+) + 2a + a(\tilde{\gamma}_-)\} \Delta \\ & + \frac{1}{4\sqrt{\Delta}} \{b(\tilde{\gamma}_+) - b(\tilde{\gamma}_-)\} \{(\Delta W_n)^2 - \Delta\} \end{aligned}$$

$$\begin{aligned}
& + \frac{1}{2\Delta} \{b(\bar{\Upsilon}_+) - 2b + b(\bar{\Upsilon}_-)\} \\
& \times \{\Delta W_n \Delta - \Delta Z_n\} \\
& + \frac{1}{4\Delta} \left[b(\bar{\Phi}_+) - b(\bar{\Phi}_-) - b(\bar{\Upsilon}_+) + b(\bar{\Upsilon}_-) \right] \\
& \times \left\{ \frac{1}{3} (\Delta W_n)^2 - \Delta \right\} \Delta W_n
\end{aligned} \tag{36}$$

with

$$\bar{\Upsilon}_{\pm} = Y_n + a \Delta \pm b \sqrt{\Delta} \tag{37}$$

and

$$\bar{\Phi}_{\pm} = \bar{\Upsilon}_{\pm} \pm b(\bar{\Upsilon}_{\pm}) \sqrt{\Delta} \tag{38}$$

Here ΔZ_n is the double integral $I_{(1,0)}$ defined in equation (32). Further higher order explicit schemes with corresponding strong order of convergence can be found in [7].

Numerical Stability

Numerical stability is very important in simulation. It can be understood as the ability of a scheme to control the propagation of errors. Such errors naturally occur in almost any simulation on a computer due to its limited precision and as a result of truncation errors in the above schemes. However, numerical methods differ in their ability to dampen the arising errors. What really matters for a scheme is that it must be numerically stable when generating sufficiently accurate results over longer time periods. Before any properties of higher order convergence can be reasonably exploited, the question of numerical stability has to be satisfactorily answered. In particular, for solutions of SDEs with multiplicative noise, which are martingales, simulation studies have shown [11] that, with the above-described explicit schemes, numerical instabilities can easily occur.

The propagation of errors depends significantly on the specific nature of the diffusion coefficient of the SDE. For general SDEs and a given scheme, it is a delicate matter to provide reasonably useful answers with respect to their numerical stability. However, it is very helpful to study representative classes of test equations. Each particular type of SDEs usually has its own numerical challenges. Test SDEs can reveal typical numerical instabilities and allow the design of appropriate schemes. For SDEs with additive noise,

that is, SDEs with deterministic diffusion coefficients, the following concept of *A-stability* can be applied. We use here a real-valued test SDE with additive noise of the form

$$dX_t = \lambda X_t dt + dW_t \tag{39}$$

for $\lambda \in \mathbb{R}$. Obviously, X_t forms an Ornstein–Uhlenbeck process, which has a stationary density for $\lambda < 0$. A discrete-time approximation Y , when applied to the test equation (39), typically yields a recursive relation of the form

$$Y_{n+1} = G^A(\lambda \Delta) Y_n + Z_n \tag{40}$$

Here, the random term Z_n is assumed not to depend on $Y_0, Y_1, \dots, Y_n, Y_{n+1}$, and we call $G^A(\lambda \Delta)$ the *transfer function* of the scheme.

Now, the *A-stability region* of a given scheme is defined as the subset of the real axis consisting of those numbers $\lambda \Delta$, which are mapped by the *transfer function* $G^A(\cdot)$ into the unit interval $(-1, 1)$. These are those $\lambda \Delta$ for which

$$|G^A(\lambda \Delta)| < 1 \tag{41}$$

If, for a scheme, the *A-stability region* covers the left half of the real axis, that is the part formed by all $\lambda \Delta$ with $\lambda < 0$, then we say that the scheme is *A-stable*. In this case, the scheme achieves numerical stability for those parameters where the test dynamics themselves show stability. Since we have used additive noise in the test equation (39) we interpret *A-stability* here as *additive noise stability*. Let us now examine some implicit strong schemes.

Drift Implicit Euler and Milstein Schemes

The simplest implicit strong scheme is the *drift implicit Euler scheme*, which has strong order $\gamma = 0.5$. It has the form

$$Y_{n+1} = Y_n + a(\tau_{n+1}, Y_{n+1}) \Delta + b \Delta W_n \tag{42}$$

Here we follow our convention in writing $b = b(\tau_n, Y_n)$. There is also a *family of drift implicit Euler schemes*

$$\begin{aligned}
Y_{n+1} = & Y_n + \{\alpha a(\tau_{n+1}, Y_{n+1}) \\
& + (1 - \alpha) a\} \Delta + b \Delta W
\end{aligned} \tag{43}$$

where the parameter $\alpha \in [0, 1]$ characterizes the *degree of implicitness*. Note that for $\alpha = 0$ we have the explicit Euler scheme (26) and for $\alpha = 1$ the drift implicit Euler scheme (42). For $\alpha = 0.5$, we obtain from (43) a stochastic generalization of the deterministic trapezoidal method.

For the test equation (39), the family of drift implicit Euler schemes with degree of implicitness $\alpha \in [0, 1]$ yields the recursion formula

$$Y_{n+1} = Y_n + \{\alpha \lambda Y_{n+1} + (1 - \alpha) \lambda Y_n\} \Delta + \Delta W_n \quad (44)$$

and thus

$$Y_{n+1} = G^A(\lambda \Delta) Y_n + \Delta W_n (1 - \alpha \lambda \Delta)^{-1} \quad (45)$$

with transfer function

$$G^A(\lambda \Delta) = (1 - \alpha \lambda \Delta)^{-1} (1 + (1 - \alpha) \lambda \Delta) \quad (46)$$

If we denote by $\bar{Y}_{n+1}$, the corresponding discrete-time approximation that starts at the initial value $\bar{Y}_0$ instead of Y_0 , then we obtain for the difference

$$\begin{aligned} Y_{n+1} - \bar{Y}_{n+1} &= G^A(\lambda \Delta) (Y_n - \bar{Y}_n) \\ &= (G^A(\lambda \Delta))^n (Y_0 - \bar{Y}_0) \end{aligned} \quad (47)$$

Obviously, as long as the absolute value of the transfer function $G^A(\lambda \Delta)$ is smaller than 1, that is

$$|G^A(\lambda \Delta)| < 1 \quad (48)$$

the impact of the initial error $|Y_0 - \bar{Y}_0|$ is decreased during the simulation of the approximate trajectory over time, as can be seen from equation (47). However, for values

$$|G^A(\lambda \Delta)| > 1 \quad (49)$$

this is not the case, and errors are propagated. For the above test equation, it turns out that the region of A -stability ranges from $-2/(1 - 2\alpha)$ up to 0. This means for a degree of implicitness $\alpha \geq 1/2$ the corresponding drift implicit scheme is A -stable.

We call the following counterpart of the Milstein scheme (28) a *drift implicit Milstein scheme*. It has the form

$$\begin{aligned} Y_{n+1} &= Y_n + a(\tau_{n+1}, Y_{n+1}) \Delta + b \Delta W_n \\ &\quad + b b' 1/2 \{(\Delta W_n)^2 - \Delta\} \end{aligned} \quad (50)$$

There exist further families of drift implicit strong schemes of higher order. Some of these are A -stable and can be found in [7].

Drift Implicit Order 1.0 Strong Runge–Kutta Scheme

Let us now discuss a family of drift implicit schemes which avoid the use of derivatives. We shall call these drift implicit strong Runge–Kutta schemes. We emphasize that these schemes are not a simple heuristic adaptation of any deterministic Runge–Kutta scheme.

A family of drift implicit order 1.0 strong Runge–Kutta schemes is given as

$$\begin{aligned} Y_{n+1} &= Y_n + \{\alpha a(\tau_{n+1}, Y_{n+1}) + (1 - \alpha) a\} \Delta \\ &\quad + b \Delta W_n + \frac{1}{\sqrt{\Delta}} \{b(\tau_n, \bar{Y}_n) - b\} \\ &\quad \times \frac{1}{2} ((\Delta W_n)^2 - \Delta) \end{aligned} \quad (51)$$

with supporting value

$$\bar{Y}_n = Y_n + a \Delta + b \sqrt{\Delta} \quad (52)$$

and degree of implicitness parameter $\alpha \in [0, 1]$. Further implicit schemes and the derivations of their strong order of convergence can be also found in [7].

Balanced Implicit Method

A major difficulty arises from the fact that all the above strong schemes do not provide implicit expressions in the diffusion terms. Only drift terms are made implicit. Unfortunately, one cannot make diffusion terms in the Euler scheme simply implicit as it was possible for the drift. An *ad hoc* implicit discrete-time approximation with implicit diffusion term would result in a scheme that includes the inverse of a Gaussian random variable. Such an algorithm may explode and, thus, does not provide a reasonable scheme.

Drift implicit methods are well adapted for systems with small noise or additive noise. However, when the diffusion part plays an essential role in the dynamics, as it is the case for martingales,

the application of fully implicit methods, involving also implicit diffusion terms, could bring numerical stability.

An illustration for such a situation is provided by the one-dimensional SDE of an exponential martingale

$$dX_t = \sigma X_t dW_t \quad (53)$$

for $t \in [0, T]$, starting at $X_0 = x_0$. Here $W = \{W_t, t \in [0, T]\}$ is a standard Wiener process. The volatility σ is, for simplicity, chosen to be constant. The SDE (53) describes the standard Black–Scholes dynamics of a discounted asset price under the risk-neutral probability measure. Alternatively, it could describe the dynamics of a security denominated in units of the growth optimal portfolio under the real-world probability measure applying the benchmark approach [12]. These are typical dynamics that one faces when simulating asset dynamics in finance. Obviously, in such cases one cannot apply drift implicit schemes to improve the numerical stability of the approximate solution of an SDE that does not have any drift term, as is the case for the martingale satisfying the SDE (53). However, we can use implicit methods that introduce implicitness in the diffusion terms in such a way that the scheme still makes sense and converges to the correct limit.

Let us now describe such an implicit method that allows to overcome a range of numerical instabilities. In [11] a family of *balanced implicit methods* has been proposed that resolves, in many cases, the problem of numerical stability. Such a balanced implicit method can be written in the form

$$Y_{n+1} = Y_n + a \Delta + b \Delta W_n + (Y_n - Y_{n+1}) C_n, \quad (54)$$

where

$$C_n = c^0(Y_n) \Delta + c^1(Y_n) |\Delta W_n| \quad (55)$$

and c^0, c^1 represent positive, real-valued uniformly bounded functions. The freedom of choosing c^0 and c^1 can be exploited to construct a numerically stable scheme tailored for the dynamics of the given SDE. Note, however, the balanced implicit method is only of strong order $\gamma = 0.5$ since it is a variation of the Euler scheme with some additional higher order terms designed to control the propagation of errors. The low order of strong convergence is a

price that is paid here for obtaining better numerical stability.

The balanced implicit method can be interpreted as a family of strong methods, providing a kind of balance between the approximating and the higher order diffusion terms in a scenario simulation. In a range of applications in finance and filtering, see [3], balanced implicit methods have shown better numerical stability than most other methods presented above. We emphasize any numerically stable scheme is better than an unstable one. An eventually theoretically higher order of strong convergence of a scheme is only of secondary importance.

Pseudorandom Number Generators

Stochastic models of quantitative finance are defined in the abstract framework of probability theory. To apply the Monte Carlo method to these models, it suffices, in principle, to sample independent realizations of the underlying random variables or random vectors. This can be achieved by sampling independent random variables uniformly distributed over the interval $(0, 1)$ (i.i.d. $\mathcal{U}(0, 1)$, for short) and applying appropriate transformations to these uniform random variables. Nonuniform variate generation techniques develop such transformations and provide efficient algorithms that implement them [3, 6]. A simple general way to obtain independent random variables $X_1, X_2, \dots$ with distribution function F from a sequence of i.i.d. $\mathcal{U}(0, 1)$ random variables $U_1, U_2, \dots$ is to define

$$X_j = F^{-1}(U_j) \stackrel{\text{def}}{=} \min\{x \mid F(x) \geq U_j\}; \quad (1)$$

this is the *inversion method*. This technique can provide a sequence of independent standard normal random variables, for example, which can, in turn, be used to generate the sample path of a geometric Brownian motion or other similar type of stochastic process. There is no closed-form expression for the inverse standard normal distribution function, but very accurate numerical approximations are available.

But how do we get the i.i.d. $\mathcal{U}(0, 1)$ random variables? Realizing these random variables exactly is very difficult, perhaps, practically impossible. With current knowledge, this can be realized only *approximately*. Fortunately, the approximation seems good enough for all practical applications of the Monte Carlo method in financial engineering and in other areas as well.

A first class of methods to realize approximations of these random variables are based on real physical noise coming from hardware devices. There is a large variety of such devices; they include gamma ray counters, fast oscillators sampled at low and slightly random frequencies, amplifiers of heat noise produced in electric resistances, photon counting and photon trajectory detectors, and so on. Some of these devices sample a signal at successive epochs and return 0 if the signal is below a given threshold,

and 1 if it is above the threshold, at each sampling epoch. Others return the parity of a counter. Most of them produce sequences of bits that are slightly correlated and often slightly biased, but the bias and correlation can be reduced to a negligible amount, that becomes practically undetectable by statistical tests in reasonable time, by combining the bits in a clever way. For example, a simple technique to eliminate the bias when there is no correlation, proposed long ago by John von Neumann, places the successive bits in nonoverlapping pairs, discards all the pairs 00 and 11, and replaces the pairs 01 and 10 by 1 and 0, respectively. Generalizations of this technique can eliminate both the bias and correlation [2]. Simpler techniques such as Xoring (adding modulo 2) the bits by blocks of 2 or more, or Xoring several bit streams from different sources, are often used in practice. Reliable devices to generate random bits and numbers, based on these techniques, are available on the market. These types of devices are needed for applications such as cryptography, lotteries, and gambling machines, for example, where some amount of real randomness (or entropy) is essential to provide the required unpredictability and security.

For Monte Carlo methods, however, these devices are unnecessary and unpractical. They are unnecessary because simple *deterministic algorithms* are available that require no other hardware than a standard computer and provide good enough imitations of i.i.d. $\mathcal{U}(0, 1)$ random variables from a statistical viewpoint, in the sense that the statistical behavior of the simulation output is pretty much the same (for all practical purposes) if we use (*pseudo*)*random numbers* produced by these algorithms in place of true i.i.d. $\mathcal{U}(0, 1)$ random variables. These deterministic algorithmic methods are much more convenient than hardware devices.

A (*pseudo*)*random number generator* (RNG, for short) can be defined as a structure comprised of the following ingredients [9]: a finite *set of states* $\mathcal{S}$; a probability distribution on $\mathcal{S}$ to select the *initial state* s_0 (also called the *seed*); a *transition function* $f : \mathcal{S} \rightarrow \mathcal{S}$; an *output space* $\mathcal{U}$; and an *output function* $g : \mathcal{S} \rightarrow \mathcal{U}$. Here, we assume that $\mathcal{U}$ is the interval $(0, 1)$. The state evolves according to the recurrence $s_i = f(s_{i-1})$, for $i \geq 1$, and the *output* at step i is $u_i = g(s_i) \in \mathcal{U}$. These u_i 's are the successive *random numbers* produced by the RNG. (Following common usage in the simulation community, here we leave out

the qualifier “pseudo”. In the area of cryptology, the term *pseudo-RNG* refers to a stronger notion, with polynomial-time unpredictability properties [20]).

Because $\mathcal{S}$ is finite, the RNG must eventually return to a previously visited state, that is, $s_{l+j} = s_l$ for some $l \geq 0$ and $j > 0$. Then, $s_{i+j} = s_i$ and $u_{i+j} = u_i$ for all $i \geq l$; that is, the output sequence eventually repeats itself. The smallest $j > 0$ for which this happens is the *period length* ρ . Clearly, ρ cannot exceed $|\mathcal{S}|$, the number of distinct states. If the state can be represented with b bits of memory, then $\rho \leq 2^b$. For good RNGs, ρ is usually close to 2^b , as it is not difficult to construct recurrences with this property. Typical values of b range from 31 to around 20 000 or even higher [18]. In our opinion, ρ should never be less than 2^{100} and preferably more than 2^{200} . Values of b that exceed 1000 are unnecessary if the RNG satisfies the quality criteria described in what follows.

A key advantage of algorithmic RNGs is their ability to repeat exactly the same sequence of random numbers without storing them. Repeating the same sequence several times is essential for the proper implementation of variance reduction techniques such as using common random numbers for comparing similar systems, sensitivity analysis, sample-path optimization, external control variates, antithetic variates, and so on [1, 5] (see also **Variance Reduction**). It is also handy for program verification and debugging. On the other hand, some real randomness can be used for selecting the seed s_0 of the RNG.

Streams and Substreams

Modern high-quality simulation software often offers the possibility to declare and create virtual RNGs just like for any other type of variable or object, in practically unlimited amount. In an implementation adopted by several simulation software vendors, these virtual RNGs are called *streams*, and each stream is split into multiple *substreams* long enough to prevent potential overlap [14, 19]. For any given stream, there are methods to generate the next number, to rewind to the beginning of the stream or to the beginning of the current substream, or to the beginning of the next substream.

To illustrate its usefulness, consider a simple model of a financial option whose payoff is a function of a geometric Brownian motion observed at fixed

points in time. We want to estimate $d = \mathbb{E}[X_2 - X_1]$ where X_1 and X_2 are the payoffs with two slightly different parameter settings, such as different volatilities or different strike prices, for example. This is often useful for sensitivity analysis (estimating the *greeks*; see **Monte Carlo Greeks**). To estimate d , we would simulate the model with the two different settings using *common random numbers* across the two versions [1, 5] (see also **Variance Reduction**), repeat this n times independently and compute a confidence interval on d from the n independent copies of $X_2 - X_1$. To implement this, we take a stream of random numbers that contains multiple substreams, use the same substream to simulate both X_1 and X_2 for each replication, and n different substreams for the n replications. At the beginning of a replication, the stream is placed to the beginning of a new substream and the model is simulated to compute X_1 . Then the stream is reset to the beginning of its current substream before simulating the model again to compute X_2 . This ensures that exactly the same random numbers are used to generate the Brownian motion increments at the same time points for both X_1 and X_2 . Then the stream is moved to the beginning of the next substream for the next pair of runs.

There are many situations where the number of calls to the RNG during a simulation depends on the model parameters and may not be the same for X_1 and X_2 . Even in that case, the above scheme ensures that the RNG restarts at the same place for both parameter settings, for each replication. In more complicated models, to ensure a good synchronization of the random numbers across the two settings (i.e., make sure that the same random numbers are used for the same purposes in both cases), it is typically convenient to have several different streams, each stream being dedicated to one specific aspect of the model. For instance, in the previous example, if we also need to simulate external events that occur according to a Poisson process and influence the payoff in some way (e.g., they could trigger jumps in the Brownian motion), it is better to use a separate stream to simulate this process, to guarantee that no random number is used for the Brownian motion increment in one setting and for the Poisson process in the other setting.

Quality Criteria and Testing

A good RNG must obviously have a very long period, to make sure that there is no chance of wrapping around. It should also be *repeatable* (able to reproduce exactly the same sequence several times), *portable* (be easy to implement and behave the same way in different software/hardware environments), and it should be easy to split its sequence into several disjoint streams and substreams, and implement efficient tools to move between those streams and substreams. The latter requires the availability of efficient jump-ahead methods, that can quickly compute s_{i+v} given s_i , for any large v . The number b of bits required to store the state should not be too large, because the computing time for jumping ahead typically increases faster than linearly with b , and also because there can be a large number of streams and substreams in a given simulation, especially for large complex models. Another key performance measure is the speed of the generator itself. Fast generators can produce up to 100 million $\mathcal{U}(0, 1)$ random numbers per second on current personal computers [18].

All these nice properties are not sufficient, however. For example, an RNG that returns $u_i = (i/10^{1000}) \bmod 1$ at step i satisfies these properties but is definitely not recommendable, because its successive output values have an obvious strong correlation. Ideally, if we select a random seed s_0 uniformly in $\mathcal{S}$, we would like the vector of the first s output values, $(u_0, \dots, u_{s-1})$, to be uniformly distributed over the s -dimensional unit hypercube $[0, 1]^s$ for each $s > 0$. This would guarantee both uniformity and independence. Formally, we cannot have this, because these s -dimensional vectors must take their values from the finite set $\Psi_s = \{(u_0, \dots, u_{s-1}) : s_0 \in \mathcal{S}\}$, whose cardinality cannot exceed $|\mathcal{S}|$. If s_0 is random, Ψ_s can be viewed as the *sample space* from which vectors of successive output values are drawn randomly. Then, to approximate the uniformity and independence, we want the finite set Ψ_s to provide a dense and uniform coverage of the hypercube $[0, 1]^s$, at least for small and moderate values of s . This is possible only if $\mathcal{S}$ has large cardinality, and it is, in fact, a more important reason for having a long period than the danger of exhausting the cycle.

Hence, the uniformity of Ψ_s in $[0, 1]^s$ is a key quality criterion. But how do we measure it? There are many ways of measuring the uniformity (or the discrepancy from the uniform distribution) for

a point set in the unit hypercube [16, 22] (*see also Quasi-Monte Carlo Methods*). To be practical, the uniformity measure must be selected so that it can be effectively computed without generating explicitly the points of Ψ_s . For this reason, the theoretical *figures of merit* that measure the uniformity usually depend on the mathematical structure of the RNG. This is also the main reason for having RNGs based on linear recurrences: their point sets Ψ_s are easier to analyze mathematically, because they have a simpler structure. One could argue that nonlinear and more complex structures give rise to point sets Ψ_s that look more random, and some of them behave very well in empirical statistical tests, but their structure is much harder to analyze. They could leave large holes in $[0, 1]^s$ that are difficult to detect.

To design a good RNG, one typically selects an algorithm together with the size of the state space, and constraints on the parameters that ensure a fast implementation. Then one makes a computerized search in the space of parameters to find a set of values that give (i) the maximal period length within this class of generators and then (ii) the largest figure of merit than can be found. RNGs are thus selected and constructed primarily based on theoretical criteria. Then, they are implemented and tested empirically.

A large variety of *empirical statistical tests* have been designed and implemented for RNGs [8, 18]. All these tests try to detect empirical evidence against the hypothesis $\mathcal{H}_0$ that the u_i are i.i.d. $\mathcal{U}[0, 1]$. A test can be any function Y of a finite set of u_i 's, which can be computed in reasonable time, and whose distribution under $\mathcal{H}_0$ can be approximated well enough. There is an unlimited number of such tests. When applying the test, one computes the realization of Y , say y , and then the probability $p^+ = \mathbb{P}[Y \geq y \mid \mathcal{H}_0]$, called the right p value. If Y takes a much larger value than expected, then p^+ will be very close to 0, and we declare that the RNG fails the test. We may also examine the left p value $p^- = \mathbb{P}[Y \leq y \mid \mathcal{H}_0]$, or both p^+ and p^- , depending on the design of the test. When a generator really fails a test, it is not unusual to find p values as small as 10^{-15} or less.

Specific batteries that contain a variety of standard tests, which detect problems often encountered in poorly designed or too simple RNGs, have been proposed and implemented [18]. The bad news is that a majority of the RNGs available in popular commercial software fail these tests unequivocally,

with p values smaller than 10^{-15} . These generators should be discarded, unless we have very good reasons to believe that for our specific simulation models, the problems detected by these failed tests will not affect the results. The good news is that some freely available high-quality generators pass all the tests in these batteries. Of course, passing all these tests is not a proof that the RNG is reliable for all the possible simulations, but it certainly improves our confidence in the generator. In fact, no RNG can pass all conceivable statistical tests. In some sense, the good RNGs fail only very complicated tests that are hard to find and implement, whereas bad RNGs fail simple tests.

Linear Recurrences

Most RNGs used for simulation are based on linear recurrences of the general form

$$x_i = (a_1 x_{i-1} + \dots + a_k x_{i-k}) \bmod m \quad (2)$$

where k and m are positive integers, and the coefficients $a_1, \dots, a_k$ are in $\{0, 1, \dots, m-1\}$, with $a_k \neq 0$. Some use a large value of m , preferably a prime number, and define the output as $u_i = x_i/m$, so the state at step i can be viewed as $s_i = \mathbf{x}_i = (x_{i-k+1}, \dots, x_i)$. The RNG is then called a *multiple recursive generator* (MRG). For $k = 1$, we obtain the classical linear congruential generator (LCG). In practice, the output transformation is modified slightly to make sure that u_i is always strictly between 0 and 1, for example, by taking $u_i = (x_i + 1)/(m + 1)$ or $u_i = (x_i + 1/2)/m$. Jumping ahead from $\mathbf{x}_i$ to $\mathbf{x}_{i+v}$ for an arbitrary large v can be implemented easily: because of the linearity, one can write $\mathbf{x}_{i+v} = \mathbf{A}_v \mathbf{x}_i \bmod m$, where $\mathbf{A}_v$ is a $k \times k$ matrix that can be precomputed once for all [13]. When m is prime, one can choose the coefficients a_j so that the period length reaches $m^k - 1$, its maximum [8].

The point set Ψ_s produced by an MRG is known to have a *lattice structure*, and its uniformity is measured *via* a figure of merit for the quality of that lattice, for several values of s . This is known as the *spectral test* [4, 8, 10].

Typically, m is chosen as one of the largest prime integers representable on the target computer, for example, $m = 2^{31} - 1$ on a 32-bit computer. Then,

a direct implementation of equation (2) with integer numbers would cause overflow, so more clever implementation techniques are needed. These techniques require that we impose additional conditions on the coefficients a_j . We have to be careful that these conditions do not oversimplify the structure of the point set Ψ_s . One extreme example of this is to take only two nonzero coefficients, say a_r and a_k , both equal to ± 1 . Implementation is then easy and fast. However, all triples of the form (u_i, u_{i-r}, u_{i-k}) produced by such a generator, for $i = 0, 1, \dots$, lie in only two planes in the three-dimensional unit cube. Despite this awful behavior, these types of generators (or variants thereof) can be found in many popular software products [18]. They should be avoided. All simple LCGs, say with $m \leq 2^{64}$, should be discarded; they have too much structure and their period length is too short for present computers.

One effective way of implementing high-quality MRGs is to combine two (or more) of them by adding their outputs modulo 1. (There are also other slightly different ways of combining.) If the components have distinct prime moduli, the combination turns out to be just another MRG with (nonprime) modulus m equal to the product of the moduli of the components, and the period can be up to half the product of the component's periods when we combine two of them. The idea is to select the components so that (i) a fast implementation is easy to construct for each individual component and (ii) the combined MRG has a more complicated structure and highly uniform sets Ψ_s , as measured by the spectral test [10]. Specific MRG constructions can be found in [10, 13, 18] and the references given therein.

A different approach uses a linear recurrence as in equation (2), but with $m = 2$. All operations are then performed modulo 2, that is, in the finite field $\mathbb{F}_2$ with elements $\{0, 1\}$. This allows very fast implementations by exploiting the binary nature of computers. A general framework for this is the matrix linear recurrence [13, 17]:

$$\mathbf{x}_i = \mathbf{A} \mathbf{x}_{i-1} \quad (3)$$

$$\mathbf{y}_i = \mathbf{B} \mathbf{x}_i \quad (4)$$

$$u_i = \sum_{\ell=1}^w y_{i,\ell-1} 2^{-\ell} \quad (5)$$

where $\mathbf{x}_i = (x_{i,0}, \dots, x_{i,k-1})^t$ is the k -bit *state vector* at step i , $\mathbf{y}_i = (y_{i,0}, \dots, y_{i,w-1})^t$ is the w -bit *output*

vector at step i , k , and w are the positive integers, $\mathbf{A}$ is a $k \times k$ binary *transition matrix*, $\mathbf{B}$ is a $w \times k$ binary *output transformation matrix*, and $u_i \in [0, 1)$ is the *output* at step i . All operations in equations (3) and (4) are performed in $\mathbb{F}_2$. These RNGs are called $\mathbb{F}_2$ -linear generators.

The theoretical analysis usually assumes the simple output definition (5), but, in practice, this definition is modified slightly to avoid returning 0 or 1. This framework covers several types of generators, including the Tausworthe, polynomial LCG, generalized feedback shift register (GFSR), twisted GFSR, Mersenne twister, Well, Xorshift, linear cellular automaton, and combinations of these [13, 17, 21]. With a carefully selected matrix $\mathbf{A}$ (its characteristic polynomial must be a primitive polynomial over $\mathbb{F}_2$), the period length can reach $2^k - 1$. In practice, the matrices $\mathbf{A}$ and $\mathbf{B}$ are chosen so that the products (3) and (4) can be implemented very efficiently on a computer by a few simple binary operations such as or, exclusive-or, shift, and rotation, on blocks of bits. The idea is to find a compromise between the number of such operations (which affects the speed) and a good uniformity of the point sets Ψ_s (which is easier to reach with more operations). The uniformity of these point sets is measured *via* their *equidistribution*; essentially, the hypercube $[0, 1]^s$ is partitioned into small subcubes (or subrectangles) of equal sizes, and for several such partitions, we check if all the subcubes contain exactly the same number of points from Ψ_s . This can be computed efficiently by computing the ranks of certain binary matrices [17]. Combined generators of this type, defined by Xoring the output vectors $\mathbf{y}_i$ of the components, are equivalent to yet another $\mathbb{F}_2$ -linear generator. Such combinations have the same motivation as for MRGs.

Nonlinear Generators

Linear RNGs have many nice properties, but they also fail certain specialized statistical tests focused at detecting linearity. When the simulation itself applies nonlinear transformations to the uniform random numbers, which is typical, one should not worry about the linearity, unless the structure of Ψ_s is not very good. However, there are cases where the linearity can matter. For example, to generate a large random binary matrix, one should not use an $\mathbb{F}_2$ -linear generator, because the rank of the matrix is

likely to be much smaller than expected, due to the excessive linear dependence [18].

There are many ways of constructing nonlinear generators. For example, one can simply add a nonlinear output transformation to a linear RNG, or permute (shuffle) the output values with the help of another generator. Another way is to combine an MRG with an $\mathbb{F}_2$ -linear generator, either by addition modulo 1 or by Xoring the outputs. An important advantage of this technique is that the uniformity of the resulting combined generator can be assessed theoretically, at least to a certain extent [15]. They can also be fast.

When combining generators, it is important to understand what we do and we should be careful to examine the structure not only of the combination but also of the quality of the components. By blindly combining two good components, it is indeed possible (and not too difficult) to obtain a bad (worst) RNG.

Generators whose underlying recurrence is nonlinear are generally harder to analyze and are slower. These are the types of generators used for cryptographic applications. Empirically, well-designed nonlinear generators tend to perform better in statistical tests than the linear ones [18], but from the theoretical perspective, their structure is not understood as well. RNGs based on chaotic dynamical systems have often been proposed in the literature, but these generators have several major drawbacks, including the fact that their s -dimensional uniformity is often very poor [7].

What to Look For and What to Avoid

A quick look at the empirical results in [12, 18] shows that many widely used RNGs are seriously deficient, including the default generators of several highly popular software products. So before running important simulation experiments, one should always check what is the default RNG, and be ready to replace it if needed. Note that the generators that pass the tests in [18] are not all recommended. Before adoption, one should verify that the RNG has solid theoretical support, that it is fast enough, and that multiple streams and substreams are available, for example. Convenient software packages with multiple streams and substreams are described in [14, 19] and are available freely from the web page of this

author. These packages are based on combined MRGs of [10], combined Tausworthe generators of [11], the Well generators [23] (which are improvements over the Mersenne twister in terms of equidistribution), and some additional nonlinear generators, among others. No uniform RNG can be guaranteed against all possible defects, but one should at least avoid those that fail simple statistical tests miserably and go for the more robust ones, for which no serious problem has been detected after years of usage and testing.

PIERRE L'ECUYER

Monte Carlo Greeks

Monte Carlo simulation (*see Monte Carlo Simulation*) allows not only to compute option prices but can also be used to estimate their sensitivity parameters (delta, gamma, vega, etc.). The baseline estimator, the one which is to be improved, is known as the *resimulation estimator*. Resimulation consists of simply rerunning the simulation (using the same sequence of pseudorandom numbers) after perturbing the parameter or variable of interest. The corresponding estimator is then taken as the change in the value of the derivative divided by the magnitude of the perturbation. The purpose of most of the sophisticated methods that are discussed is primarily that resimulation can be very demanding computationally, while the desired information is in some way already contained in the original simulation data and can be extracted with much more modest amounts of computation than with resimulation. The focus of this article is on the two main such techniques, known as the *pathwise* and *likelihood ratio methods*.

The standard integration, or expectation, that represents the value of a derivative takes the form

$$V = \int \pi(S) \psi(S) dS \quad (1)$$

where $\pi(\bullet)$ represents the payoff function and $\psi(\bullet)$ is the probability density of the underlying. The pathwise estimator is based on how the relevant parameter functionally enters into the payoff, whereas the likelihood ratio estimator is based on how the relevant parameter enters into the density function of the underlying(s), given the appropriate change of variable. We specialize this in what follows by assuming that normal variates are the drivers for all price changes and by including a vector of parameters α , which may represent the initial prices of the underlying securities or rates, volatilities, time to expiration, dividend rates, and so on. In what follows, we give the specifics of the computation of these methods and give some examples of each.

Pathwise Method

The pathwise estimator is obtained with

$$V = \int \pi[S(z, \alpha)] \varphi(z) dz \quad (2)$$

where $\varphi(z)$ is the standard normal density. The desired sensitivities are then

$$\frac{dV}{d\alpha} = \frac{d}{d\alpha} \left\{ \int \pi[S(z, \alpha)] \varphi(z) dz \right\} \quad (3)$$

or, exchanging the differentiation and integral

$$\frac{dV}{d\alpha} = \int \frac{d}{d\alpha} (\pi[S(z, \alpha)]) \varphi(z) dz \quad (4)$$

The corresponding (unbiased) pathwise estimator can then be computed as

$$\left\{ \frac{dV}{d\alpha} \right\}_P = \frac{1}{N} \sum_{i=1}^N \frac{d}{d\alpha} (\pi[S^i(z_i, \alpha)]) \quad (5)$$

where the summation is taken over N simulation paths indexed by i and the z_i are independent and identically distributed standard normal variates. As an application of the pathwise methodology, we consider computing an estimate of vega for a European call option under the Black–Scholes model where

$$dS_t = S_t [(r - \delta) dt + \sigma dB_t] \quad (6)$$

and S_t is the underlying asset price at time t , r is the domestic interest rate, δ is the dividend rate or foreign interest rate, σ is the volatility, and B_t is standard Brownian motion. A European call option with expiration T and strike price K has value equal to

$$V = E [e^{-rT} (S_T - K)^+] \quad (7)$$

where $E(\bullet)$ is the risk-neutral expectation operator. In the Black–Scholes model we have

$$S_T = S_0 \exp \left[\left(r - \delta - \frac{\sigma^2}{2} \right) T + \sigma \sqrt{T} Z \right] \quad (8)$$

where Z is a realization of a standard normal variate. Therefore

$$\begin{aligned} \frac{dS_T}{d\sigma} &= S_T (-\sigma T + \sqrt{T} Z) \\ &= \frac{S_T}{\sigma} \left[\ln(S_T/S_0) - \left(r - \delta + \frac{\sigma^2}{2} \right) T \right] \end{aligned} \quad (9)$$

Now we simply apply the chain rule

$$\frac{dV}{d\sigma} = E \left[\frac{d\pi}{dS_T} \frac{dS_T}{d\sigma} \right] \quad (10)$$

where

$$\frac{d\pi}{dS_T} = e^{-rT} I(S_T > K) \quad (11)$$

and $I(\bullet)$ is the indicator function that takes on the value 1 if the argument is true and 0 otherwise. That is, the call payoff responds one-to-one with the underlying at expiration provided that the option finishes in-the-money. We then replace the expectation with a summation, as before, to obtain the pathwise estimator

$$\left\{ \frac{dV}{d\sigma} \right\}_P = \frac{1}{N} \sum_{i=1}^N e^{-rT} 1(S_T^i > K) \frac{S_T^i}{\sigma} \times \left[\ln(S_T^i/S_0) - \left(r - \delta + \frac{\sigma^2}{2} \right) T \right] \quad (12)$$

Likelihood Ratio Method

For the likelihood ratio method, we perform a change of variables such that the dependence on α in the integrand is put into the density function *via*

$$\frac{dV}{d\alpha} = \int \pi(S) \frac{d}{d\alpha} \varphi(S; \alpha) dS \quad (13)$$

or

$$\frac{dV}{d\alpha} = \int \pi(S) \frac{\frac{d}{d\alpha} \varphi(S; \alpha)}{\varphi(S; \alpha)} \varphi(S; \alpha) dS \quad (14)$$

In this form, the calculation resembles the estimation of the price of a derivative with payoff

$$\chi(S; \alpha) \equiv \pi(S) \omega(S; \alpha) \quad (15)$$

where

$$\omega \equiv \frac{\frac{d}{d\alpha} \varphi(S; \alpha)}{\varphi(S; \alpha)} \quad (16)$$

so that we have

$$\frac{dV}{d\alpha} = \int \chi(S; \alpha) \varphi(S, \alpha) dS \quad (17)$$

As with the pathwise method, we can convert this into a discrete sum suitable for a Monte Carlo

implementation to obtain an unbiased estimator of

$$\left\{ \frac{dV}{d\alpha} \right\}_L = \frac{1}{N} \sum_{i=1}^N \chi(S_i(z_i); \alpha) \quad (18)$$

In order to illustrate this technique, we again consider the vega calculation. For the normal density we get

$$\omega = \frac{\frac{d}{d\alpha} \varphi(S; \alpha)}{\varphi(S; \alpha)} \quad (19)$$

$$= \frac{\ln(x/S_0) - (r - \delta - \sigma^2/2) T}{S_0 \sigma^2 T} \quad (20)$$

and therefore the likelihood ratio estimator is

$$\left\{ \frac{dV}{d\sigma} \right\}_L = \sum_{i=1}^N e^{-rT} (S_T^i(z_i) - K)^+ \times \left[\frac{\ln(x/S_0) - (r - \delta - \sigma^2/2) T}{S_0 \sigma^2 T} \right] \quad (21)$$

Comments

The interchange of the differentiation and integral operators that both the pathwise and likelihood ratio methods entail requires smoothness in the payoff functions and density functions, respectively. As financial derivative payoffs are often not smooth while densities generally are, the likelihood ratio method is more advantageous. For example, the call option payoff is not differentiable in the underlying asset price. The problem with the likelihood ratio method, however, is that the parameter of interest may not appear in the density function even after transformations are considered, although this is a fairly rare occurrence. For programming systems, a very significant advantage of the likelihood ratio method is that it can be coded in a modular way in that prior knowledge of the payoff is not required as made clear by equations (15–17).

It should be noted that these methods can also be applied to path-dependent payoffs (which can complicate the application of the pathwise method) as well as non-Gaussian cases (which can complicate the application of the likelihood ratio method).

It may be mentioned that there are other methods, such as the equivalent entropy projection and Malliavin calculus approaches. The equivalent entropy projection method, instead of perturbing the parameters of interest, involves perturbing the probabilities of the simulated paths. The Malliavin calculus approach (see **Sensitivity Computations: Integration by Parts**) is a more elaborate or general version of, but arguably not superior, to the likelihood ratio method [1].

Bermudan Options

A Bermudan option allows its holder to exercise the contract before maturity, and this feature makes its pricing significantly more difficult in comparison with the corresponding European option. Even for simple put options, currently there are no explicit formulae for their prices and therefore numerical methods must be employed. Although there are several such methods available for pricing Bermudan and American (see **American Options**) options depending on a single asset (see **Finite Difference Methods for Early Exercise Options**), these methods become typically ineffective for options on multiple assets. In such cases, we have to usually resort to methods based on Monte Carlo simulations. In this context, approaches that combine simulations with regression techniques have proven to be particularly effective. An attractive feature of these methods is that, in principle, they can be applied to any situation where trajectories of the underlying process can be simulated, since no other information about the process is required (unlike, e.g., the stochastic mesh method) (see **Stochastic Mesh Method**). In particular, they can be applied to path-dependent options. Since their introduction by several authors, especially Carrière [2], Thitsiklis and Van Roy [7], and Longstaff and Schwartz [4], the area of their applications has been extended beyond the pricing of Bermudan options, and currently it also includes the optimal dynamic asset allocation problem [1] and hedging [6].

Regression methods use the dynamic programming representation to determine the price of the option and also the optimal exercise strategy. To simplify the presentation of these methods, suppose that our objective is to price a Bermudan style option whose payoff depends only on the current value of the underlying security. The option can be exercised at $M + 1$ time points (including the initial time), which we shall denote by $t_0, t_1, \dots, t_M = T$. At the time of exercise, τ , the value of the option is equal to $G(\tau, S_\tau)$, where G is a payoff function. The dynamic of the price of the underlying security is described by a process $\{S_t\}_{t=0,1,\dots,M}$, which we assume to be a Markov chain with values in $\mathcal{R}^b$. This process may be obtained, for example, as a result of sampling a continuous process $\{S_t\}_{0 \leq t \leq T}$ that solves a stochastic differential equation.

From the general theory of arbitrage-free pricing (see **Risk-neutral Pricing**), it follows that an arbitrage-free price of the option can be represented as the optimal expected discounted payoff:

$$P(t_0, S_0) := \max_{\tau} E[B(t_0, \tau)G(\tau, S_\tau)] \quad (1)$$

where the expectation is taken with respect to a given risk-neutral measure Q , and $B(s, t)$ denotes the discount factor for the period (s, t) . The maximum in equation (1) is taken over all stopping times taking values in the set $\{t_0, t_1, \dots, t_M\}$.

Since we do not know the optimal exercise strategy, a direct calculation of the price from equation (1) is not feasible. However, the price of the option can also be obtained by using the dynamic programming representation. For this, we use the following backward recursion to find functions $P(t_i, \cdot)$, $i = 1, \dots, M$,

$$P(T, x) = G(T, x) \quad (2)$$

$$P(t_i, x) = \max\{G(t_i, x), C(t_i, x)\}, \quad i = M - 1, \dots, 0 \quad (3)$$

where the continuation value, $C(t_i, x)$, is defined as

$$C(t_i, x) := B_i E[P(t_{i+1}, S_{t_{i+1}}) | S_{t_i} = x] \quad (4)$$

Then the price of the option at t_0 is given by $P(t_0, S_0)$. In the last equation, we assume that the discount factor $B_i \equiv B(t_i, t_{i+1})$ is deterministic. Equation (3) lends itself to a very intuitive explanation. At the i th exercise opportunity, the owner of the option makes the decision about early exercise by comparing the immediate exercise value with the present value of continuing. The larger of these two determines the present value of the option and the optimal action.

To use this method, in practice, we must be able to calculate efficiently the conditional expectations

$$E[P(t_{i+1}, S_{t_{i+1}}) | S_{t_i} = x] \quad (5)$$

for $i = 0, \dots, M - 1$ and some selected set of points $x \in \mathcal{R}^b$ from the state space. Regression-based methods accomplish this through the regression of option values at the next time step on a set of regressors that depend on the current state. The main assumption behind these methods is that the conditional expectation (5) as a function of the state variable x

can be represented in the form of an infinite series expansion, meaning that we have

$$C(t_i, x) = \sum_{j=1}^{\infty} a_{ij} \beta_j(x) \quad (6)$$

for some basis functions $\beta_j : \mathcal{R}^b \rightarrow \mathcal{R}$ and constants $\{a_{ij}\}$. Then an approximation to the continuation value can be obtained by using only a finite number of basis functions, say L . This can be accomplished, for example, by projecting $C(t_i, \cdot)$ onto the span of the basis functions β_j , $j = 1, \dots, L$. If the projection space is equipped with a measure that corresponds to the distribution of S_{t_i} , then the coefficients in this approximation, $a_{i1}^*, \dots, a_{iL}^*$, solve the following optimization problem

$$\begin{aligned} & E \left[\left(C(t_i, S_{t_i}) - \sum_{j=1}^L a_{ij}^* \beta_j(S_{t_i}) \right)^2 \right] \\ &= \min_{\{a_{i1}, \dots, a_{iL}\}} E \left[\left(C(t_i, S_{t_i}) - \sum_{j=1}^L a_{ij} \beta_j(S_{t_i}) \right)^2 \right] \end{aligned} \quad (7)$$

Thus, here the continuation value is approximated by a member of a parametric family of functions. This method, however, cannot be implemented directly since the continuation value $C(t_i, \cdot)$ is unknown. From the definition of $C(t_i, \cdot)$, it follows that for a single realization $(s_{i1}, s_{(i+1)1})$ of the vector $(S_{t_i}, S_{t_{i+1}})$ the continuation value $C(t_i, s_{i1})$ can be approximated by $B_{t_i} P(t_{i+1}, s_{(i+1)1})$. This observation leads to the selection of the coefficients $a_{i1}^*, \dots, a_{iL}^*$ that minimize the following criterion (see [8]):

$$E \left[\left(B_{t_i} P(t_{i+1}, S_{t_{i+1}}) - \sum_{j=1}^L a_{ij} \beta_j(S_{t_i}) \right)^2 \right] \quad (8)$$

where the expectation is taken with respect to the joint distribution of $(S_{t_i}, S_{t_{i+1}})$.

The argument that motivates the use of equation (8) as a method of approximation may suggest that the method will not be accurate, since we are approximating the continuation value at a given state by using only one successor. We should observe, however, that in this method we are not approximating continuation values individually at each state but

rather we approximate the continuation value $C(t_i, \cdot)$ treated as a function. Because of this and the assumed smoothness of this function, the resulting estimate of the continuation value at any state “borrows” also information about continuation values from points in a neighborhood of this state.

A factor that indeed determines the effectiveness of this approach is the selection of the basis functions. The assumption that guarantees the existence of the infinite series expansion (6) is rather a weak one, as any sufficiently smooth function can be approximated, for example, by polynomials. In practice, however, we have to truncate this expansion to a finite sum and hence we have to decide which terms we need to keep. The choice of a finite number of basis functions determines the success of the method and often must be crafted to the problem at hand. It becomes especially difficult for options on multiple assets, since then the number of required basis functions grows quickly with the dimension of the underlying price process.

On the basis of this method of approximation of continuation values, we can define an implementable procedure for pricing Bermudan options. For this, in equation (8) we have to substitute for $P(t_{i+1}, \cdot)$ its approximation, $\hat{P}(t_{i+1}, \cdot)$, determined from the backward induction (2)–(4). In addition, to find the coefficients $a_{i1}^*, \dots, a_{iM}^*$ that minimize equation (8), typically we have to approximate the expectation by using a sample mean. The resulting algorithm can be summarized in the following way. In the first phase, we simulate N independent trajectories $\{s_{1j}, \dots, s_{Mj}\}$, $j = 1, \dots, N$, of the Markov chain $\{S_{t_i}\}_{0 \leq i \leq M}$. At maturity of the contract, we set $\hat{P}_{Mj} = G(T, s_{Mj})$ and then start the backward induction. Given the estimated values $\hat{P}_{(i+1)j}$, $j = 1, \dots, N$, we approximate the continuation value at s_{ij} by $\hat{C}_{ij} = \sum_{k=1}^M a_{ik}^* \beta_k(s_{ij})$, where $a_{i1}^*, \dots, a_{iM}^*$ minimize

$$\sum_{j=1}^N \left[B_{t_i} \hat{P}_{(i+1)j} - \sum_{k=1}^M a_{ik} \beta_k(s_{ij}) \right]^2 \quad (9)$$

Then, we set $\hat{P}_{ij} = \max\{G(t_i, s_{ij}), \hat{C}_{ij}\}$. Finally, the price of the option is calculated as $\max\{B_0(\hat{P}_{11} + \dots + \hat{P}_{1N})/N, G(t_0, s_0)\}$.

Carrière [2] has proposed a similar approach, but instead of approximating the continuation value by a member of a parametric family he suggests using

nonparametric regression techniques based on splines and a local polynomial smoother. The approach proposed by Longstaff and Schwartz [4] is similar to the one presented here except that the authors use a different formula for calculating $\hat{P}_{ij}$. They also recommend using the least-squares method (9) only for options in the money.

Convergence properties of regression-based methods have been studied in [3, 5, 7, 8]. In particular, Clément *et al.* [3] prove convergence of the method proposed by Longstaff and Schwartz as the number of simulated trajectories, N , tends to infinity. Stentoft [5] presents a detailed numerical analysis of the Longstaff and Schwartz approach. By considering alternative families of polynomials and different numbers of basis functions, the author provides a guidance into the problem of proper selection of basis functions. He also finds that in problems with high number of assets the least-squares approach is superior to the binomial model method in terms of the trade-off between computational time and precision.

Simulation of Square-root Processes

Square-root diffusion processes are popular in many branches of quantitative finance. Guaranteed to stay nonnegative, yet almost as tractable as a Gaussian process, the mean-reverting square-root process has found applications ranging from short-rate modeling of the term structure of interest rates, to credit derivative pricing, and to stochastic volatility models, just to name a few.

A thorough description of the theoretical properties of square-root processes as well as their generalization into multifactor affine jump-diffusion processes can be found in [7] where a full literature survey is also available. While we shall rely on some of these results in the remainder of this article, our focus here is on the problem of generating Monte Carlo paths for the one-factor square-root process, first in isolation and later in combination with a lognormal asset process (as required in most stochastic volatility applications). As we shall see, such path generation can, under many relevant parameter settings, be surprisingly challenging. Indeed, despite the popularity and the longevity of the square-root diffusion—the first uses in finance date back several decades—it is only in the last few years that a satisfactory palette of Monte Carlo algorithms has been established.

Problem Definition and Key Theoretical Results

Let $x(t)$ be a scalar random variable satisfying a stochastic differential equation (SDE) of the mean-reverting square-root type, that is

$$\begin{aligned} dx(t) &= \kappa (\theta - x(t)) dt + \epsilon \sqrt{x(t)} dW(t), \\ x(0) &= x_0 \end{aligned} \quad (1)$$

where κ, θ, ϵ are positive constants and $W(t)$ is a Brownian motion in a given probability measure. Applications of equation (1) in finance include the seminal CIR (Cox–Ingersoll–Ross) model for interest rates (see **Cox–Ingersoll–Ross (CIR) Model**) and the Heston stochastic volatility model (see **Heston Model**). In practical usage of such models (e.g., to price options), we are often faced with the problem of generating Monte Carlo paths of x on some

discrete timeline. To devise a simulation scheme, it suffices to contemplate the more fundamental question of how to generate, for an arbitrary increment Δ , a random sample of $x(t + \Delta)$ given $x(t)$; repeated application of the resulting one-period scheme produces a full path of x on an arbitrary set of discrete dates.

To aid in the construction of simulation algorithms, let us quickly review a few well-known theoretical results for equation (1).

Proposition 1 *Let $F(z; v, \lambda)$ be the cumulative distribution function for the noncentral chi-square distribution with v degrees of freedom and noncentrality parameter λ :*

$$\begin{aligned} F(z; v, \lambda) &= e^{-\lambda/2} \sum_{j=0}^{\infty} \frac{(\lambda/2)^j}{j! 2^{v/2+j} \Gamma(v/2 + j)} \\ &\quad \times \int_0^z y^{v/2+j-1} e^{-y/2} dy \end{aligned} \quad (2)$$

For the process (1) define

$$\begin{aligned} d &= 4\kappa\theta/\epsilon^2; \\ n(t, T) &= \frac{4\kappa e^{-\kappa(T-t)}}{\epsilon^2 (1 - e^{-\kappa(T-t)})}, \quad T > t \end{aligned} \quad (3)$$

Let $T > t$. Conditional on $x(t)$, $x(T)$ is distributed as $e^{-\kappa(T-t)}/n(t, T)$ times a noncentral chi-square distribution with d degrees of freedom and noncentrality parameter $x(t)n(t, T)$. That is,

$$\begin{aligned} \Pr(x(T) < x | x(t)) \\ &= F\left(\frac{x \cdot n(t, T)}{e^{-\kappa(T-t)}}; d, x(t) \cdot n(t, T)\right) \end{aligned} \quad (4)$$

From the known properties of the noncentral chi-square distribution, the following corollary easily follows.

Corollary 1 *For $T > t$, $x(T)$ has the following first two conditional moments:*

$$\begin{aligned} E(x(T) | x(t)) &= \theta + (x(t) - \theta) e^{-\kappa(T-t)} \\ \text{Var}(x(T) | x(t)) &= \frac{x(t)\epsilon^2 e^{-\kappa(T-t)}}{\kappa} \\ &\quad \times \left(1 - e^{-\kappa(T-t)}\right) + \frac{\theta\epsilon^2}{2\kappa} \left(1 - e^{-\kappa(T-t)}\right)^2 \end{aligned} \quad (5)$$

Proposition 2 Assume that $x(0) > 0$. If $2\kappa\theta \geq \epsilon^2$, then the process for x can never reach zero. If $2\kappa\theta < \epsilon^2$, the origin is accessible and strongly reflecting.

The condition $2\kappa\theta \geq \epsilon^2$ in Proposition 2 is often known as the *Feller condition* (see [12]) for equation (1). When equation (1) is used as a model for interest rates or credit spreads, market-implied model parameters are typically such that the Feller condition is satisfied. However, when equation (1) represent a stochastic variance process (as in the section Stochastic Volatility Simulation), the Feller condition rarely holds. As it turns out, a violation of the Feller condition may increase the difficulty of Monte Carlo path generation considerably.

Simulation Schemes

Exact Simulation

According to Proposition 1, the distribution of $x(t + \Delta)$ given $x(t)$ is known in closed form. Generation of a random sample of $x(t + \Delta)$ given $x(t)$ can therefore be done entirely bias-free by sampling from a noncentral chi-square distribution. Using the fact that a noncentral chi-square distribution can be seen as a regular chi-square distribution with Poisson-distributed degrees of freedom (see [9]), the following algorithm can be used.

1. Draw a Poisson random variable N , with mean $\frac{1}{2}x(t)n(t, t + \Delta)$.
2. Given N , draw a regular chi-square random variable χ_v^2 , with $v = d + 2N$ degrees of freedom.
3. Set $x(t + \Delta) = \chi_v^2 \cdot \exp(-\kappa\Delta) / n(t, t + \Delta)$.

Steps 1 and 3 of this algorithm are straightforward, but Step 2 is somewhat involved. In practice, generation of chi-squared variables would most often use one of several available techniques for the gamma distribution, a special case of which is the chi-square distribution. A standard algorithm for the generation of gamma variates of acceptance–rejection type is the Cheng–Feast algorithm [5], and a number of others are listed in [9], though direct generation by the aid of the inverse cumulative distribution function [6] is also a practically viable option.

We should note that if $d > 1$, it may be numerically advantageous to use a different algorithm, based

on the convenient relation

$$\chi_d^2(\lambda) \stackrel{d}{=} \left(Z + \sqrt{\lambda}\right)^2 + \chi_{d-1}^2, \quad d > 1 \quad (6)$$

where $\stackrel{d}{=}$ denotes equality in distribution, $\chi_d^2(\lambda)$ is a noncentral chi-square variable with d degrees of freedom and noncentrality parameter λ , and Z is an ordinary $\mathcal{N}(0, 1)$ Gaussian variable. We trust that the reader can complete the details on application of equation (6) in a simulation algorithm for $x(t + \Delta)$.

One might think that the existence of an exact simulation scheme for $x(t + \Delta)$ would settle once and for all the question of how to generate paths of the square-root process. In practice, however, several complications may arise with the application of the algorithm mentioned earlier. Indeed, the scheme is quite complex compared with many standard SDE discretization schemes and may not fit smoothly into existing software architecture for SDE simulation routines. Also, computational speed may be an issue, and the application of acceptance–rejection sampling will potentially cause a “scrambling effect” when process parameters are perturbed, resulting in poor sensitivity computations. While caching techniques can be designed to overcome some of these issues, storage, look-up, and interpolation of such a cache pose their own challenges. Further, the basic scheme above provides no explicit link between the paths of the Brownian motion $W(t)$ and that of $x(t)$, complicating applications in which, say, multiple correlated Brownian motions need to be advanced through time.

In light of the discussion earlier, it seems reasonable to also investigate the application of simpler simulation algorithms. These will typically exhibit a bias for finite values of Δ , but convenience and speed may more than compensate for this, especially if the bias is small and easy to control by reduction of step-size. We proceed to discuss several classes of such schemes.

Biased Taylor-type Schemes

Euler Schemes. Going forward, let us use $\hat{x}$ to denote a discrete-time (biased) approximation to x . A classical approach to constructing simulation schemes for SDEs involves the application of Itô–Taylor expansions, suitably truncated. See **Monte Carlo Simulation for Stochastic Differential Equations, Stochastic Differential Equations: Scenario Simulation, and Stochastic Taylor Expansions** for details.

The simplest of such schemes is the *Euler scheme*, a direct application of which would write

$$\begin{aligned}\hat{x}(t + \Delta) &= \hat{x}(t) + \kappa(\theta - \hat{x}(t))\Delta \\ &\quad + \epsilon\sqrt{\hat{x}(t)} Z\sqrt{\Delta}\end{aligned}\quad (7)$$

where Z is $\mathcal{N}(0, 1)$ Gaussian variable. One immediate (and fatal) problem with equation (7) is that the discrete process for x can become negative with nonzero probability, making computation of $\sqrt{\hat{x}(t)}$ impossible and causing the time-stepping scheme to fail. To get around this problem, several remedies have been proposed in the literature, starting with the suggestion in [13] that one simply replaces $\sqrt{\hat{x}(t)}$ in equation (7) with $\sqrt{|\hat{x}(t)|}$. Lord *et al.*, [14] review a number of such “fixes”, concluding that the following works best:

$$\begin{aligned}\hat{x}(t + \Delta) &= \hat{x}(t) + \kappa(\theta - \hat{x}(t)^+)\Delta \\ &\quad + \epsilon\sqrt{\hat{x}(t)^+} Z\sqrt{\Delta}\end{aligned}\quad (8)$$

where we use the notation $x^+ = \max(x, 0)$. In [14] this scheme is denoted “full truncation”; its main characteristic is that the process for $\hat{x}$ is allowed to go below zero, at which point the process for x becomes deterministic with an upward drift of $\kappa\theta$.

Higher-order Schemes. The scheme (8) has first-order weak convergence, in the sense that expectations of functions of x will approach their true values as $\mathcal{O}(\Delta)$. To improve convergence, it is tempting to apply a *Milstein scheme*, the most basic of which is

$$\begin{aligned}\hat{x}(t + \Delta) &= \hat{x}(t) + \kappa(\theta - \hat{x}(t))\Delta \\ &\quad + \epsilon\sqrt{\hat{x}(t)} Z\sqrt{\Delta} + \frac{1}{4}\epsilon^2\Delta (Z^2 - 1)\end{aligned}\quad (9)$$

As was the case for equation (7), this scheme has a positive probability of generating negative values of $\hat{x}$ and therefore cannot be used without suitable modifications. Kahl and Jäkel [11] list several other Milstein-type schemes, some of which allow for a certain degree of control over the likelihood of generating negative values. One particularly appealing variation is the *implicit Milstein scheme*, defined as

$$\begin{aligned}\hat{x}(t + \Delta) &= (1 + \kappa\Delta)^{-1} \cdot (\hat{x}(t) + \kappa\theta\Delta \\ &\quad + \epsilon\sqrt{\hat{x}(t)} Z\sqrt{\Delta} + \frac{1}{4}\epsilon^2\Delta (Z^2 - 1))\end{aligned}\quad (10)$$

It is easy to verify that this discretization scheme results in strictly positive paths for the x process if $4\kappa\theta > \epsilon^2$. For cases where this bound does not hold, it will be necessary to modify equation (10) to prevent problems with the computation of $\sqrt{\hat{x}(t)}$. For instance, whenever $\hat{x}(t)$ drops below zero, we could use equation (8) rather than equation (10).

Under certain sufficient regularity conditions, Milstein schemes have second-order weak convergence. Owing to the presence of a square root in equation (1), these sufficient conditions are violated here, and one should not expect equation (10) to have second-order convergence for all parameter values, even the ones that satisfy $4\kappa\theta > \epsilon^2$. Numerical tests of Milstein schemes for square-root processes can be found in [9] and [11]; overall these schemes perform fairly well in certain parameter regimes, but are typically less robust than the Euler scheme.

Moment-matching Schemes

Lognormal Approximation. The simulation schemes introduced in the section Biased Taylor-type Schemes all suffer to various degrees from an inability to keep the path of x nonnegative throughout. One, rather obvious, way around this is to draw $\hat{x}(t + \Delta)$ from a user-selected probability distribution that (i) is reasonably close to the true distribution of $x(t + \Delta)$ and (ii) is certain not to produce negative values. To ensure that (i) is satisfied, it is natural to select the parameters of the chosen distribution to match one or more of the true moments for $x(t + \Delta)$, conditional upon $x(t) = \hat{x}(t)$. For instance, if we assume that the true distribution of $x(t + \Delta)$ is well approximated by a lognormal distribution with parameters μ and σ , we write (see [2])

$$\hat{x}(t + \Delta) = e^{\mu + \sigma Z} \quad (11)$$

where Z is a Gaussian random variable, and μ, σ are chosen to satisfy

$$e^{\mu + \frac{1}{2}\sigma^2} = \mathbb{E}(x(t + \Delta)|x(t) = \hat{x}(t)) \quad (12)$$

$$e^{2\left(\mu + \frac{1}{2}\sigma^2\right)} (e^{\sigma^2} - 1) = \text{Var}(x(t + \Delta)|x(t) = \hat{x}(t)) \quad (13)$$

The results in Corollary 1 can be used to compute the right-hand sides of this system of equations, which can then easily be solved analytically for μ and σ .

As is the case for many other schemes, equation (11) works best if the Feller condition is satisfied. If not, the lower tail of the lognormal distribution is often too thin to capture the true distribution shape of $\hat{x}(t + \Delta)$ —see Figure 1.

Truncated Gaussian. Figure 1 demonstrates that the density of $\hat{x}(t + \Delta)$ may sometimes be nearly singular at the origin. To accommodate this, one could contemplate inserting an actual singularity through outright truncation at the origin of a distribution that may otherwise go negative. Using a Gaussian distribution for this, say, one could write

$$\hat{x}(t + \Delta) = (\mu + \sigma Z)^+ \quad (14)$$

where μ and σ are determined by moment-matching, along the same lines as in the section Lognormal Approximation. While this moment-matching exercise cannot be done in an entirely analytical fashion, a number of caching tricks outlined in [3] can be used to make the determination of μ and σ essentially instantaneous. As documented in [3], the scheme (14) is robust and generally has attractive convergence properties when applied to standard option pricing problems. Being fundamentally Gaussian when $\hat{x}(t)$ is far from the origin, equation (14) is somewhat similar to the Euler scheme (8), although the performance

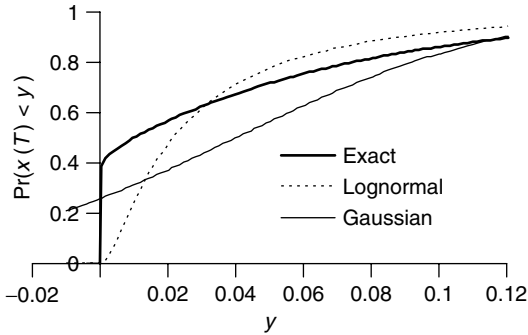

Figure 1 Cumulative distribution function for $x(T)$ given $x(0)$, with $T = 0.1$. Model parameters were $x(0) = \theta = 4\%$, $\kappa = 50\%$, and $\epsilon = 100\%$. The lognormal and Gaussian distributions in the graph were parameterized by matching mean and variances to the exact distribution of $x(T)$

of equation (14) is typically better than equation (8). Unlike equation (8), the truncated Gaussian scheme (14) also ensures, by construction, that negative values of $\hat{x}(t + \Delta)$ cannot be attained.

Quadratic-exponential. We finish our discussion of biased schemes for equation (1) with a more elaborate moment-matched scheme, based on a combination of a squared Gaussian and an exponential distribution. In this scheme, for large values of $\hat{x}(t)$, we write

$$\hat{x}(t + \Delta) = a(b + Z)^2 \quad (15)$$

where Z is a standard Gaussian random variable, and a and b are certain constants, to be determined by moment-matching. These constants a and b depend on the time step Δ and $\hat{x}(t)$, as well as the parameters in the SDE for x . While based on the well-established asymptotics for the noncentral chi-square distribution (see [3]), formula (15) does not work well for low values of $\hat{x}(t)$ —in fact, the moment-matching exercise fails to work—so we supplement it with a scheme to be used when $\hat{x}(t)$ is small. Andersen [3] shows that a good choice is to approximate the density of $\hat{x}(t + \Delta)$ with

$$\begin{aligned} &\Pr(\hat{x}(t + \Delta) \in [x, x + dx]) \\ &\approx (p\delta(x) + \beta(1 - p)e^{-\beta x}) dx, \quad x \geq 0 \end{aligned} \quad (16)$$

where δ is a Dirac delta-function, and p and β are nonnegative constants to be determined. As in the scheme in the section Truncated Gaussian, we have a probability mass at the origin, but now the strength of this mass (p) is explicitly specified, rather than implied from other parameters. The mass at the origin is supplemented with an exponential tail. It can be verified that if $p \in [0, 1]$ and $\beta \geq 0$, then equation (16) constitutes a valid density function.

Assuming that we have determined a and b , Monte Carlo sampling from equation (15) is trivial. To draw samples in accordance with equation (16), we can generate a cumulative distribution function

$$\begin{aligned} \Psi(x) &= \Pr(\hat{x}(t + \Delta) \leq x) \\ &= p + (1 - p)(1 - e^{-\beta x}), \quad x \geq 0 \end{aligned} \quad (17)$$

the inverse of which is readily computable, allowing for efficient generation of random draws by the inverse distribution method.

What remains is the determination of the constants a , b , p , and β , as well as a rule for when

to switch from equation (15) to sampling from equation (17). The first problem is easily settled by moment-matching techniques.

Proposition 3 Let $m \triangleq E(x(t + \Delta)|x(t) = \hat{x}(t))$ and $s^2 \triangleq \text{Var}(x(t + \Delta)|x(t) = \hat{x}(t))$ and set $\psi = s^2/m^2$. Provided that $\psi \leq 2$, set

$$b^2 = 2\psi^{-1} - 1 + \sqrt{2\psi^{-1} - 1} \sqrt{2\psi^{-1} - 1} \geq 0 \quad (18)$$

and

$$a = \frac{m}{1 + b^2} \quad (19)$$

Let $\hat{x}(t + \Delta)$ be as defined in equation (15); then $E(\hat{x}(t + \Delta)) = m$ and $\text{Var}(\hat{x}(t + \Delta)) = s^2$.

Proposition 4 Let m , s , and ψ be as defined in Proposition 3. Assume that $\psi \geq 1$ and set

$$p = \frac{\psi - 1}{\psi + 1} \in [0, 1) \quad (20)$$

and

$$\beta = \frac{1 - p}{m} = \frac{2}{m(\psi + 1)} > 0 \quad (21)$$

Let $\hat{x}(t + \Delta)$ be sampled from equation (17); then $E(\hat{x}(t + \Delta)) = m$ and $\text{Var}(\hat{x}(t + \Delta)) = s^2$.

The terms m , s , ψ defined in the two propositions above are explicitly computable from the result in Corollary 1. For any ψ_c in $[1, 2]$, a valid *switching rule* is to use equation (15) if $\psi \leq \psi_c$ and to sample equation (17) otherwise. The exact choice for ψ_c is noncritical; $\psi_c = 1.5$ is a good choice.

The quadratic-exponential (QE) scheme outlined above is typically the most accurate of the biased schemes introduced in this article. Indeed, in most practical applications, the bias introduced by the scheme is statistically undetectable at the levels of Monte Carlo noise acceptable in practical applications; see [3] for numerical tests under a range of challenging conditions. Variations on the QE scheme without an explicit singularity in zero can also be found in [3].

Stochastic Volatility Simulation

As mentioned earlier, square-root processes are commonly used to model stochastic movements in the volatility of some financial asset. A popular example

of such an application is the *Heston model* [10], defined by a vector SDE of the form^a

$$dY(t) = Y(t)\sqrt{x(t)} dW_Y(t) \quad (22)$$

$$dx(t) = \kappa(\theta - x(t)) dt + \epsilon\sqrt{x(t)} dW(t) \quad (23)$$

with $dW_Y(t) \cdot dW(t) = \rho dt$, $\rho \in [-1, 1]$. For numerical work, it is useful to recognize that the process for $Y(t)$ is often relatively close to geometric Brownian motion, making it sensible to work with logarithms of $Y(t)$, rather than $Y(t)$ itself. An application of Itô's Lemma shows that equations (22)–(23) are equivalent to

$$d \ln Y(t) = -\frac{1}{2}x(t) dt + \sqrt{x(t)} dW_Y(t) \quad (24)$$

$$dx(t) = \kappa(\theta - x(t)) dt + \epsilon\sqrt{x(t)} dW(t) \quad (25)$$

We proceed to consider the joint simulation of equations (24)–(25).

Broadie–Kaya Scheme

As demonstrated in [4], it is possible to simulate equations (24)–(25) bias-free. To show this, first integrate the SDE for $x(t)$ and rearrange.

$$\begin{aligned} & \int_t^{t+\Delta} \sqrt{x(u)} dW(u) \\ &= \epsilon^{-1} \left(x(t + \Delta) - x(t) - \kappa\theta\Delta + \kappa \int_t^{t+\Delta} x(u) du \right) \end{aligned} \quad (26)$$

Performing a Cholesky decomposition we can also write

$$\begin{aligned} d \ln Y(t) &= -\frac{1}{2}x(t) dt + \rho\sqrt{x(u)} dW(u) \\ &\quad + \sqrt{1 - \rho^2}\sqrt{x(u)} dW^*(u) \end{aligned} \quad (27)$$

where W^* is a Brownian motion independent of W . An integration yields

$$\begin{aligned} \ln Y(t + \Delta) &= \ln Y(t) + \frac{\rho}{\epsilon} (x(t + \Delta) - x(t) - \kappa\theta\Delta) \\ &\quad + \left(\frac{\kappa\rho}{\epsilon} - \frac{1}{2} \right) \int_t^{t+\Delta} x(u) du \\ &\quad + \sqrt{1 - \rho^2} \int_t^{t+\Delta} \sqrt{x(u)} dW^*(u) \end{aligned} \quad (28)$$

where we have used equation (26). Conditional on $x(t + \Delta)$ and $\int_t^{t+\Delta} x(u) du$, it is clear that the distribution of $\ln Y(t + \Delta)$ is Gaussian with easily computable moments. After first sampling $x(t + \Delta)$ from the noncentral chi-square distribution (as described in the section Exact Simulation), one then performs the following steps:

1. Conditional on $x(t + \Delta)$ (and $x(t)$) draw a sample of $I = \int_t^{t+\Delta} x(u) du$.
2. Conditional on $x(t + \Delta)$ and I , use equation (28) to draw a sample of $\ln Y(t + \Delta)$ from a Gaussian distribution.

While execution of the second step is straightforward, the first one is decidedly not, as the conditional distribution of the integral I is not known in closed form. In [4], the authors instead derive a characteristic function, which they numerically Fourier-invert to generate the cumulative distribution function for I , given $x(t + \Delta)$ and $x(t)$. Numerical inversion of this distribution function over a uniform random variable finally allows for generation of a sample of I . The total algorithm requires great care in numerical discretization to prevent introduction of noticeable biases and is further complicated by the fact that the characteristic function for I contains two modified Bessel functions.

The Broadie–Kaya algorithm is bias-free by construction, but its complexity and lack of speed is problematic in some applications. At the cost of introducing a (small) bias, [15] improves computational efficiency by introducing certain approximations to the characteristic function of time-integrated variance, enabling efficient caching techniques.

Other Schemes

Taylor-type Schemes. In their examination of “fixed” Euler schemes, Lord *et al.* [14] suggest simulation of the Heston model by combining equation (8) with the following scheme for $\ln Y$:

$$\begin{aligned} \ln \hat{Y}(t + \Delta) = & \ln \hat{Y}(t) - \frac{1}{2} \hat{x}(t)^+ \Delta \\ & + \sqrt{\hat{x}(t)^+} Z_Y \sqrt{\Delta} \end{aligned} \quad (29)$$

where Z_Y is a Gaussian $\mathcal{N}(0, 1)$ draw, correlated to Z in equation (8) with correlation coefficient ρ . For

the periods where $\hat{x}$ drops below zero in equation (8), the process for $\hat{Y}$ comes to a standstill.

Kahl and Jäckel [11] consider several alternative schemes for Y , the most prominent being the “IJK” scheme, defined as

$$\begin{aligned} \ln \hat{Y}(t + \Delta) = & \ln \hat{Y}(t) \\ & - \frac{\Delta}{4} (\hat{x}(t + \Delta) + \hat{x}(t)) + \rho \sqrt{\hat{x}(t)} Z \sqrt{\Delta} \\ & + \frac{1}{2} (\sqrt{\hat{x}(t + \Delta)} + \sqrt{\hat{x}(t)}) (Z_Y \sqrt{\Delta} - \rho Z \sqrt{\Delta}) \\ & + \frac{1}{4} \epsilon \rho \Delta (Z^2 - 1) \end{aligned} \quad (30)$$

Here, $\hat{x}(t + \Delta)$ and $\hat{x}(t)$ are meant to be simulated by the implicit Milstein scheme (5); again the correlation between the Gaussian samples Z_Y and Z is ρ .

Simplified Broadie–Kaya. We recall from the discussion earlier that the complicated part of the Broadie–Kaya algorithm was the computation of $\int_t^{t+\Delta} x(u) du$, conditional on $x(t)$ and $x(t + \Delta)$. Andersen [3] suggests a naive, but effective, approximation based on the idea that

$$\int_t^{t+\Delta} x(u) du \approx \Delta [\gamma_1 x(t) + \gamma_2 x(t + \Delta)] \quad (31)$$

for certain constants γ_1 and γ_2 . The constants γ_1 and γ_2 can be found by moment-matching techniques (using results from [8], p. 16), but [3] presents evidence that it will often be sufficient to use either an Euler-like setting ($\gamma_1 = 1, \gamma_2 = 0$) or a central discretization ($\gamma_1 = \gamma_2 = \frac{1}{2}$). In any case, equation (30) combined with equation (27) gives rise to a scheme for Y -simulation that can be combined with any basic algorithm that can produce $\hat{x}(t)$ and $\hat{x}(t + \Delta)$. Andersen [3] provides numerical results for the case where $\hat{x}(t)$ and $\hat{x}(t + \Delta)$ are simulated by the algorithms in the sections Truncated Gaussian and Quadratic-exponential; the results are excellent, particularly when the QE algorithm in the section Quadratic-exponential is used to sample x .

Martingale Correction. Finally, let us note that some of the schemes outlined above (including equation (29) and the one in the section Simplified Broadie–Kaya) generally do not lead to martingale-behavior of $\hat{Y}$; that is, $E(\hat{Y}(t + \Delta)) \neq E(\hat{Y}(t))$. For

the cases where the error $e = E(\hat{Y}(t + \Delta)) - E(\hat{Y}(t))$ is analytically computable, it is, however, straightforward to remove the bias by simply adding $-e$ to the sample value for $\hat{Y}(t + \Delta)$. Andersen [3] gives several examples of this idea.

Further Reading

In this article, we restricted ourselves to the presentation of relatively simple methods, which in the two-dimensional Heston model setting only require two variates per time step. Such schemes are often the most convenient in actual trading systems and for implementations that rely on Wiener processes built from low discrepancy numbers. More complicated high-order Taylor schemes, which often require extra variates, are described in [13]. The efficacy of such methods are, however, unproven in the specific setting of the Heston model.

In recent work, Alfonsi [1] constructs a second-order scheme for the CIR process, using a switching idea similar to that of the QE scheme. For the Heston process, Alfonsi develops a “second-order scheme candidate” involving three variates per time step; the numerical performance of the scheme compares favorably with Euler-type schemes.

End Notes

^aWe assume that Y is a martingale in the chosen measure; adding a drift is straightforward.

Variance Reduction

Classical convergence results for the Monte Carlo method show that the ratio $\sigma/\sqrt{n}$ governs its accuracy, n being the number of drawings and σ the variance of the random variable of which we compute the expectation. Variance reduction techniques consist in modifying the classical Monte Carlo method to reduce the order of magnitude of the simulation error. The basic idea behind variance reduction techniques consists in rewriting the quantity to be computed as the expectation of a random variable that has a smaller variance.

In other words, if the quantity to be computed is the expectation $E[X]$ of a real square integrable random variable X , variance reduction methods aim at finding an alternative representation $E(X) = E(Y) + C$, using another square integrable random variable Y such that $\text{Var}(Y) \leq \text{Var}(X)$, C being a computable constant.

The most widely used variance reduction methods are “importance sampling” and “control variate” methods. As such, distinct sections are devoted to them. We also describe other classical variance reduction methods: antithetic variables, stratified sampling, and conditioning. For each method, we give simple examples related to option pricing.

Control Variates

Let X be a real-valued random variable and assume that we want to compute its expectation using a Monte Carlo method. In this method we use Y , another square integrable random variable, called the *control variate*, to write $E(X)$ as

$$E(X) = E(X - Y) + E(Y) \quad (1)$$

When $E(Y)$ can be computed using an explicit formula and $\text{Var}(X - Y)$ is smaller than $\text{Var}(X)$, we can use a Monte Carlo method to estimate $E(X - Y)$, and add the known value of $E(Y)$. Note that a variance reduction can be obtained only if X and Y are *not* independent. In fact, the more dependent are X and Y or the nearer is Y to X , the better the control variate performs.

Let us illustrate this principle by simple financial examples.

Using Call–put Arbitrage Formula for Variance Reduction

In a financial context, the price of the underlying assets is usually a good source for control variate as under a risk neutral probability the expected value of the actualized price remains constant with time.

This idea is used when taking into account the call–put arbitrage relation. Let S_t be the price at time t of an asset, and denote by C the price of the European call option

$$C = E(e^{-rT} (S_T - K)_+) \quad (2)$$

and by P the price of the European put option

$$P = E(e^{-rT} (K - S_T)_+) \quad (3)$$

There exists a relation between the price of the put and the call, which does not depend on the models for the price of the asset, namely, the “call–put arbitrage formula”:

$$C - P = E(e^{-rT} (S_T - K)) = S_0 - Ke^{-rT} \quad (4)$$

This arbitrage formula, which remains true whatever the model, can be used to replace the computation of a call option price by a put option price.

Remark 1 For the Black–Scholes model explicit formulas for the variance of the put and the call options can be obtained. Often, the variance of the put option is smaller than the variance of the call option. Note that this is not always true but since the payoff of the put is bounded, whereas the payoff of the call is not, this is certainly true when volatility is large enough.

Remark 2 Observe that call–put relations can also be obtained for Asian options or index options.

For Asian options, set $\bar{S}_T = 1/T \int_0^T S_s ds$. We have

$$\begin{aligned} E((\bar{S}_T - K)_+) - E((K - \bar{S}_T)_+) \\ = E(\bar{S}_T) - K \end{aligned} \quad (5)$$

and, in the Black–Scholes model,

$$\begin{aligned} E(\bar{S}_T) &= \frac{1}{T} \int_0^T E(S_s) ds \\ &= \frac{1}{T} \int_0^T S_0 e^{rs} ds = S_0 \frac{e^{rT} - 1}{rT} \end{aligned} \quad (6)$$

The Kemna and Vorst Method for Asian Options

A variance reduction method based on the control variate is proposed in [11] for computing the value of a fixed-strike Asian option. The price of an average (or Asian) put option with fixed strike is

$$\mathbf{E} \left(e^{-rT} \left(K - \frac{1}{T} \int_0^T S_s ds \right)_+ \right) \quad (7)$$

where $(S_t, t \geq 0)$ is the Black–Scholes model

$$S_t = x \exp \left(\left(r - \frac{\sigma^2}{2} \right) t + \sigma W_t \right) \quad (8)$$

If σ and r are small enough, an expansion of the exponential function suggest that $1/T \int_0^T S_s ds$ can be approximated by $\exp(1/T \int_0^T \log(S_s) ds)$. This heuristic argument suggests to use Y , where

$$Y = e^{-rT} (K - \exp(Z))_+ \quad (9)$$

and $Z = 1/T \int_0^T \log(S_s) ds$, as a control variate. As the random variable Z is Gaussian, we can explicitly compute $\mathbf{E}(Y)$ using the (Black–Scholes-type) formula

$$\begin{aligned} \mathbf{E} \left((K - e^Z)_+ \right) &= K N(-d) \\ &- e^{\mathbf{E}(Z) + \frac{1}{2} \text{Var}(Z)} N \left(-d - \sqrt{\text{Var}(Z)} \right) \end{aligned} \quad (10)$$

where $d = (\mathbf{E}(Z) - \log(K)) / \sqrt{\text{Var}(Z)}$.

To have a working algorithm, it remains to sample

$$e^{-rT} \left(K - \frac{1}{T} \int_0^T S_s ds \right)_+ - Y \quad (11)$$

This method can be very efficient when $\sigma \approx 0.3$ by year, $r \approx 0.1$ by year and $T \approx 1$ year. Of course, for larger values of σ and r , the gain obtained with this control variate is less significant but this method still remains useful.

Index Options

A very similar idea can be used for pricing index options. Assume that S_t is given by the multidimensional Black–Scholes model. Let σ be a $p \times d$

matrix and $W^1, \dots, W^d$ be d independent Brownian motions. Denote by $(S_t, t \geq 0)$ the solution of

$$\begin{cases} dS_t^1 = S_t^1 (r dt + [\sigma dW_t]_1), & S_0^1 = x_1 \\ \dots \\ dS_t^p = S_t^p (r dt + [\sigma dW_t]_p), & S_0^p = x_p \end{cases} \quad (12)$$

where $[\sigma dW_t]_i = \sum_{j=1}^d \sigma_{ij} dW_t^j$. Note that this equation can be solved to get, for $i = 1, \dots, p$,

$$S_T^i = x_i e^{(r-1/2 \sum_{j=1}^d \sigma_{ij}^2)T + \sum_{j=1}^d \sigma_{ij} W_T^j} \quad (13)$$

Moreover, denote by I_t the value of an index $I_t = \sum_{i=1}^p a_i S_t^i$, where $a_1, \dots, a_p$ is a given set of positive numbers such that $\sum_{i=1}^p a_i = 1$. Suppose that we want to compute the price of a European index put option with payoff at time T given by $(K - I_T)_+$.

Consider I_T/m where $m = a_1 x_1 + \dots + a_p x_p$. Because $I_0/m = 1$, an expansion of the exponential function suggests approximation of I_T/m by Y_T/m , where Y_T is the lognormal random variable

$$Y_T = m e^{\sum_{i=1}^p a_i x_i / m \left(\left\{ r - \frac{1}{2} \sum_{j=1}^d \sigma_{ij}^2 \right\} T + \sum_{j=1}^d \sigma_{ij} W_T^j \right)} \quad (14)$$

As we can explicitly compute $\mathbf{E}[(K - Y_T)_+]$ using a Black–Scholes formula, this suggests to use the control variate $Z = (K - Y_T)_+$ and to sample $(K - I_T)_+ - (K - Y_T)_+$. We refer to Figure 1 to see the improvement in variance obtained when using this control variate in a multidimensional Black–Scholes model.

A Random Volatility Model

Consider the pricing of an option in a Black–Scholes model with stochastic volatility. The price $(S_t, t \geq 0)$ is the solution of the stochastic differential equation

$$dS_t = S_t (r dt + \sigma(Y_t) dW_t), \quad S(0) = x \quad (15)$$

where σ is a bounded function and Y_t is the solution of another stochastic differential equation

$$dY_t = b(Y_t) dt + c(Y_t) dW_t', \quad Y_0 = y \quad (16)$$

where $(W_t, t \geq 0)$ and $(W_t', t \geq 0)$ are two, not necessarily independent, Brownian motions. We want to

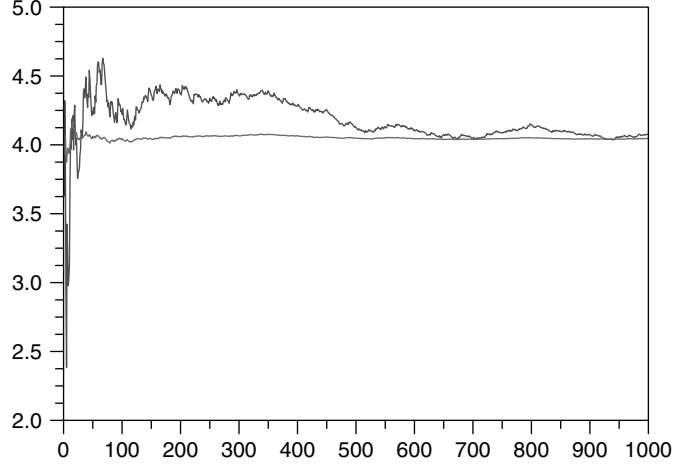

Figure 1 At the money index call option : with and without control variate, $d = 10$, $\sigma = 0.3/\sqrt{\text{year}}$ for each asset, every covariance equal to 0.5, $T = 1$

compute the price of a European option with payoff $f(S_T)$ at time T given by

$$\mathbf{E}(e^{-rT} f(S_T)) \quad (17)$$

If the volatility of the volatility (i.e., $c(Y_t)$) is not too large or if Y_t has an invariant law (as for the Ornstein–Uhlenbeck process) with mean σ_0 , we can expect σ_0 to be an acceptable approximation of σ_t .

This suggests the use of the control variate $e^{-rT} f(\bar{S}_T)$, where $\bar{S}_T$ is the solution of a Black–Scholes equation:

$$d\bar{S}_t = \bar{S}_t (r dt + \sigma_0 dW_t), \quad S(0) = x \quad (18)$$

For standard payoff f , $\mathbf{E}(e^{-rT} f(\bar{S}_T))$ can be obtained using a Black–Scholes-type formula; hence, it remains to sample

$$e^{-rT} f(S_T) - e^{-rT} f(\bar{S}_T) \quad (19)$$

and to check on simulations, using the standard estimate for the variance, that this procedure actually reduces the variance.

Using the Hedge as a Control Variate

In most standard financial models, a hedging strategy is available. This hedge can be used as a hint to construct a control variate.

Let $(S_t, t \geq 0)$ be the price of the asset. Assume that the price of the option at time t can be expressed

as $C(t, S_t)$ (this fact is satisfied for any Markovian model). When an explicit approximation $\bar{C}(t, x)$ of $C(t, x)$ is known, we can use the control variate

$$Y = \sum_{k=1}^N \frac{\partial \bar{C}}{\partial x}(t_k, S_{t_k}) \times ((S_{t_{k+1}} - S_{t_k}) - \mathbf{E}(S_{t_{k+1}} - S_{t_k})) \quad (20)$$

Note that $\mathbf{E}(Y) = 0$ by construction and so no correction is needed. If $\bar{C}$ is close to C and if N is large enough, a large reduction in the variance can be obtained.

Optimizing a Set of Control Variates

Assume that $Y = (Y^1, \dots, Y^n)$ is a given set of control variates with 0 expectation (or more generally having a known expectation) and finite variance. It is quite easy to optimize the control variate among all linear combinations of the coordinate of Y .

Let us denote by λ an $\mathbf{R}^n$ vector. As for every λ

$$\mathbf{E}(X) = \mathbf{E}(X - \langle \lambda, Y \rangle) \quad (21)$$

we can use $\langle \lambda, Y \rangle$ as a control variate and it is natural to choose λ to be the minimizer of the variance $\text{Var}(X - \langle \lambda, Y \rangle)$. A simple computation shows that this minimizer is given by

$$\lambda^* = \Gamma_Y^{-1} \text{Cov}(X, Y) \quad (22)$$

when Γ_Y , the covariance matrix of the vector Y , is invertible and where $\text{Cov}(X, Y) = (\text{Cov}(X, Y_i), 1 \leq i \leq n)$. Note that the optimizing λ^* can be estimated using independent samples of the law of (X, Y) , $((X_1, Y_1), \dots, (X_n, Y_n))$ and the standard estimators of the variances and the covariances of the random variables. This leads to a convergent estimator $\hat{\lambda}_n := \hat{\lambda}_n(X_1, Y_1, \dots, X_n, Y_n)$ of λ^* .

Using $\hat{\lambda}_n$ with an independent sample $((X'_1, Y'_1), \dots, (X'_n, Y'_n))$ leads to a convergent and *unbiased* estimator

$$E_n^1 = \frac{1}{n} \sum_{i=1}^n X'_i - \langle \hat{\lambda}_n, Y'_n \rangle \quad (23)$$

whereas using the same drawings leads to a convergent but *biased* estimator

$$E_n^2 = \frac{1}{n} \sum_{i=1}^n X_i - \langle \hat{\lambda}_n, Y_n \rangle \quad (24)$$

The bias of the second estimator is negligible, at least for large samples as it can be shown that the two estimators follow the same central limit theorem:

$$\sqrt{n} (E_n^i - \mathbf{E}(X)) \rightarrow \mathcal{N}(0, (\sigma^*)^2) \quad (25)$$

for $i = 1$ or 2 and where $(\sigma^*)^2$ is the best available variance

$$(\sigma^*)^2 = \min_{\lambda \in \mathbf{R}^d} \text{Var}(X - \langle \lambda, Y \rangle) \quad (26)$$

See [5, 12] for details and proofs on this technique known as *adaptive control variates*.

Perfect Control Variates for Diffusion Models

An interesting result is that perfect (zero-variance) control variates exist for diffusion models. Although the argumentation is mainly theoretical, it can give hints for implementation.

We want to compute $\mathbf{E}(Z)$ where $Z = \psi(X_s, 0 \leq s \leq T)$ and $(X_s, s \geq 0)$ is the solution of

$$dX_t = b(X_t) dt + \sigma(X_t) dW_t, \quad X(0) = x \quad (27)$$

We assume that $(X_t, t \geq 0)$ is $\mathbf{R}^n$ valued and $(W_t, t \geq 0)$ is an $\mathbf{R}^d$ -valued Brownian motion.

The *predictable representation theorem* shows that we are often able (at least theoretically) to cancel the variance using a stochastic integral as a control variate.

Theorem 1 (Predictable Representation Theorem). *Let Z be a random variable such that $\mathbf{E}(Z^2) < +\infty$. Assume that Z is measurable with respect to $\sigma(W_s, s \leq T)$. Then there exists a stochastic process $(H_t, t \leq T)$ adapted to the Brownian filtration, such that $\mathbf{E}\left(\int_0^T H_s^2 ds\right) < +\infty$ and*

$$Z = \mathbf{E}(Z) + \int_0^T H_s dW_s \quad (28)$$

For a proof we refer to [10, 15].

Remark 3 Note that Z needs to be measurable with respect to the σ -field generated by the Brownian motion.

The theorem shows that, in principle, we are able to cancel the variance of Z using a stochastic integral as a control variate. Nevertheless, the explicit computation of $(H_s, s \leq T)$ is much more complicated than the one of $\mathbf{E}(Z)$! The reader is referred to [14] for formulas for H_s involving Malliavin derivatives and conditional expectations. In financial applications, empirical methods are often used instead.

When the price of the underlying asset is described by a Markovian model X_t , the process $(H_t, t \leq T)$ can be written as $H_t = v(t, X_t)$, v being a function of t and x often related to the hedge in the context of financial models.

Theorem 2 *Let b and σ be two Lipschitz continuous functions. Let $(X_t, t \geq 0)$ be the unique solution of*

$$dX_t = b(X_t) dt + \sigma(X_t) dW_t, \quad X_0 = x \quad (29)$$

Denote by A the infinitesimal generator of this diffusion

$$\begin{aligned} Af(x) &= \frac{1}{2} \sum_{i,j=1}^n a_{ij}(x) \frac{\partial^2 f}{\partial x_i \partial x_j}(x) \\ &\quad + \sum_{j=1}^n b_j(x) \frac{\partial f}{\partial x_j}(x) \end{aligned} \quad (30)$$

where $a_{ij}(x) = \sum_{k=1}^d \sigma_{ik}(x) \sigma_{jk}(x)$.

Assume that there exists a $C^{1,2}([0, T] \times \mathbf{R}^d)$ function, with bounded derivatives in x , as solution to the problem

$$\begin{cases} \text{For } (t, x) \in [0, T] \times \mathbf{R}^n, \\ \left(\frac{\partial u}{\partial t} + Au \right)(t, x) = 0, \\ u(T, x) = g(x), \quad x \in \mathbf{R}^n \end{cases} \quad (31)$$

Then if $Z = g(X_T)$ and

$$Y = \int_0^T \frac{\partial u}{\partial x}(s, X_s) \sigma(s, X_s) dW_s \quad (32)$$

we have

$$\mathbf{E}(Z) = Z - Y \quad (33)$$

The random variable Y is, thus, a perfect control variate for Z .

Proof Using Itô's formula, we obtain

$$\begin{aligned} du(t, X_t) &= \left(\frac{\partial u}{\partial t} + Au \right)(t, X_t) dt \\ &\quad + \frac{\partial u}{\partial x}(t, X_t) \sigma(s, X_s) dW_t \end{aligned} \quad (34)$$

Now, integrate between 0 and T and take the expectation of both sides of the equality. Using the facts that u is a solution of equation (31) and that the stochastic integral is a martingale, we get

$$u(0, x) = Z - Y = \mathbf{E}(Z) \quad (35)$$

Remark 4 Theorem 2 shows that we only need to look for H_t as a function of t and X_t when X is a diffusion process. However, the explicit formula involves partial derivatives with respect to x and it is numerically difficult to take advantage of it.

In a practical situation, we can use the following heuristic procedure. Assume that we know an approximation $\bar{u}$ for u . The previous theorem suggests to use

$$Y = \int_0^T \frac{\partial \bar{u}}{\partial x}(t, X_t) \sigma(s, X_s) dW_t \quad (36)$$

as a control variate. Note that for every function $\bar{u}$ (even a bad approximation of u), we obtain an unbiased estimator for $\mathbf{E}(Z)$ by setting $Z' = Z - Y$. For a reasonable choice of $\bar{u}$, we can expect an improvement of the variance of the estimator. Indeed, set

$$\bar{Z} := g(X_T) - \int_0^T \frac{\partial \bar{u}}{\partial x}(t, X_t) \sigma(X_t) dW_t \quad (37)$$

$\bar{Z}$ is an unbiased estimator of $\mathbf{E}(g(X_T))$ and

$$\begin{aligned} &\mathbf{E}(|\bar{Z} - \mathbf{E}g(X_T)|^2) \\ &= \mathbf{E} \left(\int_0^T \left| \left(\frac{\partial u}{\partial x} - \frac{\partial \bar{u}}{\partial x} \right)(t, X_t) \right|^2 \sigma(t, X_t)^2 dt \right) \end{aligned} \quad (38)$$

This variance can be expected to be small if $\partial \bar{u} / \partial x$ is a good approximation of $\partial u / \partial x$.

Importance Sampling

Importance sampling methods proceed by *changing the law* of the samples. Assume that X takes its values in $\mathbf{R}^d$, ϕ is a bounded function from $\mathbf{R}^d$ to $\mathbf{R}$, and we want to compute $\mathbf{E}(\phi(X))$. The aim is to find a new random variable Y following a different law and a function i such that $\mathbf{E}(\phi(X)) = \mathbf{E}(i(Y)\phi(Y))$. The function i , the *importance function*, is needed to maintain the equality of the expectations for every function f . Obviously, this method is interesting in a Monte Carlo method only if $\text{Var}(i(Y)\phi(Y))$ is smaller than $\text{Var}(\phi(X))$.

Consider X as an $\mathbf{R}^d$ -valued random variable following a law with density $f(x)$ for which we want to compute $\mathbf{E}(\phi(X))$

$$\mathbf{E}(\phi(X)) = \int_{\mathbf{R}^d} \phi(x) f(x) dx \quad (39)$$

If $\tilde{f}$ is any density on $\mathbf{R}^d$ such that $\tilde{f}(x) > 0$ and $\int_{\mathbf{R}^d} \tilde{f}(x) dx = 1$, clearly one can rewrite $\mathbf{E}(\phi(X))$ as

$$\begin{aligned} \mathbf{E}(\phi(X)) &= \int_{\mathbf{R}^d} \frac{\phi(x) f(x)}{\tilde{f}(x)} \tilde{f}(x) dx \\ &= \mathbf{E} \left(\frac{\phi(Y) f(Y)}{\tilde{f}(Y)} \right) \end{aligned} \quad (40)$$

where Y is a random variable with density law $\tilde{f}(x)$ under $\mathbf{P}$. Hence, $\mathbf{E}(\phi(X))$ can be approximated by an alternative estimator

$$\frac{1}{n} \left(\frac{\phi(Y_1) f(Y_1)}{\tilde{f}(Y_1)} + \dots + \frac{\phi(Y_n) f(Y_n)}{\tilde{f}(Y_n)} \right) \quad (41)$$

where $(Y_1, \dots, Y_n)$ are independent copies of Y . Denoting $Z = \phi(Y) f(Y) / \tilde{f}(Y)$, this estimator will have a smaller asymptotic variance than the standard one if $\text{Var}(Z) < \text{Var}(\phi(X))$. Note that the variance of Z is given by

$$\text{Var}(Z) = \int_{\mathbf{R}} \frac{g^2(x) f^2(x)}{\tilde{f}(x)} dx - \mathbf{E}(\phi(X))^2 \quad (42)$$

An easy computation shows that when $\phi(x) > 0$, for every $x \in \mathbf{R}^d$, the choice of $\tilde{f}(x) = \phi(x) f(x) / \mathbf{E}(\phi(X))$ leads to a zero-variance estimator as

$\text{Var}(Z) = 0$. Of course, this result can seldom be used in practice as it relies on the exact knowledge of $\mathbf{E}(\phi(X))$, which is exactly what we need to compute. Nevertheless, it can lead to a useful heuristic approach : choose for $\tilde{f}(x)$ a good approximation of $|\phi(x)f(x)|$ such that $\tilde{f}(x)/\int_{\mathbf{R}} \tilde{f}(x) dx$ can be sampled easily.

An Elementary Gaussian Example

In finance, importance sampling is especially useful when computing multidimensional Gaussian expectations as all computations and simulations are completely explicit.

Let G be a Gaussian random variable with mean zero and unit variance. We want to compute $\mathbf{E}(\phi(G))$, for a function ϕ . We choose for the new sampling law, its shifted valued $\tilde{G} = G + m$, m being a real constant to be determined later; hence,

$$\mathbf{E}(\phi(G)) = \mathbf{E}\left(\phi(\tilde{G}) \frac{f(\tilde{G})}{\tilde{f}(\tilde{G})}\right) \quad (43)$$

where f is the density of the law of G and $\tilde{f}$ the density of the law of $\tilde{G}$. Easy computation leads to

$$\begin{aligned} \mathbf{E}(\phi(G)) &= \mathbf{E}\left(\phi(\tilde{G}) e^{-m\tilde{G} + (m^2/2)}\right) \\ &= \mathbf{E}\left(\phi(G + m) e^{-mG - (m^2/2)}\right) \end{aligned} \quad (44)$$

As a simple example of the use of equation (44), assume that we want to compute a European call option in the Black–Scholes model; ϕ is then given by

$$\phi(G) = (\lambda e^{\sigma G} - K)_+ \quad (45)$$

where λ , σ , and K are positive constants. When $\lambda \ll K$, $\mathbf{P}(\lambda e^{\sigma G} > K)$ is very small and the option will, very unlikely, be exercised. This fact leads to a very large relative error when using a standard Monte Carlo method. To increase to exercise probability, we can use equality (44) to obtain

$$\begin{aligned} &\mathbf{E}\left((\lambda e^{\sigma G} - K)_+\right) \\ &= \mathbf{E}\left((\lambda e^{\sigma(G+m)} - K)_+ e^{-mG - (m^2/2)}\right) \end{aligned} \quad (46)$$

and choose $m = m_0$ with $\lambda e^{\sigma m_0} = K$, since

$$\mathbf{P}(\lambda e^{\sigma(G+m_0)} > K) = \frac{1}{2} \quad (47)$$

This choice of m is certainly not optimal; however, it drastically improves the efficiency of the Monte Carlo method when $\lambda \ll K$. See Figure 2 for an illustration of the improvement, which can be obtained using this idea.

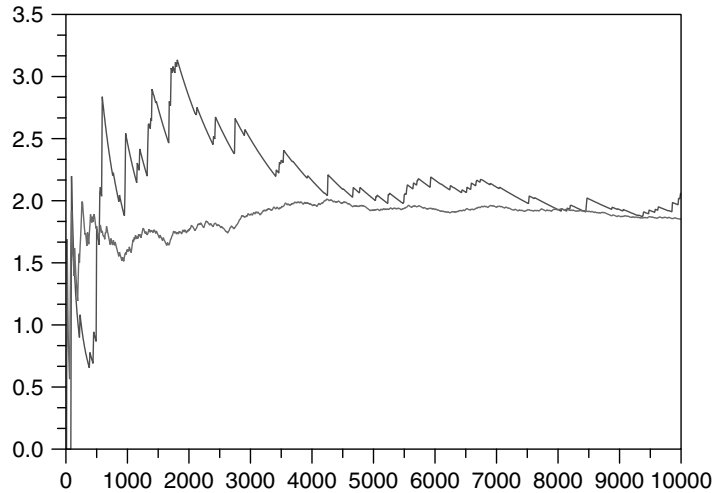

Figure 2 Call options: use of importance sampling for deep out-of-the-money call option $\sigma = 0.3/\sqrt{\text{year}}$, $S_0 = 70$, $K = 100$

A Multidimensional Gaussian Case: Index Options

The previous method can easily be extended to multidimensional Gaussian cases. Let us start by motivating this in the context of index option pricing. Denote by $(S_t, t \geq 0)$ a multidimensional Black–Scholes model solution of equation (13)

$$S_T^i = S_0^i \exp \left(\left(r - \frac{1}{2} \sum_{j=1}^d \sigma_{ij}^2 \right) T + \sum_{j=1}^d \sigma_{ij} W_T^j \right) \quad (48)$$

Moreover, denote I_t by the value of an index $I_t = \sum_{i=1}^n a_i S_t^i$, where $a_1, \dots, a_n$ is a given set of positive numbers such that $\sum_{i=1}^n a_i = 1$. Suppose that we want to compute the price of a European call or put option with payoff at time T given by $f(I_T)$. Obviously, there exists a function ϕ such that

$$f(I_T) = \phi(G_1, \dots, G_d) \quad (49)$$

where $G_j = W_T^j / \sqrt{T}$. The price of this option can be rewritten as $\mathbf{E}(\phi(G))$, where $G = (G_1, \dots, G_d)$ is a d -dimensional Gaussian vector with unit covariance matrix.

As in the one-dimensional case, it is easy (by a change of variable) to prove that if $m = (m_1, \dots, m_d)$, then

$$\mathbf{E}(\phi(G)) = \mathbf{E}(\phi(G + m) e^{-mG - (|m|^2/2)}) \quad (50)$$

where $m \cdot G = \sum_{i=1}^d m_i G_i$ and $|m|^2 = \sum_{i=1}^d m_i^2$. In view of equation (50), the second moment $V(m)$ of the random variable $X_m = \phi(G + m) e^{-m \cdot G - |m|^2/2}$ is

$$\begin{aligned} V(m) &= \mathbf{E}(\phi^2(G + m) e^{-2mG - |m|^2}) \\ &= \mathbf{E}(\phi^2(G) e^{-mG + |m|^2/2}) \end{aligned} \quad (51)$$

The choice of a minimizing m (or an approximation) is more difficult than in one dimension. From the previous formula, it follows that $V(m)$ is a strictly convex function, a property from which we can derive useful approximation methods for a minimizer of $V(m)$. The reader is referred to [6] for an almost optimal way to choose the parameter m or to [1, 2] for a use of stochastic algorithms to get convergent approximation of the m minimizing the variance $V(m)$.

The Girsanov Theorem and Path-dependent Options

We can extend further these techniques to path-dependent options, using the Girsanov theorem. Let $(S_t, t \geq 0)$ be the solution of

$$dS_t = S_t (r dt + \sigma dW_t), \quad S_0 = x \quad (52)$$

where $(W_t, t \geq 0)$ is a Brownian motion under a probability $\mathbf{P}$. We want to compute the price of a path-dependent option with payoff given by

$$\phi(S_t, t \leq T) = \psi(W_t, t \leq T) \quad (53)$$

Common examples of such a situation are

- Asian options whose payoff is given by $f(S_T, \int_0^T S_s ds)$ and
- Maximum options whose payoff is given by $f(S_T, \max_{s \leq T} S_s)$.

We start by considering the Brownian case that is a straightforward extension of the technique used in the preceding paragraph. For every real number λ , define the process $(W_t^\lambda, t \leq T)$ as

$$W_t^\lambda := W_t + \lambda t \quad (54)$$

According to the Girsanov theorem, $(W_t^\lambda, t \leq T)$ is a Brownian motion under the probability law $\mathbf{P}^\lambda$ defined by

$$\mathbf{P}^\lambda(A) = \mathbf{E}(L_T^\lambda \mathbf{1}_A), \quad A \in \mathcal{F}_T \quad (55)$$

where $L_T^\lambda = e^{-\lambda W_T - \lambda^2 T/2}$. Denote by $\mathbf{E}^\lambda$ the expectation under this new probability $\mathbf{P}^\lambda$. For every bounded function ψ we have

$$\begin{aligned} \mathbf{E}(\psi(W_t, t \leq T)) &= \mathbf{E}^\lambda(\psi(W_t^\lambda, t \leq T)) \\ &= \mathbf{E}(L_T^\lambda \psi(W_t^\lambda, t \leq T)) \end{aligned} \quad (56)$$

and thus

$$\begin{aligned} \mathbf{E}(\psi(W_t, t \leq T)) &= \mathbf{E}(e^{-\lambda W_T - (\lambda^2 T/2)} \psi(W_t + \lambda t, t \leq T)) \end{aligned} \quad (57)$$

For example, if we want to compute the price of a fixed-strike Asian option P given by

$$\mathbf{E} \left(e^{-rt} \left(\frac{1}{T} \int_0^T x e^{(r - (\sigma^2/2))s + \sigma W_s} ds - K \right) \right) \quad (58)$$

we can use the previous equality to obtain

$$P = \mathbf{E} \left(e^{-rt - \lambda W_T - \lambda^2 T/2} \left(\frac{1}{T} \int_0^T x e^{(r - \sigma^2/2)s + \sigma(W_s + \lambda s)} ds - K \right)_+ \right) \quad (59)$$

This representation can be used for deep out-of-the-money options (that is to say, $x \ll K$). Then λ can be chosen such that

$$\frac{x}{T} \int_0^T e^{(r - \sigma^2/2)s + \sigma \lambda s} ds = K \quad (60)$$

in order to increase the exercise probability.

Importance Sampling for the Poisson Process

Similar results can also be obtained for Poisson processes and can be useful to construct variance reduction methods for financial models with jumps.

Let $(N_s^\lambda, s \geq 0)$ be a Poisson process with intensity λ . Denote by

$$L_T^{\mu \rightarrow \lambda} = e^{T(\mu - \lambda)} \left(\frac{\lambda}{\mu} \right)^{N_T^\mu} \quad (61)$$

We have for every bounded functional f

$$\mathbf{E} \left(f(N_s^\lambda, s \leq T) \right) = \mathbf{E} \left(L_T^{\mu \rightarrow \lambda} f(N_s^\mu, s \leq T) \right) \quad (62)$$

See [4] for a proof and extensions. Note that the variance is given by $V(\lambda) = \mathbf{E}(X_\mu^2) - \mathbf{E}(X_\mu)^2$ where $X_\mu = L_T^{\mu \rightarrow \lambda} f(N_s^\mu, s \leq T)$ and

$$\begin{aligned} \mathbf{E}(X_\mu^2) &= \mathbf{E} \left(e^{T(\mu - \lambda)} \left(\frac{\lambda}{\mu} \right)^{N_T^\lambda} \right. \\ &\quad \left. \times f^2(N_t^\lambda, 0 \leq t \leq T) \right) \end{aligned} \quad (63)$$

From this formula, a convexity property in μ can be derived and optimization algorithms deduced from the Euler equation associated with the variance minimization problem.

This methodology can be useful for jump models in finance (e.g., the Merton model) by mixing a change of law on the underlying Brownian motion and on Poisson process.

Importance Sampling for Diffusion Processes

Following [14], we now present a result which proves that variance can be canceled using importance sampling for a diffusion process. The reader is also referred to [13] for the necessary background on simulation of diffusion processes.

Proposition 1 *Let Z be a random variable such that $Z = \psi(W_s, 0 \leq s \leq T)$, $\mathbf{E}(Z^2) < +\infty$ and $\mathbf{P}(Z \geq \epsilon) = 1$, for an $\epsilon > 0$.*

Then, there exists an adapted process $(h_t, 0 \leq t \leq T)$, such that, if

$$L_T = \exp \left(- \int_0^T h_s dW_s - \frac{1}{2} \int_0^T |h_s|^2 ds \right) \quad (64)$$

$\mathbf{E}(L_T) = 1$, then we can define a probability $\tilde{\mathbf{P}}$ by

$$\tilde{\mathbf{P}}(A) = \mathbf{E}(L_T \mathbf{1}_A) \quad (65)$$

Under this probability $\tilde{\mathbf{P}}$

$$\tilde{\mathbf{E}}(L_T^{-1} Z) = \mathbf{E}(Z) \text{ and } \tilde{\text{Var}}(L_T^{-1} Z) = 0 \quad (66)$$

Remark 5 Under $\tilde{\mathbf{P}}$, the random variable $L_T^{-1} Z$ has zero variance, and thus is almost surely constant. So if we are able to sample $L_T^{-1} Z$ under $\tilde{\mathbf{P}}$, we obtain a zero-variance estimator for $\mathbf{E}(Z)$.

Of course, an effective computation of h_t is almost always impossible. However, heuristic approximation methods can also be derived. We refer to [14] for an overview of some of these methods.

Proof The representation theorem for Brownian martingales proves the existence of a process $(H_t, t \leq T)$ such that, for $t \leq T$

$$\mathbf{E}(Z | \mathcal{F}_t) = \mathbf{E}(Z) + \int_0^t H_s dW_s \quad (67)$$

Let $\phi_t = \mathbf{E}(Z | \mathcal{F}_t) / \mathbf{E}(Z)$. Equality (67) becomes

$$\phi_t = 1 + \int_0^t \frac{H_s}{\mathbf{E}(Z)} dW_s = 1 - \int_0^t \phi_s h_s dW_s \quad (68)$$

This is a linear equation for ϕ , which can be solved to obtain

$$\begin{aligned} \phi_T &= \exp \left(- \int_0^T h_s dW_s - \frac{1}{2} \int_0^T |h_s|^2 ds \right) \\ &= L_T \end{aligned} \quad (69)$$

However, as Z is an $\mathcal{F}_T$ -measurable random variable, $L_T = \phi_T = Z/\mathbf{E}(Z)$. Thus, $\mathbf{E}(L_T) = 1$ and $L_T^{-1}Z = \mathbf{E}(Z)$ almost surely under $\mathbf{P}$ and $\tilde{\mathbf{P}}$.

The previous theorem can be used in a simulation context for diffusion processes. Let $(X_t, t \geq 0)$ be the unique solution of

$$\begin{aligned} dX_t &= b(X_t) dt + \sigma(X_t) dW_t, \\ X(0) &= x \end{aligned} \quad (70)$$

where b and σ are Lipschitz functions and $(W_t, t \geq 0)$ is a Brownian motion. If $(h_t, t \geq 0)$ is a process such that $\mathbf{E}(L_T) = 1$, then X is also a solution of

$$\begin{cases} dX_t = (b(X_t) - \sigma(X_t)h_t) dt + \sigma(X_t) d\tilde{W}_t \\ X(0) = x \end{cases} \quad (71)$$

where $(\tilde{W}_t = W_t + \int_0^t h_s ds, 0 \leq t \leq T)$ is a Brownian motion under the probability $\tilde{\mathbf{P}}$. Hence, we can, in principle, sample the process X under the new probability $\tilde{\mathbf{P}}$. This is easy when h_t can be written as $v(t, X_t)$, v being a function of t and x . Indeed, in this case, X satisfies the stochastic differential equation

$$dX_t = \tilde{b}(t, X_t) dt + \sigma(X_t) d\tilde{W}_t, \quad X(0) = x \quad (72)$$

with $\tilde{b}(t, x) = b(x) - \sigma(x)v(t, x)$. Since $\tilde{W}$ is a Brownian motion under $\tilde{\mathbf{P}}$, we can simulate X under $\tilde{\mathbf{P}}$ using a standard discretization scheme for this stochastic differential equation.

Now we give a more explicit formula for h_t when the random variable is given by

$$Z = e^{-\int_0^T r(X_s) ds} f(X_T) \quad (73)$$

when f and r are bounded positive functions and $(X_t, t \geq 0)$ is the $\mathbf{R}^d$ -diffusion process solution of equation (70). Note that such a Z has a form suitable for the computation of option or zero-coupon prices.

Assume that there exists a $C^{1,2}([0, T] \times \mathbf{R}^d)$ solution to

$$\begin{cases} u(T, x) = f(x) & \text{for } x \in \mathbf{R}^n \\ \left(\frac{\partial u}{\partial t} + Au - ru \right)(t, x) = 0 \\ \text{for } (t, x) \in [0, T] \times \mathbf{R}^n \end{cases} \quad (74)$$

where A is the infinitesimal generator of the diffusion $(X_t, t \geq 0)$ given by equation (30). Then

$$\begin{aligned} e^{-\int_0^t r(X_s) ds} u(t, X_t) &= u(0, x) \\ &+ \int_0^t e^{-\int_0^s r(X_u) du} \frac{\partial u}{\partial x}(s, X_s) \sigma(X_s) dW_s \end{aligned} \quad (75)$$

Assuming that the stochastic integral is a martingale, we have

$$\begin{aligned} &\mathbf{E} \left(e^{-\int_0^T r(X_s) ds} f(X_T) | \mathcal{F}_t \right) \\ &= \mathbf{E} \left(e^{-\int_0^T r(X_s) ds} u(T, X_T) | \mathcal{F}_t \right) \\ &= e^{-\int_0^t r(X_s) ds} u(t, X_t) \end{aligned} \quad (76)$$

Thus, we have $Z = \mathbf{E}(Z) + \int_0^T H_t dW_t$ with

$$H_t = e^{-\int_0^t r(X_s) ds} \frac{\partial u}{\partial x}(t, X_t) \sigma(X_t)$$

and

$$\begin{aligned} &\mathbf{E} \left(e^{-\int_0^T r(X_s) ds} f(X_T) | \mathcal{F}_t \right) \\ &= e^{-\int_0^t r(X_s) ds} u(t, X_t) \end{aligned} \quad (77)$$

Therefore, using the proof of Proposition 1, we can see that the process h_t defined by

$$\begin{aligned} h_t &= - \frac{e^{-\int_0^t r(X_s) ds} \frac{\partial u}{\partial x}(t, X_t) \sigma(X_t)}{e^{-\int_0^t r(X_s) ds} u(t, X_t)} \\ &= - \frac{\frac{\partial u}{\partial x}(t, X_t) \sigma(X_t)}{u(t, X_t)} \end{aligned} \quad (78)$$

allows to cancel the variance of the Monte Carlo method.

Remark 6 Note that, as h_t is a function of t and X_t , simulation is always possible in principle.

In practical terms, when we know (even rough) approximations $\bar{u}(t, x)$ of $u(t, x)$, it is natural to try to reduce the variance by substituting $\bar{u}$ for u in the previous formula. The reader is referred to [17] to see how large deviation theory can give a good approximation $\bar{u}$ and lead to effective variance reductions.

Antithetic Variables

Antithetic variables are widely used in Monte Carlo simulations because of generality and ease of implementation. Note, though, that it seldom leads to significant effects on the variance and, if not used with care, it can even lead to an increase of the variance.

First, let us consider a simple example, $I = \mathbf{E}(g(U))$ where U is uniformly distributed on the interval $[0, 1]$. As $1 - U$ has the same law as U

$$I = \mathbf{E}\left(\frac{1}{2}(g(U) + g(1 - U))\right) \quad (79)$$

Therefore, one can draw $2n$ independent random variables $U_1, \dots, U_{2n}$ following a uniform law on $[0, 1]$, and approximate I either by using

$$I_{2n}^0 = \frac{1}{2n}(g(U_1) + g(U_2) + \dots + g(U_{2n-1}) + g(U_{2n}))$$

or

$$I_{2n} = \frac{1}{2n}(g(U_1) + g(1 - U_1) + \dots + g(U_n) + g(1 - U_n)) \quad (80)$$

We can now compare the variances of I_{2n} and I_{2n}^0 . Observe that, in doing this, we assume that most of the numerical work relies on the evaluation of g and the time devoted to the simulation of the random variables is negligible; this is often a realistic assumption.

The variance of the two estimators are given, respectively, by

$$\begin{aligned} \text{Var}(I_{2n}^0) &= \frac{1}{2n} \text{Var}(g(U_1)) \\ \text{Var}(I_{2n}) &= \frac{1}{2n} (\text{Var}(g(U_1)) + \text{Cov}(g(U_1), g(1 - U_1))) \end{aligned} \quad (81)$$

Obviously, $\text{Var}(I_{2n}) \leq \text{Var}(I_{2n}^0)$ if and only if $\text{Cov}(g(U_1), g(1 - U_1)) \leq 0$. When g is either an increasing or a decreasing function, this can be shown to be true and thus the Monte Carlo method using antithetic variables (I_{2n}) is better than the standard one (I_{2n}^0).

This simple idea can be greatly generalized. If X is a random variable taking values in $\mathbf{R}^d$ (or even an infinite dimension space) and if T operates on $\mathbf{R}^d$ in

such a way that the law of X is preserved by T , we can construct a generalized antithetic method based on the equality

$$\mathbf{E}(g(X)) = 1/2 \mathbf{E}(g(X) + g(T(X))) \quad (82)$$

In other words, if $(X_1, \dots, X_{2n})$ are sampled along the law of X , we can consider the estimator

$$I_{2n} = \frac{1}{2n}(g(X_1) + g(T(X_1)) + \dots + g(X_n) + g(T(X_n))) \quad (83)$$

and compare it to

$$I_{2n}^0 = \frac{1}{2n}(g(X_1) + g(X_2) + \dots + g(X_{2n-1}) + g(X_{2n})) \quad (84)$$

The same computations as before prove that the estimator I_{2n} is better than the crude one I_{2n}^0 if and only if $\text{Cov}(g(X), g(T(X))) \leq 0$.

A Generic Example

Let T be the transformation from $\mathbf{R}^d$ to $\mathbf{R}^d$ defined by

$$(u^1, \dots, u^d) \rightarrow (1 - u^1, \dots, 1 - u^d) \quad (85)$$

Obviously, if $U = (U^1, \dots, U^d)$ is a vector of independent random variables, then the law of $T(U)$ is identical to the law of U . Hence, we can construct an antithetic estimator I_{2n} . It can be shown that this estimator improves upon the standard one when $f(u_1, \dots, u_d)$ is monotonic in each of its coordinates.

A Toy Financial Example

Let G be a standard Gaussian random variable. Clearly, the law of $-G$ and G are identical and we can consider the transformation $T(x) = -x$ to construct an antithetic method.

A very simple illustration is given by the call option in the Black–Scholes model where the payoff can be written as

$$\mathbf{E}\left((\lambda e^{\sigma G} - K)_+\right) \quad (86)$$

λ , σ , and K being positive real numbers. As this payoff is increasing as a function of G , the antithetic

estimator

$$I_{2n} = \frac{1}{2n} (g(G_1) + g(-G_1) + \dots + g(G_n) + g(-G_n)) \quad (87)$$

with $g(x) = (\lambda e^{\sigma x} - K)_+$, certainly reduces the variance.

This example can be easily extended to the (more useful) multidimensional Gaussian case, when $G = (G^1, \dots, G^d)$ are independent standard Gaussian random variables.

Antithetic Variables for Path-dependent Options

The antithetic variables method can also be applied to path-dependent options. For this, consider a path-dependent payoff $\psi(S_s, s \leq T)$, where $(S_t, t \geq 0)$ follows the Black–Scholes model

$$S_t = x \exp((r - 1/2\sigma^2)t + \sigma W_t) \quad (88)$$

$(W_t, t \geq 0)$ is a Brownian motion, r and σ positive real numbers. As the law of $(-W_t, t \geq 0)$ is identical to the law of $(W_t, t \geq 0)$

$$\begin{aligned} \mathbf{E} \left(\psi \left(x e^{(r-1/2\sigma^2)s + \sigma W_s}, s \leq T \right) \right) \\ = \mathbf{E} \left(\psi \left(x e^{(r-(1/2)\sigma^2)s - \sigma W_s}, s \leq T \right) \right) \end{aligned} \quad (89)$$

An antithetic method can be constructed using this equality.

Stratified Sampling

Stratified sampling aims at decomposing the computation of an expectation into specific subsets (called strata). Suppose we want to compute $I = \mathbf{E}(g(X))$, where X is an $\mathbf{R}^d$ -valued random variable and g a bounded measurable function from $\mathbf{R}^d$ to $\mathbf{R}$.

Let $(D_i, 1 \leq i \leq m)$ be a partition of $\mathbf{R}^d$. I can be expressed as

$$I = \sum_{i=1}^m \mathbf{E}(g(X)|X \in D_i) \mathbf{P}(X \in D_i) \quad (90)$$

where

$$\mathbf{E}(g(X)|X \in D_i) = \frac{\mathbf{E}(\mathbf{1}_{\{X \in D_i\}} g(X))}{\mathbf{P}(X \in D_i)} \quad (91)$$

Note that $\mathbf{E}(g(X)|X \in D_i)$ can be interpreted as $\mathbf{E}(g(X^i))$, where X^i is a random variable whose law is the law of X conditioned to belong to D_i . When X has a density given by $f(x)$, this conditional law also has a density given by

$$\frac{1}{\int_{D_i} f(y) dy} \mathbf{1}_{\{x \in D_i\}} f(x) dx$$

When we further assume that the numbers $p_i = \mathbf{P}(X \in D_i)$ can be explicitly computed, one can use a Monte Carlo method to approximate each conditional expectation $I_i = \mathbf{E}(g(X)|X \in D_i)$ by

$$\tilde{I}_i = \frac{1}{n_i} (g(X_1^i) + \dots + g(X_{n_i}^i)) \quad (92)$$

where $(X_1^i, \dots, X_{n_i}^i)$ are independent copies of X^i . An estimator $\tilde{I}$ of I is then given by

$$\tilde{I} = \sum_{i=1}^m p_i \tilde{I}_i \quad (93)$$

Of course, the samples used to compute $\tilde{I}_i$ are supposed to be independent and so the variance of $\tilde{I}$ is $\sum_{i=1}^m p_i^2 (\sigma_i^2 / n_i)$, where σ_i^2 be the variance of $g(X^i)$.

By fixing the total number of simulations $\sum_{i=1}^m n_i = n$ and minimizing the above variance, we obtain an *optimal allocation of points* in the strata

$$n_i = n \frac{p_i \sigma_i}{\sum_{i=1}^m p_i \sigma_i} \quad (94)$$

For these values of n_i , the variance of $\tilde{I}$, given in this case by $1/n (\sum_{i=1}^m p_i \sigma_i)^2$, is always smaller than the one obtained without stratification.

Remark 7 The optimal stratification involves the σ_i s which are almost never explicitly known. So one needs to estimate these σ_i s by some preliminary Monte Carlo simulations.

Moreover, let us underline that a bad repartition of n_i may *increase* the variance of the estimator.

A common way to circumvent these difficulties is to choose a *proportional repartition*: $n_i = n p_i$. The corresponding variance $1/n \sum_{i=1}^m p_i \sigma_i^2$, is still smaller than the original one, but not optimal. This choice is often made especially when the probabilities p_i are explicit.

For more considerations on the choice of the n_i and for hints on suitable choices of the sets D_i , see [3].

A Toy Financial Example

In the standard Black–Scholes, model the price of a call option is given by

$$\mathbf{E} \left((\lambda e^{\sigma G} - K)_+ \right) \quad (95)$$

It is natural to use the following strata for G : $\{G \leq d\}$ or $\{G > d\}$, where $d = \log(K/\lambda)/\sigma$. Of course the variance of the stratum $G \leq d$ is equal to 0. So, in the optimal allocation, we have to simulate only one point in this stratum: all other points have to be drawn in the stratum $G \geq d$. This can be done by using the (numerical) inverse of the cumulative distribution function of a Gaussian random variable.

Index Options

A European call or put index option in the multi-dimensional Black–Scholes model can be expressed as $\mathbf{E}(h(G))$, for $G = (G_1, \dots, G_n)$ a vector of independent standard Gaussian random variables and for some complicated but explicit function h from $\mathbf{R}^n$ to $\mathbf{R}$.

Now, choose a vector $u \in \mathbf{R}^n$ such that $|u| = 1$ (so $\langle u, G \rangle = \sum_{i=1}^n u_i G_i$ is also a standard Gaussian random variable) and a partition $(B_i, 1 \leq i \leq n)$ of $\mathbf{R}$ such that

$$\mathbf{P}(\langle u, G \rangle \in B_i) = \mathbf{P}(G_1 \in B_i) = 1/n \quad (96)$$

This can be done by setting $B_i =]N^{-1}((i-1)/n), N^{-1}(i/n)]$, where N is the cumulative distribution function of a standard Gaussian random variable and N^{-1} is its inverse. Then define the $\mathbf{R}^n$ -strata by $D_i = \{u \in \mathbf{R}^n, \langle u, x \rangle \in B_i\}$.

In order to implement a stratification method based on these strata, we need first to sample the Gaussian random variable $\langle u, G \rangle$ given that $\langle u, G \rangle$ belongs to B_i , then to sample the vector G when knowing already the value $\langle u, G \rangle$.

The first point is easy since, if U is uniformly distributed on $[0, 1]$, then the law of $N^{-1}((i-1)/n) + (U/N)$ is precisely the law of a standard Gaussian random variable conditioned to be in B_i .

To solve the second point, observe that $G - \langle u, G \rangle u$ is a Gaussian vector independent of

$\langle u, G \rangle$. So if Y is a copy of the vector G , $G = \langle u, G \rangle u + G - \langle u, G \rangle u$ and $\langle u, G \rangle u + Y - \langle u, Y \rangle u$ have the same distribution. This leads to a very simple simulation method for G given $\langle u, G \rangle = \lambda$ and to an effective way to implement the suggested stratification method.

Note that this method can be made efficient by choosing a good vector u . An almost optimal way to choose the vector u can be found in [6].

Conditioning

This method uses the well-known fact that conditioning reduces the variance. Indeed, for any square integrable random variable Z , we have

$$\mathbf{E}(Z) = \mathbf{E}(\mathbf{E}(Z|\mathcal{B})) \quad (97)$$

where $\mathcal{B}$ is any σ -algebra defined on the same probability space as Z . When, in addition, Z is square integrable, the conditional expectation is an L^2 projection so

$$\mathbf{E}(\mathbf{E}(Z|\mathcal{B})^2) \leq \mathbf{E}(Z^2) \quad (98)$$

and thus $\text{Var}(\mathbf{E}(Z|\mathcal{B})) \leq \text{Var}(Z)$.

When Y is a random variable defined on the same probability space as X and $\mathcal{B} = \sigma(Y)$, it is well known that $\mathbf{E}(Z|\sigma(Y))$ can be written as

$$\mathbf{E}(Z|Y) := \mathbf{E}(Z|\sigma(Y)) = \phi(Y) \quad (99)$$

for some measurable function ϕ and the practical efficiency of simulating $\phi(Y)$ instead of Z heavily relies on getting an explicit formula for the function ϕ . This can be achieved when $Z = f(X, Y)$, where X and Y are independent random variables. In this case, we have

$$\mathbf{E}(f(X, Y)|Y) = \phi(Y) \quad (100)$$

where $\phi(y) = \mathbf{E}(f(X, y))$.

A Basic Example

Suppose that we want to compute $\mathbf{P}(X \leq Y)$, where X and Y are independent random variables. This occurs in finance, in a slightly more complex setting, when computing the hedge of an exchange option (or the price of a digital exchange option). We have

$$\mathbf{P}(X \leq Y) = \mathbf{E}(F(Y)) \quad (101)$$

where $F(x) = \mathbf{P}(X \leq x)$ is the distribution function of X . This can be used to obtain a variance reduction which can be significant, especially when the probability $\mathbf{P}(X \leq Y)$ is small.

A Financial Example: A Stochastic Volatility Model

Let $(W_t, t \geq 0)$ be a Brownian motion and r be a real number. Assume that $(S_t, t \geq 0)$ follows a Black–Scholes model with stochastic volatility, which is solution of

$$dS_t = S_t (r dt + \sigma_t dW_t), \quad S_0 = x \quad (102)$$

where $(\sigma_t, t \geq 0)$ is a given continuous stochastic process independent of the Brownian motion $(W_t, t \geq 0)$. We want to compute the option price

$$\mathbf{E} (e^{-rT} f(S_T)) \quad (103)$$

where f is a bounded measurable function. Clearly S_T can be expressed as

$$S_T = x \exp \left(rT - \frac{1}{2} \int_0^T \sigma_t^2 dt + \int_0^T \sigma_t dW_t \right) \quad (104)$$

As the processes $(\sigma_t, t \geq 0)$ and $(W_t, t \geq 0)$ are independent, $\left(\int_0^T \sigma_t^2 dt, \int_0^T \sigma_t dW_t \right)$ has the same law as

$$\left(\int_0^T \sigma_t^2 dt, \sqrt{\frac{1}{T} \int_0^T \sigma_t^2 dt} \times W_T \right) \quad (105)$$

Conditioning with respect to the process $(\sigma_t, 0 \leq t \leq T)$, we obtain

$$\begin{aligned} \mathbf{E} (e^{-rT} f(S_T)) &= \mathbf{E} (\mathbf{E} [e^{-rT} f(S_T) | \sigma_t, 0 \leq t \leq T]) \\ &= \mathbf{E} (\psi(\sigma_t, 0 \leq t \leq T)) \end{aligned} \quad (106)$$

where, for a fixed volatility path $(v_t, 0 \leq t \leq T)$,

$\psi(v_t, 0 \leq t \leq T)$

$$\begin{aligned} &= \mathbf{E} \left(e^{-rT} f \left(x e^{rT - \int_0^T v_t^2/2 dt + W_T \sqrt{1/T \int_0^T v_t^2 dt}} \right) \right) \\ &= \phi \left(\sqrt{\frac{1}{T} \int_0^T v_t^2 dt} \right) \end{aligned} \quad (107)$$

$\phi(\sigma)$ being the price of the option in the standard Black–Scholes model with volatility σ , that is

$$\phi(\sigma) = \mathbf{E} \left(e^{-rT} f \left(x e^{(r - (\sigma^2/2))T + \sigma W_T} \right) \right) \quad (108)$$

Hence, we only need to sample $\int_0^T \sigma_t^2 dt$ in order to use a Monte Carlo method using the random variable $\psi(\sigma_t, 0 \leq t \leq T)$.

Additional References

For complements, we refer the reader to classical books devoted to Monte Carlo methods ([7, 9, 16, 18]). For a more specific discussion of Monte Carlo methods in finance see [5, 8].

Weighted Monte Carlo

Weighted Monte Carlo (WMC) is the name given to an algorithm used to build and calibrate asset-pricing models for financial derivatives. The algorithm combines two fixtures of the toolbox of quantitative modeling. One is Monte Carlo simulation to generate “paths” for rates and market prices on which derivatives are written [7, 9]. The other is the maximum entropy (ME) criterion, used to calculate *a posteriori* statistical weights for the paths. ME is one of the main tools in science for calculating *a posteriori* probabilities in the presence of known constraints associated with the probability measure (see [8] for classical econometric applications of ME).

The essence of the method is as follows [3]: let $X_t(\omega)$, $0 \leq t \leq T$, $\omega \in \Omega$ represent a model for the evolution of market variables or factors of interest. One of the most common applications is the case when X_t is a multivariate diffusion or jump diffusion process, *for example*,

$$dX_{\alpha t} = \sum_j \sigma_{\alpha j} dW_{jt} + \mu_{\alpha} dt, \quad 1 \leq \alpha \leq n, \quad 1 \leq j \leq m \quad (1)$$

This process represents an *a priori* model for the joint forward evolution of the market. The parameters of the model, σ, μ typically correspond to econometrically estimated factors and expected returns. We note that, since the model is used for pricing derivatives, some of the parameters can also be implied from the prices of at-the-money options and forward prices. In the language of financial economics, the measure induced by X_t is either the “physical measure” or a hybrid of the physical measure and a risk-neutral measure with respect to select observable forwards and implied volatilities.

A Monte Carlo simulation of the ensemble with N paths is generated numerically, where the paths are denoted by ω_k , that is, they can be viewed as a sampling of the probability space Ω . The WMC algorithm calibrates the Monte Carlo model so that it fits the current market prices of M *benchmarks* or reference European-style derivatives, with discounted payoffs $g_1(\omega), g_2(\omega), \dots, g_N(\omega)$ and prices $c_1, c_2, \dots, c_M$. We denote the discounted payoffs along the simulated

paths by

$$G_{ik} = g_i(\omega_k), \quad i = 1, \dots, M, \quad k = 1, \dots, N \quad (2)$$

WMC associates a probability $p_k, k = 1, \dots, N$ to each path, in such a way that the pricing equations

$$c_i = \sum_{k=1}^N G_{ik} p_k \quad (3)$$

or $\mathbf{c} = \mathbf{G}\mathbf{p}$ in vector notation, hold for all indices i . Clearly, equation (3) states that the model reprices correctly the M reference instruments. In general, we assume that the number of simulation paths is much larger than the number of benchmarks (options, forwards), which is what happens in practical situations. The choice of the probabilities is done by applying the criterion of ME, that is, by maximizing

$$H(p_1, \dots, p_N) = - \sum_{k=1}^N p_k \log p_k \quad (4)$$

subject to the M constraints in equation (3). A *least-squares* version of the algorithm least squares weighted Monte Carlo (LSWMC) proposes to solve the problem

$$\min_{\mathbf{p}} \left\{ \sum_{i=1}^M \left(\sum_{k=1}^N G_{ik} p_k - c_i \right)^2 - 2\epsilon H(\mathbf{p}) \right\} \quad (5)$$

Here, $\epsilon > 0$ is a tolerance parameter that must be adjusted by the user. If $\epsilon \ll 1$, LSWMC corresponds to the classical WMC. For finite, relatively small, values of ϵ the algorithm returns, an approximate solution of equation (3). In practice, the implementation (5) is recommended, since a solution will exist for arbitrary data $\{G_{ik}, c_i\}$.

Dual Formulation

The WMC (LSWMC) algorithm is usually solved in its *dual form*. Define the partition function

$$Z(\lambda_1, \dots, \lambda_M) = \sum_{k=1}^N e^{\sum_{i=1}^M \lambda_i G_{ik}} \quad (6)$$

where $\lambda_1, \dots, \lambda_M$ are Lagrange multipliers. The dual problem is

$$\min_{\lambda} \left\{ \log Z(\lambda) - \sum_{i=1}^M c_i \lambda_i + \frac{\epsilon}{2} \sum_{i=1}^M \lambda_i^2 \right\} \quad (7)$$

The advantage of solving the dual problem is that the number of variables is M , hence much less than the number of simulated paths. It is well known that the latter problem is convex in λ and always admits a solution if $\epsilon > 0$. Furthermore, the probabilities are given explicitly in terms of the multipliers, which solve the dual problem, namely,

$$p_k = \frac{1}{Z} e^{\sum_{i=1}^M \lambda_i G_{ik}} \quad k = 1, 2, \dots, N \quad (8)$$

In practical implementations, the dual problem can be solved with a gradient-based convex optimization routine such as L-BFGS.

Connection with Kullback–Leibler Relative Entropy

We can view WMC as an algorithm that minimizes, in a discrete setting, the relative entropy, or Kullback–Leibler distance between the prior probability measure induced by the paths (3) (call it P_0) and the posterior measure induced by the probability vector $\mathbf{p}$ (call it P), in the sense that it provides a solution of

$$\min_P \left\{ 2\epsilon D(P||P_0) + \sum_{i=1}^M [E^P(g_i(\omega)) - c_i]^2 \right\} \quad (9)$$

with

$$D(P||P_0) = E^P \left(\log \frac{dP}{dP_0} \right) \quad (10)$$

where $\frac{dP}{dP_0}$ is the Radon–Nikodym derivative of P with respect to P_0 . The latter interpretation, however, should be taken with a grain of salt since the implementation is always done in the discrete setting, ensuring that the relative entropy between two measures defined on the paths of the MC simulation is always well defined (unlike in the continuous limit, where absolute continuity in Wiener space is often a stringent condition).

Connection with Utility Maximization

It can be shown, *via* an analysis of the dual problem, that the WMC algorithm gives a pricing measure, which corresponds to optimal investment by a representative investor in the reference instruments when this investor has an exponential utility [6].

Main Known Applications

Some of the most well-known applications of this method have been in the context of multiasset equity derivatives. In this case, the *a priori* measure corresponds to a multidimensional diffusion for stock prices, generated using a factor model (or model for the correlation matrix). The *a posteriori* measure is generated by calibrating to traded options on several underlying assets. For instance, the underlying stocks can be the components of the Nasdaq 100 index and the reference instruments all listed options on the underlying stocks. In the latter case, some care must be taken with the fact that listed options are American-style, but this difficulty can be overcome by generating prices of European options using the implied volatilities of the traded options. This yields a calibrated multiasset pricer for derivatives defined on the components of the Nasdaq 100. As a general rule, it is recommended to calibrate to forward prices (zero-strike calls) in addition to options, to ensure put–call parity in the *a posteriori* measure. The value $\epsilon = 0.25$ seems to give results that are within the bid–ask spread of listed options contracts [1, 2].

Another application of WMC is to the calibration of volatility surfaces for foreign-exchange (FX) options, to obtain a volatility surface that matches forward prices, at-the-money options, strangles, and risk-reversals on all available maturities. Owing to the nature of quotes in FX, the recommended value for the tolerance parameter should be of the order of 10^{-4} in this case [1, 2].

Applications of WMC have been also proposed in the context of credit derivatives, most notably for calibrating so-called top-down models [5].

Dispersion Trading

Dispersion trading corresponds to buying and selling index options and hedging with options on the component stocks. WMC gives a method for obtaining a model price for index options based on a model,

which incorporates a view of the correlation between stocks (expressed in the *a priori* probability for X_t) and is calibrated to all the options on the components of the index. Comparing the model price (or implied volatility) with the implied volatility of index options quoted in the market provides a rational setting for comparing the prices of index options with the prices of options on the components of the index. One of the important features of WMC is that it allows the user to incorporate views on the volatility skew/smile of the components in the valuation process [1, 2].

Connection to Control Variates

The WMC framework can be generalized to any concave function $H(\mathbf{p})$. Avellaneda and Gamba [4] suggest, as one practical approach,

$$H(\mathbf{p}) = -\sum_{k=1}^N \Psi(p_k) \quad (11)$$

with $\Psi(\cdot)$ being any convex function. Obvious choices are

$$\Psi^{(Q)}(p) = \left(p - \frac{1}{N}\right)^2 \quad (\text{Quadratic}) \quad (12)$$

$$\Psi^{(S)}(p) = p \log p \quad (\text{Shannon}) \quad (13)$$

The problem of minimization of $-H(\mathbf{p})$ subject to the constraints (probability normalization and calibration)

$$1 = \mathbf{p}^\top \mathbf{n} \quad \text{and} \quad \mathbf{c} = G\mathbf{p} \quad (14)$$

with the diagonal vector $\mathbf{n} := (1, \dots, 1)^\top \in \mathbb{R}^N$ (to simplify summation notation), leads to the Lagrange function

$$\mathcal{L}(\mathbf{p}, \boldsymbol{\lambda}, \mu) = -H(\mathbf{p}) - \boldsymbol{\lambda}^\top (G\mathbf{p} - \mathbf{c}) - \mu (\mathbf{p}^\top \mathbf{n} - 1) \quad (15)$$

Assuming the existence of an extremum, solving

$$\nabla_{\mathbf{p}} \mathcal{L}(\mathbf{p}, \boldsymbol{\lambda}, \mu) = 0 \quad (16)$$

gives

$$p_k = \psi^{-1}(\boldsymbol{\lambda}^\top G\mathbf{e}_k + \mu) \quad (17)$$

with $\psi(p) = \frac{d\Psi(p)}{dp}$ and $\mathbf{e}_k$ being the unit vector along the k -th axis in $\mathbb{R}^N$. For the specific choices (12) and (13), this means

$$p_k^{(Q)} = \frac{1}{N} + \frac{1}{2} \boldsymbol{\lambda}^\top G(\mathbf{e}_k - \frac{1}{N} \mathbf{n}) \quad (\text{Quadratic}) \quad (18)$$

$$p_k^{(S)} = \frac{e^{\boldsymbol{\lambda}^\top G\mathbf{e}_k}}{Z(\boldsymbol{\lambda})} \quad (\text{Shannon}) \quad (19)$$

with $Z(\boldsymbol{\lambda}) = \sum_{k=1}^N e^{\boldsymbol{\lambda}^\top G\mathbf{e}_k}$, where we have eliminated μ using the probability normalization condition $1 = \mathbf{p}^\top \mathbf{n}$. Substituting equation (18) and, respectively, equation (19), back into equation (15) leads to the Lagrange dual functions

$$\hat{\mathcal{L}}^{(Q)}(\boldsymbol{\lambda}) = \boldsymbol{\lambda}^\top (\mathbf{c} - G\frac{\mathbf{n}}{N}) + \frac{N}{2} \boldsymbol{\lambda}^\top G \left(\frac{\mathbf{n}\mathbf{n}^\top}{N^2} - \frac{1}{N} \right) G^\top \boldsymbol{\lambda} \quad (20)$$

$$\hat{\mathcal{L}}^{(S)}(\boldsymbol{\lambda}) = \boldsymbol{\lambda}^\top \mathbf{c} - \log Z(\boldsymbol{\lambda}) \quad (21)$$

The dual formulation of the original problem is to find

$$\arg \max_{\boldsymbol{\lambda}} \hat{\mathcal{L}}(\boldsymbol{\lambda}) \quad (22)$$

For the quadratic case, this is guaranteed to have at least one solution given by the linear system

$$\frac{N}{2} G \left(\frac{1}{N} - \frac{\mathbf{n}\mathbf{n}^\top}{N^2} \right) G^\top \boldsymbol{\lambda}^{(Q)} = \mathbf{c} - G\frac{\mathbf{n}}{N} \quad (23)$$

Note that

$$G \left(\frac{1}{N} - \frac{\mathbf{n}\mathbf{n}^\top}{N^2} \right) G^\top = \langle \mathbf{g}\mathbf{g}^\top \rangle_N^{P_0} - \langle \mathbf{g} \rangle_N^{P_0} \langle \mathbf{g} \rangle_N^{P_0\top} \quad (24)$$

$$= \langle \mathbf{g}, \mathbf{g} \rangle_N^{P_0} \quad (25)$$

where $\langle \cdot \rangle_N^{P_0}$ stands for the Monte Carlo estimator of the expectation under the original measure P_0 computed as the plain average over the N simulated paths, and $\langle \cdot, \cdot \rangle_N^{P_0}$ for the according covariance (defined such that $\langle \mathbf{a}, \mathbf{b} \rangle = \langle \mathbf{b}, \mathbf{a} \rangle^\top$). In other words,

$$\boldsymbol{\lambda}^{(Q)} = \frac{2}{N} \langle \mathbf{g}, \mathbf{g} \rangle_N^{P_0^{-1}} \cdot \left(\mathbf{c} - \langle \mathbf{g} \rangle_N^{P_0} \right) \quad (26)$$

and

$$\mathbf{p}^{(Q)} = \frac{\mathbf{n}}{N} + \left(\frac{\mathbf{n}}{N} - \frac{\mathbf{n}\mathbf{n}^\top}{N^2} \right) G^\top \cdot \langle \mathbf{g}, \mathbf{g} \rangle_N^{P_0^{-1}} \cdot \left(\mathbf{c} - \langle \mathbf{g} \rangle_N^{P_0} \right) \quad (27)$$

Note that the inverse of the autocovariance matrix of the calibration instruments is to be understood in a Moore–Penrose sense to safeguard against the singular case.

When using these probabilities for the valuation of a payoff v , with $v_k := v(\omega_k)$, we arrive at

$$\langle v \rangle_N^{P^{(Q)}} = \mathbf{v}^\top \mathbf{p}^{(Q)} \quad (28)$$

$$= \langle v \rangle_N^{P_0} + \langle v, \mathbf{g} \rangle_N^{P_0} \langle \mathbf{g}, \mathbf{g} \rangle_N^{P_0^{-1}} \cdot \left(\mathbf{c} - \langle \mathbf{g} \rangle_N^{P_0} \right) \quad (29)$$

which is identical to the classic control variate rule [7, 9].

For $\hat{\mathcal{L}}^{(S)}(\boldsymbol{\lambda})$, a second-order expansion in $\boldsymbol{\lambda}$ around zero gives

$$\begin{aligned} \hat{\mathcal{L}}^{(S)} &= -\log N + \boldsymbol{\lambda}^\top \left(\mathbf{c} - \langle \mathbf{g} \rangle_N^{P_0} \right) \\ &\quad - \frac{1}{2} \boldsymbol{\lambda}^\top \langle \mathbf{g}, \mathbf{g} \rangle_N^{P_0} \boldsymbol{\lambda} + \mathcal{O}(\boldsymbol{\lambda}^3) \end{aligned} \quad (30)$$

and hence we obtain the analytical initial guess

$$\boldsymbol{\lambda}^{(S),1} := \frac{N}{2} \boldsymbol{\lambda}^{(Q)} \quad (31)$$

for any iterative procedure to solve (22). A simple algorithm can be based on a second-order expansion of $\hat{\mathcal{L}}^{(S)}(\boldsymbol{\lambda})$ around the previous iteration's estimate for $\boldsymbol{\lambda}^{(S)}$. This gives

$$\begin{aligned} \boldsymbol{\lambda}^{(S),i+1} &= \boldsymbol{\lambda}^{(S),i} \\ &\quad + \left(G \Pi^{(S),i} G^\top - G \mathbf{p}^{(S),i} \mathbf{p}^{(S),i\top} G^\top \right)^{-1} \\ &\quad \times \left(\mathbf{c} - G \mathbf{p}^{(S),i} \right) \end{aligned} \quad (32)$$

with

$$\Pi^{(S),i} := \text{diag} \left(p_1^{(S),i}, \dots, p_N^{(S),i} \right) \in \mathbb{R}^{N \times N} \quad (33)$$

and

$$p_k^{(S),i} = p_k^{(S)}(\boldsymbol{\lambda}^{(S),i}) \quad (34)$$

as defined in equation (19). Interestingly, the term

$$G \mathbf{p}^{(S),i}$$

in equation (32) is the vector of expectations for the M calibration instruments under the (numerical) measure $P^{(S),i}$ defined by the numerically computed vector of probabilities $\mathbf{p}^{(S),i}$, and

$$\left(G \Pi^{(S),i} G^\top - G \mathbf{p}^{(S),i} \mathbf{p}^{(S),i\top} G^\top \right) \quad (35)$$

is the associated (numerical) covariance matrix of the calibration instruments. The simple algorithm is thus, in a formal notation, to start with $\boldsymbol{\lambda}^{(S),0} = 0$ (in all entries of the vector), to compute

$$\mathbf{p}^{(S),i} = \mathbf{p}^{(S)}(\boldsymbol{\lambda}^{(S),i}) \quad (36)$$

using equation (19), to proceed to

$$\begin{aligned} \boldsymbol{\lambda}^{(S),i+1} &= \boldsymbol{\lambda}^{(S),i} + \langle \mathbf{g}, \mathbf{g} \rangle_N^{P^{(S),i-1}} \\ &\quad \cdot \left(\mathbf{c} - \langle \mathbf{g} \rangle_N^{P^{(S),i}} \right) \end{aligned} \quad (37)$$

and to $\mathbf{p}^{(S),i+1}$, and so on.

It is, in general, possible that a solution to equation (22) may not exist for $\hat{\mathcal{L}}^{(S)}$ if the model's initial calibration implies prices for the calibration instruments that are too far away from $\mathbf{c}$. When this happens, any iterative procedure will experience that $\hat{\mathcal{L}}^{(S)}(\boldsymbol{\lambda})$ grows at an ever decreasing rate in some direction in $\mathbb{R}^M$, and, eventually, the solver will terminate when it hits an internal minimum-progress criterion. A numerical approximation for $\boldsymbol{\lambda}^{(S)}$ computed in this way will represent an ME best-possible fit, and is still usable in a vein similar to that obtained by the least squares approach mentioned in the beginning. An inexpensive warning indication for this situation is given when any of the $p_k^{(Q)}$ are negative. Note that this then also signals that the classic control variate method implicitly uses a (numerical) measure that is not equivalent to the original model's measure, which in turn may result in arbitrageable prices.

Hedge Ratios

The fact that the fine tuning of the pricing measure P is achieved by varying the probabilities of the paths such that hedge instruments are correctly repriced allows for the calculation of hedge ratios *without recalibration* of the original model, and *without resimulation*. This can be seen as follows. We seek to compute the sensitivity of $\langle v \rangle_N^P$ with respect to the calibration prices $\mathbf{c}$. Since the probability vector $\mathbf{p}(\boldsymbol{\lambda})$ is computed as an analytical function of the Lagrange multipliers, which in turn are computed numerically from $\mathbf{c}$, we have

$$\nabla_{\mathbf{c}} \langle v \rangle_N^P = \nabla_{\mathbf{c}} (\mathbf{p}^\top \mathbf{v}) = J \cdot \nabla_{\boldsymbol{\lambda}} \mathbf{p}^\top \mathbf{v} \quad (38)$$

with the elements of the Jacobian matrix J given by

$$J_{lm} = \partial_{c_l} \lambda_m \quad (39)$$

Given any Ψ , which, together with the calibration constraints, ultimately *defines* our desired pricing measure P , we can combine equation (17) and the probability normalization condition $1 = \mathbf{p}^\top \mathbf{n}$ to arrive at

$$\nabla_c \langle v \rangle_N^P = s^{P_H} \cdot J \cdot \langle \mathbf{g}, v \rangle_N^{P_H} \quad (40)$$

where we have defined the hedge measure P_H in terms of the (numerical) probabilities $\mathbf{p}^{P_H}$ whose elements are given by

$$s^{P_H} := \sum_{k=1}^N 1/\psi'(p_k^P) \quad \text{with} \quad p_k^{P_H} := \frac{1/\psi'(p_k^P)}{s^{P_H}} \quad (41)$$

What remains to be calculated is the Jacobian J . This can be done in one of three ways, depending on the choice of Ψ :

1. Analytically (explicitly). For instance, for $\Psi^{(Q)}$, we obtain $s^{P_H^{(Q)}} = 1$, $p_k^{P_H^{(Q)}} = \frac{1}{N}$, $P_H^{(Q)} = P_0$, and therefore

$$\nabla_c \langle v \rangle_N^{P^{(Q)}} = \langle \mathbf{g}, \mathbf{g} \rangle_N^{P_0} \cdot \langle \mathbf{g}, v \rangle_N^{P_0} \quad (42)$$

2. Numerically. If λ^P is computed by an iterative procedure that starts with no information other than the simulated paths and $\mathbf{c}$ itself as indicated in equation (32), the chain rule propagation can be derived and implemented as part of the iterative procedure. This approach may have to be chosen if no solution to equation (22) exists. An alternative would be to precalibrate the original model better such that a Monte Carlo weighting scheme can be found that reprices the calibration instruments exactly.
3. Analytically (implicitly). As long as a solution to equation (22) exists, that is, as long as the WMC scheme reprices the calibration instruments correctly, we can use the fact that $\nabla_c \langle \mathbf{g} \rangle_N^P$ must be the $M \times M$ identity matrix. This gives the generic result

$$\nabla_c \langle v \rangle_N^P = \langle \mathbf{g}, \mathbf{g} \rangle_N^{P_H} \cdot \langle \mathbf{g}, v \rangle_N^{P_H} \quad (43)$$

which means that for any P_0 and P , that is, Ψ , that permit perfect repricing of the hedges (calibration instruments) under P , the hedge ratios for any payoff v can be seen as a regression of the covariances between v and the hedge instruments against the autocovariances of the hedge instruments under the calibration-adjusted measure P_H .

It is worth mentioning that for $\Psi^{(S)}(p) = p \log p$, we obtain $s^{P_H^{(S)}} = 1$, $p_k^{P_H^{(S)}} = p_k^{P^{(S)}}$, $P_H^{(S)} = P^{(S)}$, and

$$\nabla_c \langle v \rangle_N^{P^{(S)}} = \langle \mathbf{g}, \mathbf{g} \rangle_N^{P^{(S)}} \cdot \langle \mathbf{g}, v \rangle_N^{P^{(S)}} \quad (44)$$

In other words, the calibration-adjusted measure is the same as the pricing measure. This is a special property of the Shannon entropy pricing measure $P^{(S)}$.

As a final note on hedge ratio calculations with WMC, it should be noted that unlike most of the other sensitivity calculation schemes used with Monte Carlo methods, the above shown analysis results directly in *hedge ratios*, bypassing the otherwise common intermediate stage of *model parameter sensitivities*, which require remapping to hedge ratios for tradable instruments. This feature greatly reduces the noise often observed on risk figures that are computed by numerically fitting model parameters to market observable prices since the noise-compounding effects of recalibration and numerical calculation of sensitivities of hedge instrument prices to model parameters are avoided.

Sensitivity Computations: Integration by Parts

Traditional Monte Carlo Sensitivity Estimators and Their difficulties

The calculation of price sensitivities is a central modeling and computational problem for derivative securities. The prices of derivative securities are observable in the market; however, price sensitivities, the important inputs in the hedging of derivative securities, are not. Models and computational tools are thus required to establish such information which the market does not provide directly.

Mathematically, price sensitivities or greeks are partial derivatives of financial derivative prices with respect to some specific parameters of the underlying market variables. For instance, “delta” means the sensitivity to changes in the price of the underlying asset. More formally, suppose that the underlying model dynamic under the risk neutral probability is given by a stochastic differential equation (SDE) on $[0, T]$,

$$dX_t = \mu(X_t) dt + \sigma(X_t) dW_t, X_0 = x \quad (1)$$

where W is a standard Brownian motion. By the no-arbitrage argument, the present value of a derivative should be

$$V(x) = E[\Phi(X_T)|X_0 = x] \quad (2)$$

where Φ is the (discounted) payoff function. For notation at simplicity, we restrict attention to scalar X and such Φ that depends only on X_T in the article. Then, the delta of such a model is defined as $dV(x)/dx$.

The simplest and crudest approach to the Monte Carlo estimation of greeks is *via* finite-difference approximation. In other words, we simulate the derivative prices at two or more values of the underlying parameter and then estimate greeks by taking difference quotients between these values. Finite-difference estimators are easy to implement, but are prone to large bias, large variance, and added computational requirements.

To overcome the shortages of the finite-difference method, traditionally there have been two categories

of methods for estimating sensitivities: methods that differentiate paths and methods that differentiate densities. The former one is known as the *pathwise derivative method* or the infinitesimal perturbation analysis in the literature and the latter is usually referred to as the *likelihood ratio method* (see **Monte Carlo Greeks**). Both of them yield unbiased estimators. But the former requires smooth conditions on the payoff function Φ . It fails to provide any sensible estimators for options with discontinuous payoff functions such as digital options. The estimator produced by the latter involves the transition density function of X_T , which is unavailable in most circumstances when the dynamics (1) is not trivial.

Method of Integration by Parts

Fournié *et al.* [7, 8] developed an approach to bypass both the difficulties the traditional methods encounter. It is based on the *integration-by-parts* formula, which lies at the heart of the theory of the Malliavin calculus. Here, we state several relevant conclusions only and leave readers with interest to find more on the detailed and rigorous treatment of the Malliavin calculus and the related financial applications in Nualart [11] and Malliavin and Thalmaier [10]. For notational simplicity, we use the scalar case only in the article to demonstrate the basic idea of the method and refer readers to the relevant literature for more general and rigorous treatments.

Let $\{W_t : 0 \leq t \leq T\}$ be a standard Brownian motion defined on a probability space $(\Omega, \mathcal{F}, P)$ and let $\{\mathcal{F}_t : 0 \leq t \leq T\}$ be the filtration generated by W . Consider a random variable F of the form

$$F = f \left(\int_0^T h_u dW_u \right) \quad (3)$$

where f is a real function with some proper smoothness and $\{h_u : 0 \leq t \leq T\}$ is an $L^2[0, T]$ -valued stochastic process on $(\Omega, \mathcal{F}, P)$. The *Malliavin derivative* of F is defined as a stochastic process $DF = \{D_t F : 0 \leq t \leq T\}$, where

$$D_t F = f' \left(\int_0^T h_u dW_u \right) \cdot h_t \quad (4)$$

Notice that $\int_0^T h_u dW_u$ is defined as the limiting summation $\sum_{u < T} h_u \cdot dW_u := \sum_{u < T} h_u \cdot (W_{u+du} - W_u)$.

2 Sensitivity Computations: Integration by Parts

So, one can view the Malliavin derivative as an ordinary derivative of the random variable F with respect to dW_t , the small increment of the Brownian motion over $[t, t + dt]$, heuristically.

The Malliavin derivative satisfies the chain rule as the ordinary derivative, that is, for any differentiable real function ϕ , $D\phi(F) = \phi'(F) \cdot DF$. Apply D_t on X_T defined by the SDE (1). Recall that

$$X_T = X_t + \int_t^T \mu(X_u) du + \int_t^T \sigma(X_u) dW_u \quad (5)$$

X_t depends only on the Brownian increments before t . Thus, $D_t X_t = 0$. By the chain rule, $D_t \left(\int_t^T \mu(X_u) du \right) = \int_t^T \mu'(X_u) \cdot D_t X_u du$. And

$$\begin{aligned} D_t \left(\int_t^T \sigma(X_u) dW_u \right) &= D_t(\sigma(X_t) dW_t) + \int_{t+dt}^T \sigma(X_u) dW_u \\ &= \sigma(X_t) + \int_{t+dt}^T \sigma'(X_u) \cdot D_t X_u dW_u \end{aligned} \quad (6)$$

So we have

$$\begin{aligned} D_t X_T &= \sigma(X_t) + \int_t^T \mu'(X_u) \cdot D_t X_u du \\ &\quad + \int_t^T \sigma'(X_u) \cdot D_t X_u dW_u \end{aligned} \quad (7)$$

On the other hand, if one introduces a new process Y such that it is the derivative of X with respect to its initial value, that is, $Y_t = dX_t/dx$, then

$$dY_t = \mu'(X_t)Y_t dt + \sigma'(X_t)Y_t dW_t, \quad Y_0 = 1 \quad (8)$$

Comparing equations (7) and (8), we can see the process $\{D_t X_u : t \leq u \leq T\}$ should follow the same SDE as Y but with different initial value at t . Thus,

$$D_t X_T = \frac{Y_T}{Y_t} \cdot \sigma(X_t) \quad (9)$$

One of the most important properties of the Malliavin derivative is the following duality property:

given a process $h = \{h_t : 0 \leq t \leq T\}$, there exists a random variable $D^*(h)$ such that

$$E \left[\int_0^T D_t \Phi(X_T) \cdot h_t dt \right] = E[\Phi(X_T) \cdot D^*(h)] \quad (10)$$

for all functions Φ with some proper smoothness conditions. Viewing D^* as a “derivative” in the weak sense—recall that the weak derivative in the PDE theory is defined in this way—one can see that equation (10) is exactly an analog to the integration-by-parts formula in the ordinary calculus. In the literature, D^* is called the *Skorohod integral*. It is easy to show that $D^*(h)$ should be equal to the Ito integral $\int_0^T h_u dW_u$ if h is adapted to the filtration $\mathcal{F}_t$.

Equation (10) is the cornerstone for the development of unbiased greeks estimators. Turn back to the derivation of unbiased estimators for the delta. Consider a smooth payoff function Φ first. Choose $h_t \equiv \frac{1}{T}(Y_t/\sigma(X_t))$, which is adapted, in equation (10). By the chain rule of D , the left-hand side of equation (10) is

$$\begin{aligned} E \left[\int_0^T D_t \Phi(X_T) \cdot h_t dt \right] &= E \left[\int_0^T \Phi'(X_T) \cdot D_t X_T \cdot \frac{1}{T} \frac{Y_t}{\sigma(X_t)} dt \right] \\ &= E[\Phi'(X_T) \cdot Y_T] \end{aligned} \quad (11)$$

where the last step uses equation (9). The right hand side of equation (10) equals

$$E \left[\Phi(X_T) \cdot \frac{1}{T} \int_0^T \frac{Y_t}{\sigma(X_t)} dW_t \right] \quad (12)$$

So,

$$E[\Phi'(X_T) \cdot Y_T] = E \left[\Phi(X_T) \cdot \frac{1}{T} \int_0^T \frac{Y_t}{\sigma(X_t)} dW_t \right] \quad (13)$$

Using the pathwise derivative method, we can easily derive that $\Phi'(X_T) \cdot Y_T$ is an unbiased estimator of the delta. Therefore we have another unbiased estimator

$$\frac{dV}{dx} = E \left[\Phi(X_T) \cdot \frac{1}{T} \int_0^T \frac{Y_t}{\sigma(X_t)} dW_t \right] \quad (14)$$

For any nonsmooth Φ such that $E[(\Phi(X_T))^2] < +\infty$, we can always find a sequence of differentiable $\Phi^{(n)}$ convergent to it in L^2 , that is, $E[\|\Phi^{(n)}(X_T) - \Phi(X_T)\|^2 | X_0 = x] \rightarrow 0$ as $n \rightarrow +\infty$ for all x . Let $V^{(n)}(x) = E[\Phi^{(n)}(X_T) | X_0 = x]$. Following the above arguments,

$$\frac{dV^{(n)}}{dx} = E \left[\Phi^{(n)}(X_T) \cdot \frac{1}{T} \int_0^T \frac{Y_t}{\sigma(X_t)} dW_t \right] \quad (15)$$

Using the Cauchy–Schwartz inequality, we can easily show that the right-hand side of equation (15) converges to $E \left[\Phi(X_T) \cdot \frac{1}{T} \int_0^T \frac{Y_t}{\sigma(X_t)} dW_t \right]$. Thus, equation (14) should hold for such Φ too. The advantage of such an estimator is that it does not involve the density functions of X_T nor does it require Φ to be smooth.

Implementation and Some Extensions

To implement equation (14), we discretize $[0, T]$ into grids: $0 = t_0 < t_1 < \dots < t_N = T$, where $t_i = iT/N$. Simulate the underlying process X and the derivative process Y simultaneously by

$$\begin{aligned} \hat{X}_{t_i} &= \hat{X}_{t_{i-1}} + \mu(\hat{X}_{t_{i-1}})\Delta t + \sigma(\hat{X}_{t_{i-1}})\Delta W_i, \\ \hat{X}_0 &= x \end{aligned} \quad (16)$$

$$\begin{aligned} \hat{Y}_{t_i} &= \hat{Y}_{t_{i-1}} + \mu'(\hat{X}_{t_{i-1}})\hat{Y}_{t_{i-1}}\Delta t + \sigma'(\hat{X}_{t_{i-1}})\hat{Y}_{t_{i-1}}\Delta W_i, \\ \hat{Y}_0 &= 1 \end{aligned} \quad (17)$$

where $\Delta t = T/N$ and $\Delta W_i = W_{t_i} - W_{t_{i-1}} \sim N(0, \Delta t)$. Then, approximately we have a delta estimator

$$\Phi(\hat{X}_T) \cdot \frac{1}{T} \sum_{i=1}^N \frac{\hat{Y}_{t_{i-1}}}{\sigma(\hat{X}_{t_{i-1}})} \Delta W_i \quad (18)$$

All the above derivations can be generalized to the cases in which X and W are both vectors, which has been shown by Fournié *et al.* [7]. They also established unbiased estimators for other greeks for European style options contingent on multidimensional underlying assets, such as the vega, the price sensitivity with respect to the underlying volatility; the rho, the sensitivity with respect to the riskless interest rate; the gamma, the second-order sensitivity with respect

to the underlying price. One crucial assumption they needed is that the underlying model is elliptic, that is, $\sigma(x)$ is a symmetric positive definite matrix function.

It is worth mentioning that the integration-by-parts method is still applicable for the market where the ellipticity assumption does not hold. For instance, the interest rate market has a high-dimensional state space constituted by the values of bonds at a large number of distinct maturities and a low-dimensionality variance driven by a few noise sources (Brownian motions). Under this setting, $\sigma(x)$ cannot be positive definite because it has more rows than columns. Malliavin and Thalmaier [10] provide the details on how to develop the corresponding unbiased estimators.

A lot of research has already been done so far in the literature to extend the seminal work of Fournié *et al.* [7]. Among others, Davis and Johansson [5], El-Khatib and Privault [6], and Bally *et al.* [1] considered greeks in a market driven by jump-diffusion processes; Gobet and Kohatsu-Higa [9], Bernis *et al.* [3] derived greek estimators for lookback and barrier options; Bally *et al.* [2] applied the Malliavin calculus method to pricing and hedging American options.

As shown here, Malliavin estimators have been derived directly for diffusion processes, but implementation typically requires simulation of a discrete-time approximation. This raises the question of whether one should discretize first and then differentiate, or differentiate first and then discretize. Chen and Glasserman [4] illustrated that both approaches will lead to the same estimators in several important cases, but the first approach uses only elementary techniques such as likelihood ratio and pathwise derivative methods.

Stochastic Mesh Method

The stochastic mesh method has been proposed by Broadie and Glasserman [2] to price multivariate Bermudan options. These contracts include an early exercise feature, which makes their pricing a challenging computational problem. There are several methods available for options with payoff functions depending only on one asset. They include finite difference methods and approaches based on lattices (see **Finite Difference Methods for Early Exercise Options**). These methods, however, become typically ineffective for high-dimensional problems, like basket options.

The stochastic mesh approach belongs to simulation-based methods, whose attractiveness for complex computational problems stems from the fact that the convergence rate is typically independent of the dimension of the problem.

The method is based on the dynamic programming representation and in each period uses a finite collection of points from the state space. In these aspects, the method is similar to the binomial tree approach. Its distinctive feature is that at each time interval the nodes are selected randomly and their number is always the same.

To illustrate the method, we consider a Bermudan option whose payoff depends only on the current price of an underlying asset. We assume that changes of the asset's price can be described by a Markov chain: $\{S_{t_i}\}_{i=0,\dots,M}$, with values in $\mathcal{R}^b$. Since Bermudan options are often used to approximate prices of American options, $\{S_{t_i}\}_{i=0,\dots,M}$ may be obtained as a result of sampling a continuous process $\{S_t\}_{0 \leq t \leq T}$. The option can be exercised at $M + 1$ time points (including the initial time), which we shall denote as $t_0, t_1, \dots, t_M = T$. At the time of exercise τ , the options are equal to $G(\tau, S_\tau)$, where G is a given function.

An arbitrage-free price of the option can be obtained by using the risk-neutral representation:

$$P(t_0, S_0) := \max_{\tau} E[B(t_0, \tau)G(\tau, S_\tau)] \quad (1)$$

where τ is a stopping time that takes values in the set $\{t_0, t_1, \dots, T\}$. Here, the expectation is taken with respect to a given risk-neutral measure, Q , and $B(s, t)$ denotes the discount factor for the period (s, t) . The main difficulty in using equation (1) is

due to the fact that the optimal exercise strategy is unknown. The price of the option and the optimal strategy can be obtained, however, from the dynamic programming characterization of the problem. For this, we use the following backward recursion to calculate, for $i = M, \dots, 0$, functions $P(t_i, \cdot)$:

$$P(T, x) = G(T, x) \quad (2)$$

$$P(t_i, x) = \max\{G(t_i, x), C(t_i, x)\},$$

$$i = M - 1, \dots, 0 \quad (3)$$

where the continuation value, $C(t_i, x)$, is defined as

$$C(t_i, x) := B_{t_i} E[P(t_{i+1}, S_{t_{i+1}}) | S_{t_i} = x] \quad (4)$$

Then the price of the instrument at t_0 is given by $P(t_0, S_0)$. For simplicity of exposition, we assume that the discount factor $B_{t_i} \equiv B(t_i, t_{i+1})$ is deterministic, but in a more general formulation of the method it can be stochastic.

To use this method in practice, we must be able to efficiently calculate the conditional expectation

$$E[P(t_{i+1}, S_{t_{i+1}}) | S_{t_i} = x] \quad (5)$$

for $i = 0, \dots, M - 1$ and the selected set of points x from the state space. To accomplish this, several techniques have been proposed, including binomial trees and Monte Carlo simulations.

In the stochastic mesh method, the expectation (5) are approximated by arithmetic sums. For this, in the first phase, we generate at each exercise time t_i , $i = 0, \dots, M$, the same number of random points, $\{x_{ij}, j = 1, \dots, d\}$. Then, at each node of the mesh the option price is calculated using the backward recursion. At the terminal nodes, we take $\hat{P}(T, x_{Mj}) = G(T, x_{Mj})$, $j = 1, \dots, d$. At all other exercise times, we estimate the price of the option using the following mesh estimator

$$\hat{P}(t_i, x_{ij}) = \max\{G(t_i, x_{ij}), \hat{C}(t_i, x_{ij})\} \quad (6)$$

with the estimate $\hat{C}$ of the continuation value defined by

$$\hat{C}(t_i, x_{ij}) := B_{t_i} \frac{1}{d} \sum_{k=1}^d \hat{P}(t_{i+1}, x_{(i+1)k}) w_i(j, k) \quad (7)$$

where $w_i(j, k) \equiv w_i(x_{ij}, x_{(i+1)k})$ is a weight attached to the pair $(x_{ij}, x_{(i+1)k})$. Thus, for each fixed node at

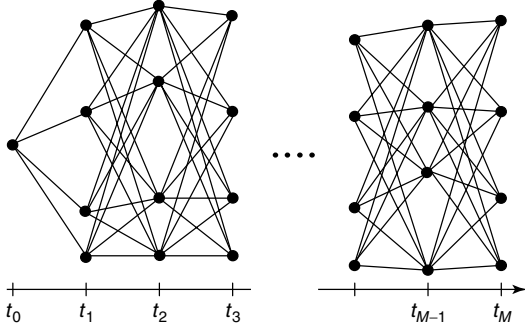

Figure 1 An example of a stochastic mesh with $d = 4$. Weight that is attached to each arc is used in a weighted-sum approximation to the corresponding continuation value

time t_i , all nodes at the next time are used to calculate the corresponding continuation value. This has been depicted in Figure 1 for $d = 4$. Selection of these weights depends on the mechanism we have used to generate the mesh points $\{x_{ij}\}$. The weighted sum (7) can be interpreted as an estimate of the conditional expectation (5) when the process is in state x_{ij} at time t_i . Since in calculations we always use all mesh points at the next time, regardless of the current state of the process, the main purpose of these weights is to estimate the continuation values without bias. We provide more details about different mechanisms of selecting mesh points and weights in the following section.

Selection of the Mesh Points and Weights

Proper choices of the mesh points and weights $w_i(j, k)$ in equation (7) are essential for the method to be successful. The approaches suggested in the literature are based on the assumption that the

Markov process $\{S_{t_i}\}_{i=0,\dots,M}$ admits transition densities and they are known or can be evaluated numerically. We therefore assume that conditional on $S_{t_i} = x$ the value of the process at the next time instance, $S_{t_{i+1}}$, has density $f(t_i, x, \cdot)$. Denote by $h(t_i, \cdot)$ the density of S_{t_i} conditional on the initial value S_0 . We refer to $h(t_i, \cdot)$ as the marginal density of S_{t_i} .

Broadie and Glasserman [2] have considered two constructions of mesh points, which we present in Figure 2. In both, the points $\{x_{ij}, j = 1, \dots, b\}$ at time t_i are generated as independent and identically distributed observations from some density $g(t_i, \cdot)$, called the *mesh density function*. In the first method, the mesh density is allowed to depend on time but not on the mesh points generated at previous time intervals. In the second method, the mesh is constructed in a forward procedure where at time t_i the points $\{x_{ij}, j = 1, \dots, b\}$ are generated as samples from a mesh density that depends on observations at the previous time t_{i-1} . Although other methods of generating mesh points have been proposed later (e.g., [4]), we focus only on these two.

A natural choice for the mesh density $g(t_i, \cdot)$ is to take it equal to the marginal density function $h(t_i, \cdot)$. In this case, the mesh points at time t_i are generated independently of points at previous times $t_1, \dots, t_{i-1}$. Using a simple change of measure, we can transform conditional expectation (5) to an expectation with respect to the density $h(t_{i+1}, \cdot)$:

$$\begin{aligned} E[P(t_{i+1}, S_{t_{i+1}}) | S_{t_i} = x_{ij}] &= \int P(t_{i+1}, z) f(t_i, x_{ij}, z) dz \\ &= \int P(t_{i+1}, z) \frac{f(t_i, x_{ij}, z)}{h(t_{i+1}, z)} h(t_{i+1}, z) dz \quad (8) \end{aligned}$$

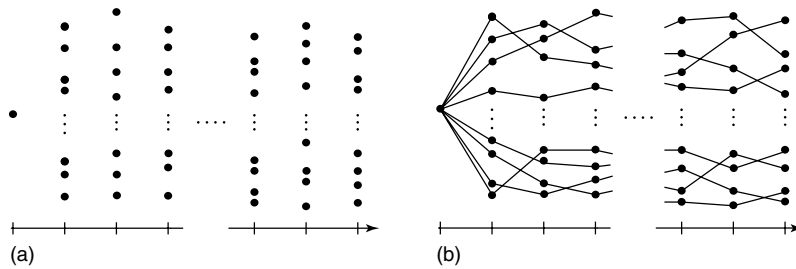

Figure 2 Two methods of generating mesh points. (a) The points are generated independently at each time interval. (b) The points are generated by independent paths

Since this result is valid for any integrable function P , it implies that weighted sums with weights equal to the likelihood ratio

$$w_i(j, k) := \frac{f(t_i, x_{ij}, x_{(i+1)k})}{g(t_{i+1}, x_{(i+1)k})} \quad (9)$$

provide unbiased estimates of conditional expectations with respect to the transition density $f(t_i, x_{ij}, \cdot)$, meaning that

$$E \left[\frac{B_{t_i}}{d} \sum_{k=1}^d P(t_{i+1}, X_k) w_i(x_{ij}, X_k) \right] = C(t_i, x_{ij}) \quad (10)$$

where $X_1, \dots, X_d$ are independent and identically distributed random variables with the common density equal to $g(t_{i+1}, \cdot)$.

A drawback of selecting the mesh density equal to the marginal density function is that it can lead to estimators whose variance grows exponentially with the number of exercise times. In the context of an European option, this fact has been demonstrated by Broadie and Glasserman [2]. The authors have also observed that this build up of variance can be avoided if we choose the mesh density equal to the average of transition density functions

$$g^A(t_{i+1}, x_i, x) = \frac{1}{d} \sum_{j=1}^d f(t_i, x_{ij}, x), \quad i = 1, \dots, M-1 \quad (11)$$

and $g^A(t_1, x) = f(t_0, S_0, x)$, where x_i denotes the vector of mesh points at time t_i . For this choice of the density, points at time t_{i+1} are generated from a distribution that depends on the position of the mesh points at the previous time t_i . The particular form of the mesh density (11) as a mixture of transition densities allows for two equivalent interpretations of the generation mechanism. In the first, we use a forward procedure where at each time we independently generate all points from the same distribution. To generate a point at time t_i from the density $g(t_i, x_{(i-1)\cdot}, \cdot)$, we first randomly choose a point from the set $\{x_{(i-1)1}, \dots, x_{(i-1)d}\}$, say $x_{(i-1)j^*}$, and then sample from the transition density $f(t_{i-1}, x_{(i-1)j^*}, \cdot)$. This procedure is repeated until all d points have been obtained, after which we proceed to the next time interval. Alternatively, generating a

mesh using equation (11) is equivalent to generating d independent paths of the process $\{S_0, S_{t_1}, \dots, S_{t_M}\}$, as presented in Figure 2(b), and then disconnecting the nodes on each path.

For this construction of a mesh, we can use the likelihood ratio weights (9) with the mesh density $g(t_i, \cdot)$ replaced by $g^A(t_i, x_i, \cdot)$. These weights preserve the property of the weighted sum being an unbiased estimator of conditional expectation. In this case, however, expectation (10) is conditional on the position of the mesh points at the previous time t_{i-1} .

Properties of the Method and Its Extensions

The stochastic mesh method has an important property of being asymptotically consistent, meaning that by increasing the number of mesh points it can be assured that the mesh estimates will converge to the true price of the option. When the distributions used to sample mesh points are set to marginal distributions of the process, this result has been established by Broadie and Glasserman [2]. Avramidis and Matzinger [1] have proved the asymptotic consistency under weaker assumptions on the generating mechanism, which, in particular, cover the construction based on independent paths of the process $\{S_{t_i}\}_{i=0, \dots, M}$.

Broadie and Glasserman [2] and Glasserman [4] have also shown that under some conditions on the mechanism of selecting the mesh points and weights in equation (7), the mesh estimator defined by equations (6) and (7) is biased high. This means that for a fixed number of mesh points and a fixed number of exercise opportunities, if we randomly generate sufficiently many meshes and calculate the corresponding mesh estimates, then the arithmetic average of all these estimates will be strictly greater than the true price of the option. The proof of this result uses Jensen's inequality and relies on a particular choice of weights that guarantees the unbiasedness property of the weighted sums (10). In particular, the likelihood ratios and the two constructions of the mesh points described in the previous section lead to mesh estimators that are bias high.

The bias high property of the method can be used to construct conservative confidence intervals for the option price. For this, we can combine the mesh estimator with any bias low estimator. The latter can be constructed quite easily, since an application of

any exercise strategy in equation (1) that is different from the optimal one will lead to a bias low estimate of the price. Such a suboptimal stopping rule can also be constructed within the stochastic mesh method [2]. In the process of finding the mesh estimate through the dynamic programming procedure (6) and (7), each node of the mesh can be classified as either belonging to the exercise region or not, depending whether the maximum in equation (6) is equal to the current value of the option or the continuation value. This classification can be extended to an arbitrary state of the process. Because the immediate exercise value $G(t_i, x)$ in equation (6) is defined for all x , we need to estimate a continuation value $\hat{C}(t_i, x)$ at an arbitrary state x . To do this, it suffices to extend the weights $w_i(j, k)$ to all points in the state space, which for the likelihood ratio weights (9) can be easily accomplished by simply replacing x_{ij} with x .

A bias low estimator, called *path estimator*, is based on the exercise region corresponding to these continuation values. Its value is obtained by randomly generating a certain number of trajectories of the underlying process and then stopping each trajectory if it reaches this exercise region. Thus, for the j th simulated path, S^j , the exercise time $\hat{\tau}$ is defined as

$$\hat{\tau}(S^j) = \min\{t_i : G(t_i, S^j_{t_i}) \geq \hat{C}(t_i, S^j_{t_i})\} \quad (12)$$

in the case when the trajectory reaches the exercise region, and $\hat{\tau} = T$, otherwise. Then, conditional on this mesh, the path estimate based on N -simulated trajectories is simply the average of the discounted payoffs at the exercise time

$$\frac{1}{N} \sum_{j=1}^N B(t_0, \hat{\tau}(S^j)) G(\hat{\tau}(S^j), S^j_{\hat{\tau}(S^j)}) \quad (13)$$

If we repeat this procedure for a number of independently generated meshes, then the sample mean of the estimates (13) obtained for each copy of the mesh will give a bias low estimate of the price of the option. Under some conditions, this estimator is asymptotically unbiased as the number of mesh points d increases to infinity. Therefore, the confidence interval that combines the bias high and the bias low estimators will shrink to the true price of the option as $d \rightarrow \infty$ and the number of generated trajectories N increases to infinity.

Several numerical examples illustrating applications of the stochastic mesh method have been presented by Broadie and Glasserman [2]. Numerical

tests conducted by the authors suggest that the efficiency of the method can be significantly improved when it is combined with some standard variance reduction techniques, in particular, those based on control variates (*see Variance Reduction*). Another way of enhancing the method is proposed in Boyle *et al.*, where mesh points are generated using low-discrepancy points (*see Quasi-Monte Carlo Methods*). A serious limitation of the method is the need for a transition density. To address this issue, in [3] the authors extend the stochastic mesh method by proposing to choose mesh weights through a constrained optimization problem.

LIBOR Market Models: Simulation

The Libor market (LM) model (*see LIBOR Market Model*) involves a large number of Markov state variables—namely, the full number of Libor forward rates on the yield curve plus any additional variables such as stochastic volatility—so finite difference methods are rarely applicable, and securities pricing will nearly always require Monte Carlo methods. The specific form of the stochastic differential equations (SDEs) governing the dynamics of forward Libor rates gives rise to some specialized approaches, as well as to particular challenges, that are covered in this article. The notation used throughout is that of **LIBOR Market Model**.

Euler-type Schemes

Basic Stepping Method

Assume that we stand at time t , and Libor forwards (L) maturing at all dates in the tenor structure are known. We wish to devise a scheme to advance time to $t + \Delta$ and construct a sample^a of $L_{q(t+\Delta)}(t + \Delta), \dots, L_{N-1}(t + \Delta)$. Notice that $q(t + \Delta)$ may or may not exceed $q(t)$; if it does, some of the front-end forward rates expire and “drop off” the curve in the move to $t + \Delta$.

Under the spot measure $\mathbf{P}^B$, general LM model dynamics are of the form (*see LIBOR Market Model*)

$$dL_n(t) = \sigma_n(t)^\top (\mu_n(t) dt + dW_B(t)),$$

$$\mu_n(t) = \sum_{j=q(t)}^n \frac{\tau_j \sigma_j(t)}{1 + \tau_j L_j(t)} \quad (1)$$

where $\sigma_n(t)$ are adapted vector-valued volatility functions and W_B is an m -dimensional Brownian motion in measure $\mathbf{P}^B$. The simplest way of drawing an approximate sample $\hat{L}_n(t + \Delta)$ for $L_n(t + \Delta)$ would be to apply a first-order Euler-type scheme,^b

$$\begin{aligned} \text{Euler : } \hat{L}_n(t + \Delta) \\ = \hat{L}_n(t) + \sigma_n(t)^\top (\mu_n(t) \Delta + \sqrt{\Delta} z) \end{aligned} \quad (2)$$

$$\text{log-Euler : } \hat{L}_n(t + \Delta)$$

$$= \hat{L}_n(t) \exp \left\{ \frac{\sigma_n(t)^\top}{\hat{L}_n(t)} \left(\mu_n(t) \Delta - \frac{1}{2} \frac{\sigma_n(t)}{\hat{L}_n(t)} \Delta + \sqrt{\Delta} z \right) \right\} \quad (3)$$

where z is a vector of m independent $\mathcal{N}(0, 1)$ Gaussian draws. For specifications of $\sigma_n(t)^\top$ that are close to proportional in $L_n(t)$ (e.g., the lognormal LM model), the log-Euler scheme (3) can be expected to produce lower biases than the Euler scheme (2). The log-Euler scheme will keep forward rates positive, whereas the Euler scheme will not.

As shown, both schemes (2) and (3) advance time only by a single time step, but creation of a full path of forward curve evolution through time is merely a matter of repeated application of the single-period stepping schemes on a (possibly nonequidistant) time line $t_0, t_1, \dots$.

While Euler-type schemes such as (2) and (3) are not very sophisticated and result in rather slow convergence of the discretization bias ($O(\Delta)$), these schemes are appealing in their straightforwardness and universal applicability.

Iterative Drift Calculations

In the straight Euler scheme (2), the computational effort involved in advancing L_n is dominated by the computation of $\mu_n(t)$ which, in a direct implementation of equation (1), involves $m \cdot (n - q(t) + 1) = O(mn)$ operations for a given value of n . To advance all $N - q(t + \Delta)$ forwards, it follows that the computational effort is $O(mN^2)$ for a single time step. Generation of a full path of forward curve scenarios from time 0 to time T_{N-1} will thus require a total computational effort of $O(mN^3)$.

A simple observation allows one to substantially reduce the computational effort. Invoking the recursive relationship

$$\mu_n(t) = \mu_{n-1}(t) + \frac{\tau_n \sigma_n(t)}{1 + \tau_n \hat{L}_n(t)} \quad (4)$$

allows one to compute all $\mu_n, n = q(t + \Delta), \dots, N - 1$, by an $O(N)$ -step iteration starting from $\mu_{q(t+\Delta)}(t) = \sum_{j=q(t)}^{q(t+\Delta)} \tau_j \sigma_j(t) / (1 + \tau_j \hat{L}_j(t))$. In total, the computational effort of advancing the full curve one-

time step will be $O(mN)$, and the cost of taking N such time steps will be $O(mN^2)$ —and not $O(mN^3)$.

This reduction in effort is discussed, in considerable level of detail, in [6]. It can be verified to hold for any of the probability measures used in LM modeling; the starting point of recursions would depend on which measure is used.

Long Time Steps

Most exotic interest rate derivatives involve revolving cash flows paid on a tightly spaced schedule (e.g., quarterly). Hence, the average time spacing used in path generation will thus normally, by necessity, be quite small. In certain cases, however, there may be large gaps between cash flow dates, for example, when a security is forward-starting or has an initial lockout period. One may want, then, to be able to take a “large” time step in the simulation; here “large” is defined as spanning more than one period in the tenor structure.

When taking large time steps in simulation, not all probability measures are equally useful. In particular, the usage of the spot measure $\mathbf{P}^B$ is inconvenient, as skipping over points in the tenor structure will preclude one from “rolling” $B(t)$ correctly. Circumventing this issue, however, is merely a matter of changing the numeraire from B to an asset that involves no rollover in the time step in question. For instance, we could use the discount bond $P(t, T_N)$, the choice of which corresponds to running simulated paths in the terminal measure. Model dynamics under this measure are given in **LIBOR Market Model**.

Other Simulation Schemes

When simulating on a reasonably tight time schedule, the performance of the Euler scheme is often sufficiently accurate to serve as the default scheme for many types of LM models. However, as discussed above, in some cases, it could be beneficial to use coarse time steps in some parts of the path-generation algorithm, requiring one to pay more attention to the discretization scheme.

Special-purpose Schemes with Drift Predictor–Corrector

In integrated form, the general LM dynamics in equation (1) become

$$\begin{aligned} L_n(t + \Delta) &= L_n(t) + \int_t^{t+\Delta} \sigma_n(u)^\top \mu_n(u) du \\ &\quad + \int_t^{t+\Delta} \sigma_n(u)^\top dW_B(u) \\ &\equiv L_n(t) + D_n(t + \Delta) + M_n(t + \Delta) \end{aligned} \quad (5)$$

where M_n and D_n is a martingale and a predictable process, respectively, on the interval $[t, t + \Delta]$. In many cases of practical interest, high-performance special-purpose schemes exist for simulation of the martingale process M_n . A simple approach is to use Euler stepping for the predictable part,

$$\hat{L}_n(t + \Delta) = \hat{L}_n(t) + \sigma_n(t)^\top \mu_n(t) \Delta + \hat{M}_n(t + \Delta) \quad (6)$$

where $\hat{M}_n(t + \Delta)$ is generated by a special-purpose scheme.

The drift adjustments in equation (6) are explicit in nature, as they are based only on the forward curve at time t . To incorporate information from time $t + \Delta$, one can use the *predictor–corrector* scheme, see [8] and **Monte Carlo Simulation for Stochastic Differential Equations**, which for equation (6) takes the two-step form

$$\begin{aligned} \bar{L}_n(t + \Delta) &= \hat{L}_n(t) + \sigma_n(t; \{\hat{L}_i(t)\})^\top \mu_n(t; \{\hat{L}_i(t)\}) \Delta \\ &\quad + \hat{M}_n(t + \Delta) \\ \hat{L}_n(t + \Delta) &= \hat{L}_n(t) + \theta \sigma_n(t; \{\hat{L}_i(t)\})^\top \mu_n(t; \{\hat{L}_i(t)\}) \Delta \\ &\quad + (1 - \theta) \sigma_n(t + \Delta; \{\bar{L}_i(t + \Delta)\})^\top \\ &\quad \times \mu_n(t + \Delta; \{\bar{L}_i(t + \Delta)\}) \Delta + \hat{M}_n(t + \Delta) \end{aligned} \quad (7)$$

where θ is a parameter in $[0, 1]$ that determines the degree of implicitness in the scheme ($\theta = 1$: fully explicit; $\theta = 0$: fully implicit). In practice, one would

nearly always make the balanced choice of $\theta = 1/2$. In equations (7) and (8) the short-hand notation

$$\mu_n \left(t; \left\{ \hat{L}_i(t) \right\} \right)$$

is used to indicate that μ_n (and σ_n) may depend on the state of the entire forward curve at time t .

Clearly, the same idea could be developed with the log-Euler scheme (3) as a starting point.

While the weak convergence order of simulation schemes may not be affected by predictor–corrector schemes, experiments show that equations (7) and (8) often will reduce the bias significantly relative to a fully explicit Euler scheme. Some results (and further refinements) can be found in [4, 9] and [10]. As the computational effort of computing the predictor–step is not insignificant, the speed–accuracy trade-off must be evaluated on a case-by-case basis.

Further Refinements of Drift Estimation

For large time steps, it may be useful to explicitly integrate the time-dependent parts of the drift, rather than rely on pure Euler-type approximations. Focusing on, say, equation (6), assume that one can write

$$\sigma_n(u)^\top \mu_n(u) \approx f(u, \{L_i(t)\}), \quad u \geq t \quad (9)$$

for a function f that depends on time as well as the state of the forward curve frozen at time t . Then,

$$\begin{aligned} D_n(t + \Delta) &= \int_t^{t+\Delta} \sigma_n(u)^\top \mu_n(u) du \\ &\approx \int_t^{t+\Delta} f(u, \{L_i(t)\}) du \end{aligned} \quad (10)$$

As f evolves deterministically for $u > t$, the integral on the right-hand side can be evaluated either analytically (if f is simple enough) or by numerical quadrature.

The approach in equation (10) easily combines with predictor–corrector logic, that is,

$$\begin{aligned} D_n(t + \Delta) &\approx \theta \int_t^{t+\Delta} f(u, \{L_i(t)\}) du \\ &\quad + (1 - \theta) \int_t^{t+\Delta} f(u, \{\bar{L}_i(t + \Delta)\}) du \end{aligned} \quad (11)$$

where $\bar{L}_i(t + \Delta)$ has been found in a predictor step using equation (10) in equation (6).

Brownian Bridge Schemes and Other Ideas

As a variation on the predictor–corrector scheme, a further refinement to take into account variance of the Libor curve between the sampling dates t and $t + \Delta$ could be made. Schemes attempting to do so by application of *Brownian bridge* techniques were proposed in [9], among others. While performance of these schemes vary—tests in [7] show rather mixed results in comparison to simpler predictor–corrector schemes—the basic idea is sufficiently simple and instructive to merit a brief mention. In a nutshell, the Brownian bridge approach aims to replace in equation (10) all forward rates $\{L_i(t)\}$ with their expected values at time u , *conditional* upon the forward rates ending up at $\{\bar{L}_i(t + \Delta)\}$, with $\{\bar{L}_i(t + \Delta)\}$ generated in a predictor step. Under simplifying assumptions on the dynamics of $L_n(t)$, a closed-form expression is possible for this expectation. For example, if we assume that

$$dL_n(t) \approx \sigma_n(t)^\top dW(t) \quad (12)$$

where σ_n is *deterministic* and $W(t)$ is an m -dimensional Brownian motion in some probability measure $\mathbf{P}$, then, for $u \in [t, t + \Delta]$,

$$\begin{aligned} E(L_n(u) | L_n(t), L_n(t + \Delta)) \\ = L_n(t) + \frac{\Sigma_1}{\Sigma_2} (L_n(t + \Delta) - L_n(t)) \end{aligned} \quad (13)$$

where

$$\Sigma_1 = \int_t^u |\sigma_n(s)|^2 ds, \quad \Sigma_2 = \int_t^{t+\Delta} |\sigma_n(s)|^2 ds \quad (14)$$

If it is more appropriate to assume that L_n is roughly lognormal, that is,

$$dL_n(t)/L_n(t) \approx \sigma_n(t)^\top dW(t) \quad (15)$$

for a deterministic volatility σ_n , then, for $u \in [t, t + \Delta]$,

$$\begin{aligned}
& E(L_n(u)|L_n(t), L_n(t + \Delta)) \\
&= L_n(t) \left(\frac{L_n(t + \Delta)}{L_n(t)} \right)^{\Sigma_1 \Sigma_2^{-1}} \\
&\quad \times \exp \left(\frac{1}{2} \Sigma_2^{-1} \Sigma_1 (\Sigma_2 - \Sigma_1) \right) \quad (16)
\end{aligned}$$

The article [7] investigates a number of other possible discretization schemes for the drift term in the LM model, including those that attempt to incorporate information about the correlation between various forward rates. In general, many of these schemes will result in some improvement of the discretization error, but at the cost of more computational complexity and effort—effort that in some instances might be better spent on just using a finer time discretization in a simpler discretization scheme.

High-order Schemes

Higher order schemes (such as the Milstein scheme and similar Taylor-based approaches, *see Monte Carlo Simulation for Stochastic Differential Equations* and *Stochastic Taylor Expansions*) are cumbersome to use for LM modeling due to the high dimensionality of the model. Consequently, there are very few empirical results on their relative performance. Andersen and Andreasen [1] list some results for Richardson extrapolation (see [8]), the effect of which seems to be rather modest.

Martingale Discretization

It is possible to select a measure such that a particular zero-coupon bond and a particular forward rate agreement (FRA) will be priced bias-free^c by Monte Carlo simulation, even when using a simple Euler scheme. While one is rarely interested in pricing zero-coupon bonds by Monte Carlo methods, this observation can, nevertheless, occasionally help guide the choice of simulation measure, particularly if, say, a security can be argued to depend primarily on a single forward rate (e.g., caplet-like securities). In practice, matters are rarely this clear-cut, and one wonders whether perhaps simulation schemes exist that will simultaneously price all zero-coupon bonds $P(\cdot, T_1)$, $P(\cdot, T_2)$, $\dots$, $P(\cdot, T_N)$ bias-free. It should be obvious that this cannot be accomplished by a simple measure

shift, but will require a more fundamental change in simulation strategy.

Deflated Bond Price Discretization

To develop a simulation scheme, which, by construction, will ensure that all numeraire-deflated bond prices are martingales, one can follow the suggestion offered in [3]: instead of discretizing the dynamics for Libor rates directly, simply discretize the deflated bond prices themselves. Consider the spot measure, and define

$$U(t, T_{n+1}) = \frac{P(t, T_{n+1})}{B(t)} \quad (17)$$

The dynamics for deflated zero-coupon bond prices (17) are given by

$$\begin{aligned}
\frac{dU(t, T_{n+1})}{U(t, T_{n+1})} &= - \sum_{j=q(t)}^n \tau_j \frac{U(t, T_{j+1})}{U(t, T_j)} \sigma_j(t)^\top dW_B(t), \\
n &= q(t), \dots, N-1 \quad (18)
\end{aligned}$$

Discretization schemes for equation (18), which preserve the martingale property, are easy to construct. For instance, the log-Euler scheme

$$\begin{aligned}
\hat{U}(t + \Delta, T_{n+1}) &= \hat{U}(t, T_{n+1}) \\
&\times \exp \left(-\frac{1}{2} |\eta_{n+1}(t)|^2 \Delta + \eta_{n+1}(t)^\top z \sqrt{\Delta} \right) \quad (19)
\end{aligned}$$

has this property where, as before, z is an m -dimensional standard Gaussian variable, and

$$\eta_{n+1}(t) \triangleq - \sum_{j=q(t)}^n \tau_j \frac{\hat{U}(t, T_{j+1})}{\hat{U}(t, T_j)} \sigma_j(t) \quad (20)$$

One can replace equation (19) with another discretization of equation (18), or one can try to discretize a quantity other than the deflated bonds $U(t, T_n)$. The latter idea is pursued in [3], where several suggestions for discretization variables are considered. For instance, one can consider the differences

$$U(t, T_n) - U(t, T_{n+1}) \quad (21)$$

which are martingales, since the U s are. Discretizing $U(t, T_n) - U(t, T_{n+1})$ is, in a sense, close to discretizing L_n itself, which may be advantageous. [7]

contains some tests of discretization schemes based on equation (21), in a lognormal model setting.

End Notes

^aWe recall from **LIBOR Market Model** that $q(t)$ is an index function, indicating which bucket of a tenor structure $\{T_n\}_{n=0}^N$ time t belongs to.

^bIn the interest of brevity and conciseness, the simulation schemes discussed in this article omit a number of real-life details, such as proper rate fixing conventions, interpolation techniques and introduction of stochasticity in the front stub, that is, in the bucket $[t, T_{q(t)}]$. Interpolation and propagation of “nonstandard” rates, that is, rates with dates not aligned with the tenor structure $\{T_n\}$, are covered in, for example, [2], and a simple representative technique for stochastic front stubs can be found in [5].

^cBut not error-free, obviously—there will still be a statistical mean-zero error on the simulation results.

Quasi-Monte Carlo Methods

Many typical problems of modern computational finance can be rephrased mathematically as problems of calculating integrals with high-dimensional integration domains (see the section Applications to Computational Finance for several examples). In fact, the dimensions may very well be in the hundreds or even in the thousands. Very often in such finance problems the integrand will be quite complicated, so that the integral cannot be evaluated analytically and precisely. In such cases, one has to resort to *numerical integration*, that is, to a numerical scheme for the approximation of integrals.

High-dimensional numerical integration is a challenging problem. Classical methods for multidimensional numerical integration, namely Cartesian products of one-dimensional integration rules such as the trapezoidal rule and Simpson's rule (see [15]), work well only for dimensions up to three or four, or if the given high-dimensional integral can be reduced to a low-dimensional integral by analytic tricks. For most high-dimensional integrals arising in finance, the classical methods fail.

A more powerful approach to multidimensional numerical integration employs Monte Carlo methods. In a nutshell, a *Monte Carlo method* is a numerical method based on random sampling. A comprehensive treatment of Monte Carlo methods can be found in [20].

Monte Carlo methods for numerical integration can be explained in a straightforward manner. In many cases, by using suitable transformations, we can assume that the integration domain is an s -dimensional unit cube $I^s := [0, 1]^s$, so this is the situation on which we focus. We assume also that the integrand f is square integrable over I^s . Then the *Monte Carlo approximation* for the integral is

$$\int_{I^s} f(\mathbf{u}) \, d\mathbf{u} \approx \frac{1}{N} \sum_{n=1}^N f(\mathbf{x}_n) \quad (1)$$

where $\mathbf{x}_1, \dots, \mathbf{x}_N$ are independent random samples drawn from the uniform distribution on I^s . In statistics, we approximate the expected value of a random variable by sample means. The law of large numbers

guarantees that with probability 1 (i.e., for “almost all” sequences of sample points) we have

$$\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N f(\mathbf{x}_n) = \int_{I^s} f(\mathbf{u}) \, d\mathbf{u} \quad (2)$$

and so the Monte Carlo method for numerical integration converges almost surely.

We can, in fact, be more precise about the error committed in the Monte Carlo approximation (1). It can be verified quite easily that the square of the error in equation (1) is, on the average over all samples of size N , equal to $\sigma^2(f)N^{-1}$, where $\sigma^2(f)$ is the variance of f . Thus, with overwhelming probability we have

$$\int_{I^s} f(\mathbf{u}) \, d\mathbf{u} - \frac{1}{N} \sum_{n=1}^N f(\mathbf{x}_n) = O(N^{-1/2}) \quad (3)$$

This means, very roughly, that if we want to compute the given integral with an error tolerance of the order 10^{-2} , say, then we need about 10^4 sample points, and to reduce the error tolerance by one order of magnitude, we need to increase the sample size by a factor of about 100. An important fact here is that the convergence rate in equation (3) is independent of the dimension s , and this makes Monte Carlo methods attractive for high-dimensional problems.

Despite the initial appeal of Monte Carlo methods for numerical integration, there are several drawbacks of these methods: (i) it is difficult to generate truly random samples; (ii) Monte Carlo methods for numerical integration provide only probabilistic error bounds; and (iii) in many applications the convergence rate in equation (3) is considered too slow. Quasi-Monte Carlo (QMC) methods were introduced to address these concerns.

General Background on QMC Methods

A *QMC method* is a deterministic version of a Monte Carlo method, in the sense that the random samples used in the implementation of a Monte Carlo method are replaced by *quasi-random points*, which are judiciously chosen deterministic points with good distribution properties. The general idea is that the Monte Carlo error bound (3) describes the average performance of integration points $\mathbf{x}_1, \dots, \mathbf{x}_N$, and there should exist points that perform better than

average. These are the quasi-random points we are seeking.

We again consider these methods in the context of numerical integration over an s -dimensional unit cube $I^s = [0, 1]^s$. The approximation scheme is the same as for the Monte Carlo method, namely

$$\int_{I^s} f(\mathbf{u}) \, d\mathbf{u} \approx \frac{1}{N} \sum_{n=1}^N f(\mathbf{x}_n) \quad (4)$$

but now $\mathbf{x}_1, \dots, \mathbf{x}_N$ are deterministic points in I^s . For such a deterministic numerical integration scheme we expect a deterministic error bound, and this is indeed provided by the Koksma–Hlawka inequality. It depends on the star discrepancy, a measure for the irregularity of distribution of a point set P consisting of $\mathbf{x}_1, \dots, \mathbf{x}_N \in I^s$. For any Borel set $M \subseteq I^s$, let $A(M; P)$ be the number of integers n , with $1 \leq n \leq N$ such that $\mathbf{x}_n \in M$. We put

$$R(M; P) = \frac{A(M; P)}{N} - \lambda_s(M) \quad (5)$$

which is the difference between the relative frequency of the points of P in M and the s -dimensional Lebesgue measure $\lambda_s(M)$ of M . If the points of P have a very uniform distribution over I^s , then the values of $R(M; P)$ will be close to 0 for a reasonable collection of Borel sets, such as for all subintervals of I^s .

Definition 1 *The star discrepancy of the point set P is given by*

$$D_N^* = D_N^*(P) = \sup_J |R(J; P)| \quad (6)$$

where the supremum is extended over all intervals $J = \prod_{i=1}^s [0, u_i]$ with $0 < u_i \leq 1$ for $1 \leq i \leq s$.

Koksma–Hlawka Inequality

For any function f of bounded variation $V(f)$ on I^s in the sense of Hardy and Krause and any points $\mathbf{x}_1, \dots, \mathbf{x}_N \in [0, 1]^s$, we have

$$\left| \int_{I^s} f(\mathbf{u}) \, d\mathbf{u} - \frac{1}{N} \sum_{n=1}^N f(\mathbf{x}_n) \right| \leq V(f) D_N^* \quad (7)$$

where D_N^* is the star discrepancy of $\mathbf{x}_1, \dots, \mathbf{x}_N$.

Note that $V(f)$ is a measure for the oscillation of the function f . The precise definition of the variation

$V(f)$ can be found in [49, p. 19]. For $f(\mathbf{u}) = f(u_1, \dots, u_s)$, a sufficient condition for $V(f) < \infty$ is that the partial derivative $\partial^s f / \partial u_1 \cdots \partial u_s$ be continuous on I^s . A detailed proof of the Koksma–Hlawka inequality is by Kuipers and Niederreiter [37, Section 2.5]. There are all types of variants of this inequality; see [46, 49, Section 2.2, 24].

A different kind of error bound for QMC integration was shown by Niederreiter [50]. It relies on the following concept.

Definition 2 *Let $\mathcal{M}$ be a nonempty collection of Borel sets in I^s . Then a point set P of elements of I^s is called $(\mathcal{M}, \lambda_s)$ -uniform if $R(M; P) = 0$ for all $M \in \mathcal{M}$.*

Now let $\mathcal{M} = \{M_1, \dots, M_k\}$ be a partition of I^s into nonempty Borel subsets of I^s . For a bounded Lebesgue-integrable function f on I^s and for $1 \leq j \leq k$, we put

$$G_j(f) = \sup_{\mathbf{u} \in M_j} f(\mathbf{u}), \quad g_j(f) = \inf_{\mathbf{u} \in M_j} f(\mathbf{u}) \quad (8)$$

Then for any $(\mathcal{M}, \lambda_s)$ -uniform point set consisting of $\mathbf{x}_1, \dots, \mathbf{x}_N \in I^s$ we have the error bound

$$\begin{aligned} & \left| \int_{I^s} f(\mathbf{u}) \, d\mathbf{u} - \frac{1}{N} \sum_{n=1}^N f(\mathbf{x}_n) \right| \\ & \leq \sum_{j=1}^k \lambda_s(M_j) (G_j(f) - g_j(f)) \end{aligned} \quad (9)$$

An analog of the bound (9) holds, in fact, for numerical integration over any probability space (see [50]).

A family of QMC methods that is particularly suited for periodic integrands is formed by lattice rules. For a given dimension $s \geq 1$, consider the factor group $\mathbb{R}^s / \mathbb{Z}^s$, which is an abelian group under addition of residue classes. Let $L / \mathbb{Z}^s$ be an arbitrary finite subgroup of $\mathbb{R}^s / \mathbb{Z}^s$ and let $\mathbf{x}_n + \mathbb{Z}^s$ with $\mathbf{x}_n \in [0, 1]^s$ for $1 \leq n \leq N$ be the distinct residue classes making up the group $L / \mathbb{Z}^s$. The points $\mathbf{x}_1, \dots, \mathbf{x}_N$ form the integration points of an N -point lattice rule. This terminology stems from the fact that the subset $L = \bigcup_{n=1}^N (\mathbf{x}_n + \mathbb{Z}^s)$ of $\mathbb{R}^s$ is an s -dimensional lattice. The dual lattice $L^\perp$ of L is defined by

$$L^\perp = \{\mathbf{h} \in \mathbb{Z}^s : \mathbf{h} \cdot \mathbf{x} \in \mathbb{Z} \text{ for all } \mathbf{x} \in L\} \quad (10)$$

where $\mathbf{h} \cdot \mathbf{x}$ denotes the standard inner product of $\mathbf{h}$ and $\mathbf{x}$. For real numbers, $\alpha > 1$ and $C > 0$, let $\mathcal{E}_\alpha^s(C)$ be the class of all continuous periodic functions f on $\mathbb{R}^s$ with period interval I^s and with Fourier coefficients $\hat{f}(\mathbf{h})$ satisfying

$$|\hat{f}(\mathbf{h})| \leq Cr(\mathbf{h})^{-\alpha} \quad \text{for all nonzero } \mathbf{h} \in \mathbb{Z}^s \quad (11)$$

where for $\mathbf{h} = (h_1, \dots, h_s) \in \mathbb{Z}^s$, we put

$$r(\mathbf{h}) = \prod_{i=1}^s \max(1, |h_i|) \quad (12)$$

Then it can be shown that with the notation above,

$$\begin{aligned} \max_{f \in \mathcal{E}_\alpha^s(C)} \left| \int_{I^s} f(\mathbf{u}) d\mathbf{u} - \frac{1}{N} \sum_{n=1}^N f(\mathbf{x}_n) \right| \\ = C \sum_{\mathbf{h} \in \mathbb{Z}^s \setminus \{0\}} r(\mathbf{h})^{-\alpha} \end{aligned} \quad (13)$$

Further analysis leads to the result that for any $s \geq 2$ and $N \geq 2$ there exists an s -dimensional N -point lattice rule with an error bound of order $O(N^{-\alpha}(\log N)^{c(\alpha,s)})$ for all $f \in \mathcal{E}_\alpha^s(C)$, where the exponent $c(\alpha, s) > 0$ depends only on α and s . Expository accounts of the theory of lattice rules are given in [49, Chapters 5, 71]. A more recent detailed discussion of lattice rules can be found in [25]. Algorithms for the construction of efficient lattice rules are presented, for example, in [16, 58, 72].

This article can present only a rough overview of QMC methods. For a full treatment of QMC methods, we refer to [49]. Developments from the invention of QMC methods in the early 1950s up to 1978 are covered in detail in the survey article [46].

Low-discrepancy Sequences

The Koksma–Hlawka inequality leads to the conclusion that point sets with small star discrepancy guarantee small errors in QMC integration over I^s . This raises the question of how small we can make the star discrepancy of N points in I^s for fixed N and s . For any $N \geq 2$ and $s \geq 1$, the least order of magnitude that can be achieved at present is

$$D_N^*(P) = O(N^{-1}(\log N)^{s-1}) \quad (14)$$

where the implied constant is independent of N . (Strictly speaking, one has to consider infinitely many values of N , that is, an infinite collection of point sets of increasing size, for this O -bound to make sense in a rigorous fashion, but this technicality is often ignored.) A point set P achieving equation (14) is called a *low-discrepancy point set*. The points in a low-discrepancy point set are an ideal form of quasi-random points. It is conjectured that the order of magnitude in equation (14) is best possible, that is, the star discrepancy of any $N \geq 2$ points in I^s is at least of the order of magnitude $N^{-1}(\log N)^{s-1}$. This conjecture is proved for $s = 1$ and $s = 2$ (see [37, Sections 2.1 and 2.2]).

A very useful concept is that of a *low-discrepancy sequence*, which is an infinite sequence S of points in I^s such that for all $N \geq 2$ the star discrepancy $D_N^*(S)$ of the first N terms of S satisfies

$$D_N^*(S) = O(N^{-1}(\log N)^s) \quad (15)$$

with an implied constant independent of N . It is conjectured that the order of magnitude in equation (15) is best possible, but in this case the conjecture has been verified only for $s = 1$ (see [37, Section 2.2]).

Low-discrepancy sequences have several practical advantages. In the first place, if $\mathbf{x}_1, \mathbf{x}_2, \dots \in I^s$ is a low-discrepancy sequence and $N \geq 2$ is an integer, then it is easily seen that the points

$$\mathbf{y}_n = \left(\frac{n-1}{N}, \mathbf{x}_n \right) \in I^{s+1}, \quad n = 1, \dots, N \quad (16)$$

form a low-discrepancy point set. Thus, if a low-discrepancy sequence has been constructed, then we immediately obtain arbitrarily large low-discrepancy point sets. Hence, in the following, we concentrate on the construction of low-discrepancy sequences. Furthermore, given a low-discrepancy sequence S and a budget of N integration points, we can simply use the first N terms of the sequence S to get a good QMC method. If later on we want to increase N to achieve a higher accuracy, we can do so while retaining the results of the earlier computation. This is an advantage of low-discrepancy sequences over low-discrepancy point sets.

It is clear from the Koksma–Hlawka inequality and equation (15) that if we apply QMC integration with an integrand f of bounded variation on I^s in the sense of Hardy and Krause and with the first N terms

$\mathbf{x}_1, \dots, \mathbf{x}_N \in [0, 1]^s$ of a low-discrepancy sequence, then

$$\int_{I^s} f(\mathbf{u}) \, d\mathbf{u} - \frac{1}{N} \sum_{n=1}^N f(\mathbf{x}_n) = O(N^{-1}(\log N)^s) \quad (17)$$

This yields a significantly faster convergence rate than the convergence rate $O(N^{-1/2})$ in equation (3). Thus, for many types of integrals, the QMC method will outperform the Monte Carlo method.

Over the years, various constructions of low-discrepancy sequences have been obtained. Historically, the first one was designed by Halton [23]. For integers $b \geq 2$ and $n \geq 1$, let

$$n-1 = \sum_{j=0}^{\infty} a_j(n) b^j, \quad a_j(n) \in \{0, 1, \dots, b-1\} \quad (18)$$

be the digit expansion of $n-1$ in base b . Then put

$$\phi_b(n) = \sum_{j=0}^{\infty} a_j(n) b^{-j-1} \quad (19)$$

Now let $p_1 = 2, p_2 = 3, \dots, p_s$ be the first s prime numbers. Then

$$\mathbf{x}_n = (\phi_{p_1}(n), \dots, \phi_{p_s}(n)) \in I^s, \quad n = 1, 2, \dots \quad (20)$$

is the *Halton sequence* in the bases $p_1, \dots, p_s$. This sequence S satisfies

$$D_N^*(S) = O(N^{-1}(\log N)^s) \quad (21)$$

for all $N \geq 2$, with an implied constant depending only on s . The standard software implementation of Halton sequences is that of Fox [21]. More sophisticated constructions of better low-discrepancy sequences are described in the following section.

Nets and $(\mathbf{T}, s)$ -Sequences

Current methods of constructing low-discrepancy sequences rely on the following definition, which is a special case of Definition 2.

Definition 3 Let $s \geq 1$, $b \geq 2$, and $0 \leq t \leq m$ be integers and let $\mathcal{M}_{b,m,t}^{(s)}$ be the collection of all subintervals J of I^s of the form

$$J = \prod_{i=1}^s [a_i b^{-d_i}, (a_i + 1) b^{-d_i}) \quad (22)$$

with integers $d_i \geq 0$ and $0 \leq a_i < b^{d_i}$ for $1 \leq i \leq s$ and with $\lambda_s(J) = b^{t-m}$. Then an $(\mathcal{M}_{b,m,t}^{(s)}, \lambda_s)$ -uniform point set consisting of b^m points in I^s is called a (t, m, s) -net in base b .

It is important to note that the smaller the value of t for given b, m , and s , the larger the collection $\mathcal{M}_{b,m,t}^{(s)}$ of intervals in Definition 3, and so the stronger the uniform point set property in Definition 2. Thus, the primary interest is in (t, m, s) -nets in base b with a small value of t .

There is an important sequence analog of Definition 3. Given a real number $x \in [0, 1]$, let

$$x = \sum_{j=1}^{\infty} z_j b^{-j}, \quad z_j \in \{0, 1, \dots, b-1\} \quad (23)$$

be a b -adic expansion of x , where the case $z_j = b-1$ for all but finitely many j is allowed. For an integer $m \geq 1$, we define the truncation

$$[x]_{b,m} = \sum_{j=1}^m z_j b^{-j} \quad (24)$$

If $\mathbf{x} = (x^{(1)}, \dots, x^{(s)}) \in I^s$ and the $x^{(i)}$, $1 \leq i \leq s$, are given by prescribed b -adic expansions, then we define

$$[\mathbf{x}]_{b,m} = ([x^{(1)}]_{b,m}, \dots, [x^{(s)}]_{b,m}) \quad (25)$$

We write $\mathbb{N}$ for the set of positive integers and $\mathbb{N}_0$ for the set of nonnegative integers.

Definition 4 Let $s \geq 1$ and $b \geq 2$ be integers and let $\mathbf{T} : \mathbb{N} \rightarrow \mathbb{N}_0$ be a function with $\mathbf{T}(m) \leq m$ for all $m \in \mathbb{N}$. Then a sequence $\mathbf{x}_1, \mathbf{x}_2, \dots$ of points in I^s is a $(\mathbf{T}, s)$ -sequence in base b if for all $k \in \mathbb{N}_0$ and $m \in \mathbb{N}$, the points $[\mathbf{x}_n]_{b,m}$ with $kb^m < n \leq (k+1)b^m$ form a $(\mathbf{T}(m), m, s)$ -net in base b . If for some integer $t \geq 0$, we have $\mathbf{T}(m) = m$ for $m \leq t$ and $\mathbf{T}(m) = t$ for $m > t$, then we speak of a (t, s) -sequence in base b .

A general theory of (t, m, s) -nets and (t, s) -sequences was developed by Niederreiter [47]. The

concept of a $(\mathbf{T}, s)$ -sequence was introduced by Larcher and Niederreiter [40], with the variant in Definition 4 being due to Niederreiter and Özbudak [53]. Recent surveys of this topic are presented in [51, 52]. For a (t, s) -sequence in base b we have

$$D_N^*(S) = O(b^t N^{-1} (\log N)^s) \quad (26)$$

for all $N \geq 2$, where the implied constant depends only on b and s . Thus, any (t, s) -sequence is a low-discrepancy sequence.

The standard technique of constructing $(\mathbf{T}, s)$ -sequences is the *digital method*. Fix a dimension $s \geq 1$ and a base $b \geq 2$. Let R be a finite commutative ring with identity and of order b . Set up a map $\rho : R^\infty \rightarrow [0, 1]$ by selecting a bijection $\eta : R \rightarrow \mathbb{Z}_b := \{0, 1, \dots, b-1\}$ and putting

$$\rho(r_1, r_2, \dots) = \sum_{j=1}^{\infty} \eta(r_j) b^{-j} \quad \text{for } (r_1, r_2, \dots) \in R^\infty \quad (27)$$

Furthermore, choose $\infty \times \infty$ matrices $C^{(1)}, \dots, C^{(s)}$ over R which are called *generating matrices*. For $n = 1, 2, \dots$ let

$$n-1 = \sum_{j=0}^{\infty} a_j(n) b^j, \quad a_j(n) \in \mathbb{Z}_b \quad (28)$$

be the digit expansion of $n-1$ in base b . Choose a bijection $\psi : \mathbb{Z}_b \rightarrow R$ with $\psi(0) = 0$ and associate with n the sequence

$$\mathbf{n} = (\psi(a_0(n)), \psi(a_1(n)), \dots) \in R^\infty \quad (29)$$

Then the sequence $\mathbf{x}_1, \mathbf{x}_2, \dots$ of points in I^s is defined by

$$\mathbf{x}_n = (\rho(\mathbf{n}C^{(1)}), \dots, \rho(\mathbf{n}C^{(s)})) \quad \text{for } n = 1, 2, \dots \quad (30)$$

Note that the products $\mathbf{n}C^{(i)}$ are well defined since $\mathbf{n}$ contains only finitely many nonzero terms. In practice, the ring R is usually chosen to be a finite field $\mathbb{F}_q$ of order q , where q is a prime power. The success of the digital method depends on a careful choice of the generating matrices $C^{(1)}, \dots, C^{(s)}$.

The first application of the digital method occurred in the construction of *Sobol' sequences* in [76]. This construction uses primitive polynomials over $\mathbb{F}_2$ to set up the generating matrices $C^{(1)}, \dots, C^{(s)}$ and leads

to (t, s) -sequences in base 2. The wider family of irreducible polynomials was used in the construction of *Niederreiter sequences* in [48], and this construction works for arbitrary prime-power bases q . Let $p_1, \dots, p_s$ be the first s monic irreducible polynomials over $\mathbb{F}_q$, ordered according to nondecreasing degrees and put,

$$T_q(s) = \sum_{i=1}^s (\deg(p_i) - 1) \quad (31)$$

The construction of Niederreiter sequences yields (t, s) -sequences in base q with $t = T_q(s)$. Let $U(s)$ denote the least value of t that can be achieved by Sobol' sequences for given s . Then $T_2(s) = U(s)$ for $1 \leq s \leq 7$ and $T_2(s) < U(s)$ for all $s \geq 8$. Thus, according to equation (26), for all dimensions $s \geq 8$ Niederreiter sequences in base 2 lead to a smaller upper bound on the star discrepancy than Sobol' sequences. Convenient software implementations of Sobol' and Niederreiter sequences are described in [8–10].

The potentially smallest, and thus best, t -value for any (t, s) -sequence in base b would be $t = 0$. However, according to [49, Corollary 4.24], a necessary condition for the existence of a $(0, s)$ -sequence in base b is $s \leq b$. For primes p , a construction of $(0, s)$ -sequences in base p for $s \leq p$ was given by Faure [18]. For prime powers q , a construction of $(0, s)$ -sequences in base q for $s \leq q$ was given by Niederreiter [47]. Since $T_q(s) = 0$ for $s \leq q$ by equation (31), the Niederreiter sequences in [48] also yield $(0, s)$ -sequences in base q for $s \leq q$.

An important advance in the construction of low-discrepancy sequences was made in the mid-1990s with the design of *Niederreiter–Xing sequences*, which utilizes powerful tools from algebraic geometry and the theory of algebraic function fields and generalizes the construction of Niederreiter sequences. The basic articles here are [54, 83], and expository accounts of this work and further results are given in [55, 56, 57, Chapter 8]. Niederreiter–Xing sequences are (t, s) -sequences in a prime-power base q with $t = V_q(s)$. Here, $V_q(s)$ is a number determined by algebraic curves (or equivalently algebraic function fields) over $\mathbb{F}_q$, and we have $V_q(s) \leq T_q(s)$ for all $s \geq 1$. In fact, much more is true. If we fix q and consider $V_q(s)$ and $T_q(s)$ as functions of s , then $V_q(s)$ is of the order of magnitude s , whereas $T_q(s)$ is of the order of magnitude $s \log s$.

This yields an enormous improvement on the bound for the star discrepancy in equation (7). It is known that for any (t, s) -sequences in base b the parameter t must grow at least linearly with s for fixed b (see [55, Section 10]), and so Niederreiter–Xing sequences yield t -values of the optimal order of magnitude as a function of s . A software implementation of Niederreiter–Xing sequences is described in [68] and available at <http://math.iit.edu/~mcqmc/Software.html> by following the appropriate links.

To illustrate the comparative quality of the above constructions of (t, s) -sequences, we consider the case of the most convenient base 2 and tabulate some values of $U(s)$ for Sobol’ sequences, of $T_2(s)$ for Niederreiter sequences, and of $V_2(s)$ for Niederreiter–Xing sequences in Table 1. Note that the values of $V_2(s)$ in Table 1 for $2 \leq s \leq 7$ are the least values of t for which a (t, s) -sequence in base 2 can exist.

The approach by algebraic function fields was followed up recently by Mayor and Niederreiter [45] who gave an alternative construction of Niederreiter–Xing sequences using differentials of global function fields. Niederreiter and Özbudak [53] obtained the first improvement on Niederreiter–Xing sequences for some special pairs (q, s) of prime-power bases q and dimensions s . For instance, consider the case where q is an arbitrary prime power and $s = q + 1$. Then $T_q(q + 1) = 1$ by equation (8) and this is the least possible t -value for a $(t, q + 1)$ -sequence in base q . However, the construction in [53] yields a $(\mathbf{T}, q + 1)$ -sequence in base q with $\mathbf{T}(m) = 0$ for even m and $\mathbf{T}(m) = 1$ for odd m , which is even better.

We remark that all constructions mentioned in this section are based on the digital method. We note also that the extensive database at <http://mint.sbg.ac.at> is devoted to (t, m, s) -nets and (t, s) -sequences. In summary, for a given prime-power base q , the currently best low-discrepancy sequences are as follows: (i) the Faure or Niederreiter sequences (depending on whether q is prime or not) for all dimensions

$s \leq q$ and (ii) the Niederreiter–Xing sequences for all dimensions $s > q$, except for some special values of $s > q$ where the Niederreiter–Özbudak sequences are better. We emphasize that the bound (7) on the star discrepancy of (t, s) -sequences is completely explicit; see [49, Section 4.1] and a recent improvement in [36]. For the best (t, s) -sequences, the coefficient of the leading term $N^{-1}(\log N)^s$ in the bound on the star discrepancy tends to 0 at a superexponential rate as $s \rightarrow \infty$.

Effective Dimension

In view of equation (6), the QMC method for numerical integration performs asymptotically better than the Monte Carlo method for any dimension s . However, in practical terms, the number N of integration points cannot be taken too large, and then already for moderate values of s the size of the factor $(\log N)^s$ may wipe out the advantage over the Monte Carlo method. On the other hand, numerical experiments with many types of integrands have shown that even for large dimensions s the QMC method will often lead to a convergence rate $O(N^{-1})$ rather than $O(N^{-1}(\log N)^s)$ as predicted by the theory, thus beating the Monte Carlo method by a wide margin. One reason may be that the Koksma–Hlawka inequality is in general overly pessimistic. Another explanation can sometimes be given by means of the nature of the integrand f . Even though f is a function of s variables, the influence of these variables could differ greatly. For numerical purposes, f may behave like a function of much fewer variables, so that the numerical integration problem is in essence a low-dimensional one with a faster convergence rate. This idea is captured by the notion of effective dimension.

We start with the ANOVA decomposition of a random variable $f(\mathbf{u}) = f(u_1, \dots, u_s)$ on I^s of finite variance. This decomposition amounts to writing f in the form

$$f(\mathbf{u}) = \sum_{K \subseteq \{1, \dots, s\}} f_K(\mathbf{u}) \quad (32)$$

where $f_\emptyset$ is the expected value of f and each $f_K(\mathbf{u})$ with $K \neq \emptyset$ depends only on the variables u_i with $i \in K$ and has expected value 0. Furthermore, f_{K_1} and f_{K_2} are orthogonal whenever $K_1 \neq K_2$. Then the

Table 1 Values of $U(s)$, $T_2(s)$, and $V_2(s)$

s	2	3	4	5	6	7	8	9	10	15	20
$U(s)$	0	1	3	5	8	11	15	19	23	45	71
$T_2(s)$	0	1	3	5	8	11	14	18	22	43	68
$V_2(s)$	0	1	1	2	3	4	5	6	8	15	21

variance $\sigma^2(f)$ of f decomposes as

$$\sigma^2(f) = \sum_{K \subseteq \{1, \dots, s\}} \sigma^2(f_K) \quad (33)$$

The following definition relates to this decomposition.

Definition 5 *Let d be an integer with $1 \leq d \leq s$ and r a real number with $0 < r < 1$. Then the function f has effective dimension d at the rate r in the superposition sense if*

$$\sum_{|K| \leq d} \sigma^2(f_K) \geq r \sigma^2(f) \quad (34)$$

The function f has effective dimension d at the rate r in the truncation sense if

$$\sum_{K \subseteq \{1, \dots, d\}} \sigma^2(f_K) \geq r \sigma^2(f) \quad (35)$$

Values of r of practical interest are $r = 0.95$ and $r = 0.99$, for instance. The formalization of the idea of effective dimension goes back to the articles of Caflisch *et al.* [13] and Hickernell [25]. There are many problems of high-dimensional numerical integration arising in computational finance for which the integrands have a relatively small effective dimension, one possible reason being discount factors, which render variables corresponding to distant time horizons essentially negligible. The classical example here is that of the valuation of mortgage-backed securities (see [13, 66]). For further interesting work on the ANOVA decomposition and effective dimension, with applications to the pricing of Asian and barrier options, we refer to [32, 42, 43, 81].

A natural way of capturing the relative importance of variables is to attach weights to them. More generally, one may attach weights to any collection of variables, thus measuring the relative importance of all projections—and not just of the one-dimensional projections—of the given integrand. This leads then to a weighted version of the theory of QMC methods, an approach that was pioneered by Sloan and Woźniakowski [75].

Given a dimension s we consider the set $\{1, \dots, s\}$ of coordinate indices. To any nonempty subset K of $\{1, \dots, s\}$ we attach a weight $\gamma_K \geq 0$. To avoid a trivial case, we assume that not all weights are 0. Let γ denote the collection of all these weights γ_K . Then we

introduce the *weighted star discrepancy* $D_{N,\gamma}^*$, which generalizes Definition 1. For $\mathbf{u} = (u_1, \dots, u_s) \in I^s$, we abbreviate the interval $\prod_{i=1}^s [0, u_i]$ by $[\mathbf{0}, \mathbf{u}]$. For any nonempty $K \subseteq \{1, \dots, s\}$, let $\mathbf{u}_K$ denote the point in I^s with all coordinates whose indices are not in K replaced by 1. Now for a point set P consisting of N points from I^s , we define

$$D_{N,\gamma}^* = \sup_{\mathbf{u} \in I^s} \max_K \gamma_K |R([\mathbf{0}, \mathbf{u}_K]; P)| \quad (36)$$

We recover the classical star discrepancy if we choose $\gamma_{\{1, \dots, s\}} = 1$ and $\gamma_K = 0$ for all nonempty proper subsets K of $\{1, \dots, s\}$. With this weighted star discrepancy, one can then prove a weighted analog of the Koksma–Hlawka inequality (see [75]).

There are some special kinds of weights that are of great practical interest. In the case of *product weights*, one attaches a weight η_i to each $i \in \{1, \dots, s\}$ and puts

$$\gamma_K = \prod_{i \in K} \eta_i \quad \text{for all } K \subseteq \{1, \dots, s\}, K \neq \emptyset \quad (37)$$

In the case of *finite-order weights*, one chooses a threshold k and puts $\gamma_K = 0$ for all K of cardinality larger than k .

The theoretical analysis of the performance of weighted QMC methods requires the introduction of weighted function spaces in which the integrands live. These can, for instance, be weighted Sobolev spaces or weighted Korobov spaces. In this context again, the weights reflect the relative importance of variables or collections of variables. The articles [38, 70, 75] are representative for this approach.

The analysis of the integration error utilizing weighted function spaces also leads to powerful results on tractability, a concept stemming from the theory of information-based complexity. The emphasis here is on the performance of multidimensional numerical integration schemes as a function not only of the number N of integration points but also of the dimension s as $s \rightarrow \infty$. Let $\mathcal{F}_s$ be a Banach space of integrands f on I^s with norm $\|f\|$. Write

$$L_s(f) = \int_{I^s} f(\mathbf{u}) \, d\mathbf{u} \quad \text{for } f \in \mathcal{F}_s \quad (38)$$

Consider numerical integration schemes of the form

$$\mathcal{A}(f) = \sum_{n=1}^N a_n f(\mathbf{x}_n) \quad (39)$$

with real numbers $a_1, \dots, a_N$ and points $\mathbf{x}_1, \dots, \mathbf{x}_N \in I^s$. The QMC method is of course a special case of such a scheme. For $\mathcal{A}$ as in equation (39), we write $\text{card}(\mathcal{A}) = N$. Furthermore, we put

$$\text{err}(\mathcal{A}, \mathcal{F}_s) = \sup_{\|f\| \leq 1} |L_s(f) - \mathcal{A}(f)| \quad (40)$$

For any $N \geq 1$ and $s \geq 1$, the N th minimal error of the s -dimensional numerical integration problem is defined by

$$\text{err}(N, \mathcal{F}_s) = \inf \{ \text{err}(\mathcal{A}, \mathcal{F}_s) : \mathcal{A} \text{ with } \text{card}(\mathcal{A}) = N \} \quad (41)$$

The numerical integration problem is called *tractable* if there exist constants $C \geq 0$, $e_1 \geq 0$, and $e_2 > 0$ such that

$$\begin{aligned} \text{err}(N, \mathcal{F}_s) &\leq C s^{e_1} N^{-e_2} \|L_s\|_{\text{op}} \\ \text{for all } N &\geq 1, s \geq 1 \end{aligned} \quad (42)$$

where $\|L_s\|_{\text{op}}$ is the operator norm of L_s . If, in addition, the exponent e_1 may be chosen to be 0, then the problem is said to be *strongly tractable*.

Tractability and strong tractability depend very much on the choice of the spaces $\mathcal{F}_s$. Weighted function spaces using product weights have proved particularly effective in this connection. Since the interest is in $s \rightarrow \infty$, product weights are set up by choosing a sequence $\eta_1, \eta_2, \dots$ of positive numbers and then, for fixed $s \geq 1$, defining appropriate weights γ_K by equation (37). If the η_i tend to 0 sufficiently quickly as $i \rightarrow \infty$, then in a Hilbert-space setting strong tractability can be achieved by QMC methods based on Halton, Sobol', or Niederreiter sequences (see [29, 79]). Further results on (strong) tractability as it relates to QMC methods can be found, for example, in [27, 28, 73, 74, 80, 82].

Randomized QMC

Conventional QMC methods are fully deterministic and thus do not allow statistical error estimation as in Monte Carlo methods. However, one may introduce an element of randomness into a QMC method by randomizing (or “scrambling”) the deterministic integration points used in the method. In this way,

one can combine the advantages of QMC methods, namely faster convergence rates, and those of Monte Carlo methods, namely the possibility of error estimation.

Historically, the first scrambling scheme is *Cranley–Patterson rotation*, which was introduced in [14]. This scheme can be applied to any point set in I^s . Let $\mathbf{x}_1, \dots, \mathbf{x}_N \in I^s$ be given and put

$$\mathbf{y}_n = \{\mathbf{x}_n + \mathbf{r}\} \quad \text{for } n = 1, \dots, N \quad (43)$$

where $\mathbf{r}$ is a random vector uniformly distributed over I^s and $\{\cdot\}$ denotes reduction modulo 1 in each coordinate of a point in $\mathbb{R}^s$. This scheme transforms low-discrepancy point sets into low-discrepancy point sets.

A sophisticated randomization of (t, m, s) -nets and (t, s) -sequences is provided by *Owen scrambling* (see [60]). This scrambling scheme works with mutually independent random permutations of the digits in the b -adic expansions of the coordinates of all points in a (t, m, s) -net in base b or a (t, s) -sequence in base b . The scheme is set up in such a way that the scrambled version of a (t, m, s) -net, respectively (t, s) -sequence, in base b is a (t, m, s) -net, respectively (t, s) -sequence, in base b with probability 1. Further investigations of this scheme, particularly regarding the resulting mean square discrepancy and variance, were carried out, for example, by Hickernell and Hong [26], Hickernell and Yue [30], and Owen [61–63].

Since Owen scrambling is quite time consuming, various faster special versions have been proposed, such as a method of Matoušek [44] and the method of *digital shifts* in which the permutations in Owen scrambling are additive shifts modulo b and the shift parameters may depend on the coordinate index $i \in \{1, \dots, s\}$ and on the position of the digit in the digit expansion of the coordinate. In the binary case $b = 2$, digital shifting amounts to choosing s infinite bit strings $\mathbf{B}_1, \dots, \mathbf{B}_s$ and then taking each point $\mathbf{x}_n$ of the given (t, m, s) -net or (t, s) -sequence in base 2 and bitwise XORing the binary expansion of the i th coordinate of $\mathbf{x}_n$ with $\mathbf{B}_i$ for $1 \leq i \leq s$. Digital shifts and their applications are discussed, for example, in [17, 41]. The latter article presents also a general survey of randomized QMC methods and stresses the interpretation of these methods as variance reduction techniques.

Convenient scrambling schemes are also obtained by operating on the generating matrices of (t, m, s) -nets and (t, s) -sequences constructed by the digital method. The idea is to multiply the generating matrices by suitable random matrices from the left or from the right in such a way that the value of the parameter t is preserved. We refer to [19, 64] for such scrambling schemes. Software implementations of randomized low-discrepancy sequences are described in [22, 31] and are integrated into the Java library SSJ available at <http://www.iro.umontreal.ca/~simardr/ssj>, which contains also many other simulation tools.

Applications to Computational Finance

The application of Monte Carlo methods to challenging problems in computational finance was pioneered by Boyle [3] in 1977. Although QMC methods were already known at that time, they were not applied to computational finance because it was thought that they would be inefficient for problems involving the high dimensions occurring in this area.

A breakthrough came in the early 1990s when Paskov and Traub applied QMC integration to the problem of pricing a 30-year collateralized mortgage obligation provided by Goldman Sachs; see [67] for a report on this work. This problem required the computation of 10 integrals of dimension 360 each, and the results were astounding. For the hardest of the 10 integrals, the QMC method achieved accuracy 10^{-2} with just 170 points, whereas the Monte Carlo method needed 2700 points for the same accuracy. When higher accuracy is desired, the QMC method can be about 1000 times faster than the Monte Carlo method. For further work on the pricing of mortgage-backed securities, we refer to [13, 66, 78].

Applications of QMC methods to option pricing were first considered in the technical report of Birge [2] and the article of Joy *et al.* [35]. These works concentrated on European and Asian options. In the case of path-dependent options, if the security's terminal value depends only on the prices at s intermediate times, then after discretization the expected discounted payoff under the risk-neutral measure can be converted into an integral over the s -dimensional unit cube I^s . For instance, in [35] an Asian option with 53 time steps is studied numerically.

A related problem in which an s -dimensional integral arises is the pricing of a multiasset option

with s assets; see [1] in which numerical experiments comparing Monte Carlo and QMC methods are reported for dimensions up to $s = 100$. This article also discusses Brownian bridge constructions for option pricing. Related work on the pricing of multiasset European-style options using QMC and randomized QMC methods was carried out in [39, 69, 77], and comparative numerical experiments for Asian options can be found in [4, 59]. Jiang [33] gave a detailed error analysis of the pricing of European-style options using QMC methods, which is based on a variant of the bound (3) and requires only minimal smoothness assumptions.

Owing to its inherent difficulty, it took much longer for Monte Carlo and QMC methods to be applied to the problem of pricing American options. An excellent survey of early work on Monte Carlo methods for pricing American options is presented in [4]. The first important idea in this context was the *bundling algorithm* in which paths in state space for which the stock prices behave in a similar way are grouped together in the simulation. Initially, the bundling algorithm was applicable only to single-asset American options. Jin *et al.* [34] recently extended the bundling algorithm in order to price high-dimensional American-style options, and they also showed that computing representative states by a QMC method improves the performance of the algorithm.

Another approach to pricing American options by simulation is the *stochastic mesh method*. The choice of mesh density functions at each discrete time step is crucial for the success of this method. The standard mesh density functions are mixture densities, and so in a Monte Carlo approach one can use known techniques for generating random samples from mixture densities. In a QMC approach, these random samples are replaced by deterministic points whose empirical distribution function is close to the target distribution function. Work on the latter approach was carried out by Boyle, Kolkiewicz, and Tan [5–7] and Broadie *et al.* [11]. Another application of QMC methods to the pricing of American options occurs in *regression-based methods*, which are typically least-squares Monte Carlo methods. Here Caffisch and Chaudhary [12] have shown that QMC versions improve the performance of such methods.

We conclude by mentioning two more applications of QMC methods to computational finance, namely by Papageorgiou and Paskov [65] to value-at-risk

computations and by Jiang [33] to the pricing of interest-rate derivatives in a LIBOR market model.

HARALD NIEDERREITER

Rare-event Simulation

In finance, the need for evaluation of the probability $\mathbb{P}(A)$ that an event is rare (in the sense that $\mathbb{P}(A)$ is small) arises, for example, in pricing out-of-the-money options and **Value-at-Risk** (VaR) calculations in **credit risk** and **operational risk**. However, similar problems arise in a large variety of application areas: insurance risk (ruin probabilities and probabilities of large accumulated claims); communications engineering (probabilities of blocking, bit errors, packet loss, etc.); reliability (probabilities of unavailability in steady state or in a given time interval); and so on.

In all of these examples, explicit evaluation of $\mathbb{P}(A)$ is seldom possible unless unrealistically simple model assumptions have been made. **Monte Carlo simulation** is therefore one of the main tools in this area. However, the fact that $\mathbb{P}(A)$ is small raises some specific problems.

By an estimator Z for $z = \mathbb{P}(A)$, we refer to a random variable (rv) Z that can be generated by simulation and satisfies $\mathbb{E}Z = z$. In practice, one simulates R (say) independent copies of Z and gives the estimate of z as the average $\bar{Z}_R$, supplemented with a confidence interval, say, an equitailed 95% confidence interval $\bar{Z}_R \pm w_R$ where s^2 is the empirical variance of the R simulated values of Z (the natural estimator of $\sigma_Z^2 = \text{Var} Z$) and $w_R = 1.96s/R^{1/2}$ is the half-width. In most other Monte Carlo contexts, a small w_R is the relevant criterion for an estimator to be efficient. However, in a rare-event setting, one is rather interested in the relative half-width $w_R/\mathbb{P}(A)$. For example, the confidence interval $10^{-5} \pm 10^{-4}$ may look narrow, but it does not help to tell whether z is of the magnitude 10^{-4} , 10^{-5} , or even much smaller. Another way to illustrate the problem is in terms of the sample size R needed to acquire a given relative precision, say 10%, in terms of the half-width of the 95% confidence interval. This leads to the equation $1.96 \sigma_Z / (z\sqrt{R}) = 0.1$, that is,

$$R = \frac{100 \cdot 1.96^2 z(1-z)}{z^2} \sim \frac{100 \cdot 1.96^2}{z} \quad (1)$$

which increases like z^{-1} as $z \downarrow 0$. Thus, if z is small, large sample sizes are required.

The standard formal setup for discussing such efficiency concepts is to consider a family $\{A(x)\}$

where $x \in (0, \infty)$ or $x \in \mathbb{N}$, assume that $z(x) \stackrel{\text{def}}{=} \mathbb{P}(A(x)) \rightarrow 0$ as $x \rightarrow \infty$, and for each x let $Z(x)$ be an unbiased estimator for $z(x)$, that is, $\mathbb{E}Z(x) = z(x)$. An algorithm is defined as a family $\{Z(x)\}$ of such rv's.

The best performance that has been observed in realistic rare-event settings is *bounded relative error* as $x \rightarrow \infty$, meaning

$$\limsup_{x \rightarrow \infty} \frac{\text{Var} Z(x)}{z(x)^2} < \infty \quad (2)$$

In particular, such an algorithm will have the feature that R as computed in equation (1), with $z(1-z)$ replaced by $\text{Var} Z(x)$, remains bounded as $x \rightarrow \infty$.

An efficiency concept slightly weaker than equation (2) is *logarithmic efficiency*: $\text{Var}(Z(x)) \rightarrow 0$ so quickly that

$$\limsup_{x \rightarrow \infty} \frac{\text{Var} Z(x)}{z(x)^{2-\varepsilon}} = 0 \quad (3)$$

for all $\varepsilon > 0$, or, equivalently, that

$$\liminf_{x \rightarrow \infty} \frac{|\log \text{Var} Z(x)|}{|\log z(x)^2|} \geq 1 \quad (4)$$

The most established method for producing estimators with such efficiency properties is *importance sampling*, where one simulates not from the physical measure $\mathbb{P}$ but another probability measure $\tilde{\mathbb{P}}$ with changed parameters. Then $Z = I(A)W$ where $W = d\tilde{\mathbb{P}}/d\mathbb{P}$ is the likelihood ratio. Here are two standard examples:

Example 1 $A = I(S_n > nm)$ where $S_n = X_1 + \dots + X_n$ with $X_1, X_2, \dots$ independent and identically distributed (i.i.d.) with density f and $m > \mathbb{E}X$. Here one defines $\tilde{f}(y) = e^{\theta y} f(y) / \mathbb{E}e^{\theta X}$ with θ chosen such that $\int y \tilde{f}(y) dy = m$. The estimator becomes

$$Z(n) = I(S_n > nm) \prod_{k=1}^n \frac{f(X_k)}{\tilde{f}(X_k)} \quad (5)$$

and is logarithmically efficient as $n \rightarrow \infty$.

Example 2 $A = I(\max S_n > x)$ with $X_1, X_2, \dots$ as in (1) and $\mathbb{E}X < 0$. Here one defines $\tilde{f}(y) = e^{\theta y} f(y)$ with $\theta > 0$ chosen such that $\int \tilde{f}(y) dy = 1$

(this θ is always unique and will exist for most standard light-tailed distributions). The estimator becomes $Z(x) = \exp\{-S_{\tau(x)}\}$ where $\tau(x) = \inf\{n : S_n > x\}$ and has bounded relative error as $x \rightarrow \infty$.

The definition of bounded relative error implies that in Example 2, the variance, compared to crude Monte Carlo, is reduced by a factor of order $z(x) = \mathbb{P}(A(x))$. Similar remarks apply to Example 1, though the variance reduction may be slightly smaller since there is only logarithmical efficiency there.

The principle behind the choice of $\tilde{\mathbb{P}}$ in these two examples (exponential change of measure) is to take $\tilde{\mathbb{P}}$ as an asymptotic conditional distribution given the rare event A . This is motivated from the exact conditional distribution giving zero variance. Often, the asymptotics of the conditional distribution is found by using the theory of large deviations, as illustrated by the following example:

Example 3 For a digital **barrier option**, the problem that arises (after some rewriting) is of estimating

$$z = \mathbb{P}(\underline{W}(T) \leq -a, W(T) \geq b),$$

$$\text{where } \underline{W}(T) \stackrel{\text{def}}{=} \inf_{t \leq T} W(t) \quad (6)$$

and W is a Brownian motion with drift μ and volatility σ , denoted as $\text{BM}(\mu, \sigma^2)$. If a, b are not too close to 0, this is a rare-event problem: if $\mu < 0$, W is unlikely to go from $-a$ to b , and if $\mu > 0$, W is unlikely to ever hit $-a$. It seems reasonable that on a fluid scale, the most likely path φ^* should be piecewise linear as in Figure 1.

The theory of large deviations suggests that finding φ^* is equivalent to a one-dimensional minimization problem, where one looks for the infimum over t of

$$2 \int_0^T I(\varphi'(t)) dt = \int_0^t (-a/t - \mu)^2 ds$$

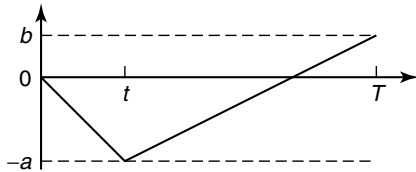

Figure 1 The most likely path for the barrier option

$$+ \int_t^T (c/(T-t) - \mu)^2 ds$$

$$= t(a/t + \mu)^2 + (T-t)$$

$$\times (c/(T-t) - \mu)^2 \quad (7)$$

where $c = b + a$, we have taken $\sigma^2 = 1$, and $I(y) = (y - \mu)^2/2$ is the so-called rate function for $\text{BM}(\mu, 1)$ (see **Large Deviations**). Elementary calculus shows that the minimum is attained at $t = aT/(a + c)$. This means that the most likely path is linear with slope $-\mu^*$ on $[0, t]$ and slope μ^* on $(t, T]$ where $\mu^* = (a + 2b)/T$, so that the above principle of approximating the conditional distribution given the rare event suggests that importance sampling may be done with the Brownian drift changed as stated.

This suggests simulating with drift $-\mu^*$ until the time τ where $-a$ is hit and then changing the drift to μ^* . Since the likelihood ratio for changing the drift from μ to $\tilde{\mu}$ in an interval $[0, t]$ is

$$Q = Q(t, \tilde{\mu}) = \exp\{-(\tilde{\mu} - \mu)W(t) + (\tilde{\mu} - \mu)^2 t\} \quad (8)$$

and this formula extends to stopping times, it follows that the importance sampling estimator is

$$Q(\tau, -\mu^*)Q((T - \tau), \mu^*)$$

$$\times I(\underline{W}(T) \leq -a, W(T) \geq b) \quad (9)$$

(modified to 0 if $\tau > T$). For a further discussion, see [4, pp. 264 ff].

Example 4 Glasserman *et al.* [5] considered a portfolio exposed to d (dependent) risk factors $X_1, \dots, X_d$ in a certain time horizon h , say, 1 day or 2 weeks. The initial value of the portfolio is denoted by v and the (discounted) terminal value by $V = V(h, X_1, \dots, X_d)$. The loss is $L = v - V$, and the VaR is a quantile of L (say the 99% one or the 99.97% one). It is assumed that $X \sim \mathcal{N}(\mathbf{0}, \Sigma)$.

The basis of the algorithm is to invoke the *delta-gamma approximation*, which is based on the Taylor expansion

$$L \approx -\frac{\partial V}{\partial h} h - \sum_{i=1}^d \delta_i X_i - \frac{1}{2} \sum_{i,j=1}^d \gamma_{ij} X_i X_j \quad (10)$$

where $\delta_i \stackrel{\text{def}}{=} \partial V / \partial x_i$, $\gamma_{ij} \stackrel{\text{def}}{=} \partial^2 V / \partial x_i \partial x_j$. For brevity, we rewrite the right-hand side of equation (10) as $a_0 + Q$, where $Q \stackrel{\text{def}}{=} -\delta^T X - X^T \Gamma X / 2$, $a_0 \stackrel{\text{def}}{=} -h \partial V / \partial h$, and the proposal of Glasserman *et al.* [5] is to use the same exponential change of measure for the X_i as one would if the conditional distribution of Q , not L , was the target. Writing $X = CY$ where the components of $Y = (Y_1 \dots Y^d)$ are i.i.d. standard normal, one can choose C to satisfy

$$Q = \sum_{i=1}^d (b_i Y_i + \lambda_i Y_i^2) \quad (11)$$

and then it can be seen (e.g., [1] pp. 432–434) that under the conditional probability thus described, $Y_1, \dots, Y^d$ are still independent and Gaussian but have mean and variance parameters

$$\mu_i = \frac{\theta b_i}{1 - \theta \lambda_i}, \quad \sigma_i^2 = \frac{1}{1 - \theta \lambda_i} \quad (12)$$

where θ is determined by

$$x - a_0 = \tilde{\mathbb{E}} Q = \sum_{i=1}^d [b_i \mu_i + \lambda_i (\mu_i^2 + \sigma_i^2)] \quad (13)$$

Thus, the importance sampling estimator for estimating $\mathbb{P}(L > \ell)$ is

$$I(L > \ell) \prod_{i=1}^2 \frac{e^{-Y_i^2/2} / \sqrt{2\pi}}{e^{-(Y_i - \mu_i)^2/2\sigma_i^2} / \sqrt{2\pi\sigma_i^2}} \quad (14)$$

The empirical finding of Glasserman *et al.* [5] is that this procedure typically (i.e., in the case of a number of selected test portfolios) reduces the variance by a factor of 20–50.

The examples we have mentioned so far involve light tails. However, **heavy tails** are relevant particularly in areas such as credit risk and operational risk. The algorithms with heavy tails typically look completely different from those with light tails since exponential moments do not exist and hence exponential change of measure is impossible. We consider only the most important case of a tail $\bar{F}(x)$ that is regularly varying, that is, of the form $\bar{F}(x) = L(x)/x^{\alpha+1}$ with $L(\cdot)$ slowly varying (e.g., a Pareto tail). Statistical tests for distinguishing between light and heavy tails based on i.i.d. observations $X_1, \dots, X_n$ from F are discussed

in [6] (see also [1] VI.4). A popular tool is the mean excess plot, where the mean of the observations exceeding x is plotted as function of x . For a heavy-tailed distribution, and not for a light-tailed one, one expects to see a function going to infinity. The standard tool for estimating α in the regularly varying case is the so-called Hill estimator; see [1, 6].

Example 5 Let $X_1, \dots, X_n$ be i.i.d. with regularly varying distribution F and $S_N = X_1 + \dots + X_N$ where N is fixed or an independent rv. The problem of estimating $z(x) = \mathbb{P}(S_N > x)$ arises in a number of areas, for example, insurance risk, credit risk, and operational risk. The first efficient algorithms for this problem are remarkable in that they use conditional Monte Carlo, and not importance sampling. Currently, the most efficient of such algorithms uses the identity $z(x) = n \mathbb{P}(S_n > x, M_n = X_n)$ (keeping $N = n$ fixed and writing $M_k = \max(X_1, \dots, X_k)$); the intuition behind involving M_n is the fact that basically one X_i is large (and then equal to M_n) when $S_N > x$. One then simulates $X_1, \dots, X_{n-1}$ and returns the conditional expectation

$$\begin{aligned} Z(x) &= n \mathbb{P}(S > x, M_n = X_n \mid X_1, \dots, X_{n-1}) \\ &= n \bar{F}(\max(x - S_{n-1}, M_{n-1})) \end{aligned} \quad (15)$$

Example 6 A very active area is dynamic importance sampling, where the importance distribution varies with time and current state (e.g., in the barrier option example one would let the Brownian drift depend on both time t and $W(t)$). A principle for doing this is based upon Doob's h transform and requires that approximations for $z(x)$ are available; see [1] VI.7. Some of the important recent examples in the heavy-tailed area are found in [2] and [3], and the approach seems to carry greater hope for generality than conditional Monte Carlo.

We conclude by mentioning some ideas beyond standard importance sampling (as exemplified above) that are relevant in the general area of rare-event simulation. An interesting recent development is the cross-entropy method [7], which performs an automatic search for a good importance distribution within a given parametric class. Another development is that of splitting the methods (cf [1] V.6, VI.9), where the rare event is decomposed as the intersection of events, each of which is nonrare.

End Notes

^aNote that the parameter indexing the rare event is discrete in this example and hence denoted as n rather than x .

Stochastic Taylor Expansions

Deterministic Taylor Formula

As the concept of a stochastic Taylor expansion can be widely applied, we first review the *deterministic Taylor expansion*, using some terminology which will facilitate the presentation of its stochastic counterparts. Let us consider the solution $X = \{X_t, t \in [0, T]\}$ of the ordinary differential equation $dX_t = a(X_t) dt$, for $t \in [0, T]$ with initial value X_0 . We can write this equation in its integral form as

$$X_t = X_0 + \int_0^t a(X_s) ds \quad (1)$$

To justify the following calculations, we require the drift function a to be smooth and such that the solution of equation (1) does not explode. Then by using the deterministic chain rule, we can write

$$df(X_t) = a(X_t) \frac{\partial}{\partial x} f(X_t) dt \quad (2)$$

Using the operator $L = a \partial / \partial x$, we may express equation (2) as the integral equation

$$f(X_t) = f(X_0) + \int_0^t L f(X_s) ds \quad (3)$$

for all $t \in [0, T]$. Note for the special case $f(x) \equiv x$ we have $Lf = a$, $LLf = (L)^2 f = La, \dots$, and equation (3) reduces to equation (1). If we now apply relation (3) to the integrand $f = a$ in equation (1), then we obtain

$$\begin{aligned} X_t &= X_0 + \int_0^t \left(a(X_0) + \int_0^s L a(X_z) dz \right) ds \\ &= X_0 + a(X_0) \int_0^t ds + \int_0^t \int_0^s L a(X_z) dz ds \end{aligned} \quad (4)$$

which is the simplest nontrivial Taylor expansion for X_t . We can now apply equation (3) to the function

$f = La$ in the above double integral in equation (4). Consequently, we obtain

$$\begin{aligned} X_t &= X_0 + a(X_0) \int_0^t ds \\ &\quad + L a(X_0) \int_0^t \int_0^s dz ds + R_1 \end{aligned} \quad (5)$$

with remainder term

$$R_1 = \int_0^t \int_0^s \int_0^z (L)^2 a(X_u) du dz ds \quad (6)$$

for $t \in [0, T]$. Continuing this way then we get a version of the classical deterministic *Taylor formula*

$$\begin{aligned} f(X_t) &= f(X_0) + \sum_{l=1}^r \frac{t^l}{l!} (L)^l f(X_0) \\ &\quad + \int_0^t \cdots \int_0^{s_2} (L)^{r+1} f(X_{s_1}) ds_1 \cdots ds_{r+1} \end{aligned} \quad (7)$$

for $t \in [0, T]$ and $r \in \mathcal{N}$. In the sum on the right-hand side of equation (5), we find the expansion terms that are expanded at time zero or, more precisely, at the value X_0 . Furthermore, the last term, which is a multiple integral, represents the remainder term. Its integrand is, in general, not a constant. The deterministic Taylor formula allows the approximation of a sufficiently smooth function in a neighborhood of a given expansion point to any desired order of accuracy as long as f and a are sufficiently smooth.

Wagner–Platen Expansion

It is important to be able to approximate the increments of smooth functions of solutions of stochastic differential equations. For these tasks, a stochastic expansion, with analogous properties to the deterministic Taylor formula, is needed. The *Wagner–Platen expansion* (see [1, 2, 5, 8, 10, 11]) is such a stochastic Taylor expansion. We derive here one of its versions for a diffusion process $X = \{X_t, t \in [0, T]\}$ satisfying

$$X_t = X_0 + \int_0^t a(X_s) ds + \int_0^t b(X_s) dW_s \quad (8)$$

for $t \in [0, T]$, where W is a standard Wiener process. The coefficient functions a and b are assumed to be sufficiently smooth, real valued, and such that a unique solution of equation (6) exists. Then, for a sufficiently smooth function $f : \Re \rightarrow \Re$, the Itô formula provides the representation

$$\begin{aligned} f(X_t) &= f(X_0) + \int_0^t L^0 f(X_s) ds \\ &\quad + \int_0^t L^1 f(X_s) dW_s \end{aligned} \quad (9)$$

for $t \in [0, T]$, where we used the operators $L^0 = a(\partial/\partial x) + 1/2b^2(\partial^2/\partial x^2)$ and $L^1 = b(\partial/\partial x)$.

Obviously, for the special case $f(x) \equiv x$, we have $L^0 f = a$ and $L^1 f = b$, for which the representation (9) reduces to equation (8). Since the representation (9) involves integrands that are functions of processes, we can now apply the Itô formula (9) to the functions a and b in equation (8) to obtain

$$\begin{aligned} X_t &= X_0 + \int_0^t \left(a(X_0) + \int_0^s L^0 a(X_z) dz \right. \\ &\quad \left. + \int_0^s L^1 a(X_z) dW_z \right) ds + \int_0^t \left(b(X_0) \right. \\ &\quad \left. + \int_0^s L^0 b(X_z) dz + \int_0^s L^1 b(X_z) dW_z \right) dW_s \\ &= X_0 + a(X_0) \int_0^t ds + b(X_0) \int_0^t dW_s + R_2 \end{aligned} \quad (10)$$

with remainder term

$$\begin{aligned} R_2 &= \int_0^t \int_0^s L^0 a(X_z) dz ds \\ &\quad + \int_0^t \int_0^s L^1 a(X_z) dW_z ds \\ &\quad + \int_0^t \int_0^s L^0 b(X_z) dz dW_s \\ &\quad + \int_0^t \int_0^s L^1 b(X_z) dW_z dW_s \end{aligned} \quad (11)$$

This already represents a simple example of a Wagner–Platen expansion. We can extend the above expansion by applying the Itô formula (9), for

instance, to the function $L^1 b$ in the remainder. In this case, we obtain the expansion

$$\begin{aligned} X_t &= X_0 + a(X_0) \int_0^t ds + b(X_0) \int_0^t dW_s \\ &\quad + L^1 b(X_0) \int_0^t \int_0^s dW_z dW_s + R_3 \end{aligned} \quad (12)$$

with a new remainder R_3 . In equation (12), the leading terms are functions of the value of the diffusion at the expansion point, which are weighted by corresponding multiple stochastic integrals. In principle, one can derive such an expansion for a general multifactor diffusion process X , a general smooth function f , and an arbitrary high expansion level (see [6]). The main properties of this type of expansion are already apparent in the preceding example. The Wagner–Platen expansion can be interpreted as a generalization of both the Itô formula and the classical deterministic Taylor formula. It can be derived via an iterated application of the Itô formula.

The following version of a Wagner–Platen expansion, involving triple integrals in the expansion part, can be useful in various applications:

$$\begin{aligned} X_t &= X_0 + a I_{(0)} + b I_{(1)} + (a a' + 1/2 b^2 a'') I_{(0,0)} \\ &\quad + (a b' + 1/2 b^2 b'') I_{(0,1)} + b a' I_{(1,0)} + b b' I_{(1,1)} \\ &\quad + [a (a a'' + (a')^2 + b b' a'' + 1/2 b^2 a''') \\ &\quad + 1/2 b^2 (a a''' + 3 a' a'' + ((b')^2 + b b'') a'' \\ &\quad + 2 b b' a''') + 1/4 b^4 a^{(4)}] I_{(0,0,0)} \\ &\quad + [a (a' b' + a b'' + b b' b'' + 1/2 b^2 b''') \\ &\quad + 1/2 b^2 (a'' b' + 2 a' b'' + a b''' + ((b')^2 + b b'') b'' \\ &\quad + 2 b b' b''' + 1/2 b^2 b^{(4)})] I_{(0,0,1)} + [a (b' a' + b a'') \\ &\quad + 1/2 b^2 (b'' a' + 2 b' a'' + b a''')] I_{(0,1,0)} \\ &\quad + [a ((b')^2 + b b'') + 1/2 b^2 (b'' b' + 2 b b'' \\ &\quad + b b''')] I_{(0,1,1)} + b (a a'' + (a')^2 + b b' a'' \\ &\quad + 1/2 b^2 a''') I_{(1,0,0)} + b (a b'' + a' b' + b b' b'' \\ &\quad + 1/2 b^2 b''') I_{(1,0,1)} + b (a' b' + a'' b) I_{(1,1,0)} \\ &\quad + b ((b')^2 + b b'') I_{(1,1,1)} + R_6 \end{aligned} \quad (13)$$

Here, the coefficient functions a , b , and their derivatives a' , b' , a'' , b'' , a''' , b''' are valued at the

expansion point X_0 , which we suppress in our notation. The multiple stochastic integrals $I_{(j_1, j_2, j_3)} = \int_0^t \int_0^s \int_0^z dW_u^{j_1} dW_z^{j_2} dW_s^{j_3}$, where we set $dW_t^0 = dt$ and $dW_t^1 = dW_t$, are taken on $[0, t]$. Important applications of Wagner–Platen expansions arise in the construction of strong and weak discrete time approximations for scenario simulation (see **Stochastic Differential Equations: Scenario Simulation**) and Monte Carlo simulation (see **Monte Carlo Simulation for Stochastic Differential Equations**). Detailed results for higher level stochastic Taylor expansions and derivations of estimates for the remainder can be found in [6].

Generalized Wagner–Platen Expansions

By following the same ideas, one can expand the changes of a function value with respect to the underlying diffusion process X itself. For example, from an iterated application of the Itô formula it follows for a sufficiently smooth function $f : [0, T] \times \mathfrak{R} \rightarrow \mathfrak{R}$ an expansion of the form

$$\begin{aligned} f(t, X_t) = & f(0, X_0) + \frac{\partial}{\partial t} f(0, X_0) t \\ & + \frac{\partial}{\partial x} f(0, X_0) (X_t - X_0) \\ & + \frac{1}{2} \frac{\partial^2}{\partial x^2} f(0, X_0) \langle X \rangle_t \\ & + \frac{\partial^2}{\partial x \partial t} f(0, X_0) \int_0^t \int_0^s dX_z ds \\ & + \frac{1}{2} \frac{\partial^2}{\partial x^2} \frac{\partial}{\partial t} f(0, X_0) \int_0^t \int_0^s d\langle X \rangle_z ds \\ & + \frac{\partial^2}{\partial t \partial x} f(0, X_0) \int_0^t \int_0^s dz dX_s \\ & + \frac{\partial^2}{\partial x^2} f(0, X_0) \int_0^t \int_0^s dX_z dX_s \\ & + \frac{1}{2} \frac{\partial^3}{\partial x^3} f(0, X_0) \int_0^t \int_0^s d\langle X \rangle_z dX_s \\ & + \frac{1}{2} \frac{\partial^3}{\partial t \partial x^3} f(0, X_0) \int_0^t \int_0^s dz d\langle X \rangle_s \\ & + \frac{1}{2} \frac{\partial^3}{\partial x^3} f(0, X_0) \int_0^t \int_0^s dX_z d\langle X \rangle_s \end{aligned}$$

$$\begin{aligned} & + \frac{1}{4} \frac{\partial^4}{\partial x^4} f(0, X_0) \int_0^t \int_0^s d\langle X \rangle_z d\langle X \rangle_s \\ & + \bar{R}_f(0, t) \end{aligned} \quad (14)$$

for $t \in [0, T]$, where $\bar{R}_f(0, t)$ expresses the corresponding remainder term.

There exist multidimensional versions of Wagner–Platen expansions with respect to several driving processes. By using such expansions, one can, for instance, expand the increment of an option price in a multifactor setting. This provides a better understanding of the sensitivities with respect to given factor processes. Another application is the approximate evaluation of risk measures, for instance, **Value-at-Risk** (see [12]).

General stochastic Taylor expansions in a semimartingale setting have been derived in [8, 10]. Stochastic Taylor expansions based on multiple Stratonovich integrals are detailed in [5]. Wagner–Platen expansions for jump-diffusions and pure jump processes can be found in [3, 4, 9]. Expansions of functionals of Lévy processes *via* power processes have been described in [7].

ECKHARD PLATEN

Exercise Boundary Optimization Methods

One of the most important characteristics of the Monte Carlo simulation method is its intrinsically forward-looking nature. While this feature enables us to take into account inherently path-dependent payoff structures of any derivative contract with comparative ease, it makes it difficult to accommodate the inclusion of any early exercise rights into the contract. The two most commonly used methods to handle products with early exercise opportunities within a Monte Carlo simulation framework are *regression-based* techniques (which are covered in **Bermudan Options**) and *exercise boundary optimization* approaches that are discussed in this article.

Optimal Stopping Time as Exercise Boundary Optimization

For the sake of generality, we assume that we are dealing with the valuation of a financial product Π_0 , with embedded exercise optionality and discrete cash flows that span m time horizons $t_1 < \dots < t_m$, with the current time being $t \equiv t_0$. The product is considered to have two underlying contracts A and B of contingent cash flows, both of which, individually, contain no exercise optionality. The product Π_0 initially pays the same cash flows as product A , but, in addition, permits the exercise option holder to switch into B at one of the time horizons t_j . This formulation is fairly generic and encompasses practically all callable structures, including what is sometimes referred to as *options on options* or *higher order options* since they can be reformulated as a sequence of payable cash flows to continue until a final contingent payoff is attained, or to opt out at any of the intermediate exercise times.

Assuming a finite-dimensional Markovian representation of our usual probability space given a state vector $\mathbf{x}$, the contingency of the cash flows a_j in product A means that $a_j = a_j(\mathbf{x}(t_j))$, and likewise for product B . Risk-neutral valuation of the exercisable financial product Π_0 requires that we identify the optimal exercise strategy represented by the *optimal stopping time*. Valuation of Π_0 in the filtration

$\mathcal{F}_{t_0}$, denoted by $\mathcal{V}_{t_0}[\Pi_0]$, is given by

$$\mathcal{V}_{t_0}[\Pi_0] = N(\mathbf{x}(t_0)) \cdot \sup_{\tau} \mathbb{E}_{t_0}^{\mathcal{M}(N)} \left[\sum_{j=1}^{\tau-1} \frac{a_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} + \sum_{j=\tau}^m \frac{b_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} \right] \quad (1)$$

wherein the discrete random variable $\tau \in 1, \dots, m$ is the stopping time index, $N(\cdot)$ is the chosen numéraire, and $\mathbb{E}_{t_0}^{\mathcal{M}(N)}[f]$ is the expectation of any given f under the measure induced by the numéraire in the filtration $\mathcal{F}_{t_0}$. Define Π_k in complete analogy to the financial product Π_0 except that it can only be exercised on or after t_k . A crucial observation in the following is that if we had knowledge of the optimal stopping time process

$$\tau_k^* := \arg \sup_{\tau | \tau \geq k} \mathbb{E}_{t_0}^{\mathcal{M}(N)} \left[\sum_{j=1}^{\tau-1} \frac{a_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} + \sum_{j=\tau}^m \frac{b_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} \right] \quad (2)$$

we could value Π_k by means of the simple expectation

$$\mathcal{V}_{t_0}[\Pi_k] = N(\mathbf{x}(t_0)) \cdot \mathbb{E}_{t_0}^{\mathcal{M}(N)} \left[\sum_{j=1}^{k-1} \frac{a_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} + \sum_{j=k}^{\tau_k^*-1} \frac{a_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} + \sum_{j=\tau_k^*}^m \frac{b_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} \right] \quad (3)$$

By virtue of the assumed Markovian representation in the state vector $\mathbf{x}(t)$, it is possible to rephrase the valuation problem based on an indicator function $\mathcal{I}_k(\mathbf{x}(t_k))$, which takes the value 1 when exercise is optimal and 0 otherwise. This gives us the recursive formulation

$$\begin{aligned} \mathcal{V}_{t_0}[\Pi_k] &= N(\mathbf{x}(t_0)) \cdot \mathbb{E}_{t_0}^{\mathcal{M}(N)} \left[\mathcal{I}_k(\mathbf{x}(t_k)) \cdot \left(\sum_{j=1}^{k-1} \frac{a_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} + \sum_{j=k}^m \frac{b_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} \right) + \tilde{\mathcal{I}}_k(\mathbf{x}(t_k)) \cdot \frac{\mathcal{V}_{t_k}[\Pi_{k+1}]}{N(\mathbf{x}(t_k))} \right] \quad (4) \end{aligned}$$

2 Exercise Boundary Optimization Methods

wherein $\tilde{\mathcal{I}}_k = 1 - \mathcal{I}_k$. If we define the product $\hat{\Pi}_k$ as Π_k minus all cash flows occurring before t_k such that the first cash flow of $\hat{\Pi}_k$ is b_k or a_k at t_k , depending on whether exercise was invoked at t_k or not, we have

$$\begin{aligned} \mathcal{V}_{t_0}[\hat{\Pi}_k] &= N(\mathbf{x}(t_0)) \cdot \mathbb{E}_{t_0}^{\mathcal{M}(N)} \left[\tilde{\mathcal{I}}_k(\mathbf{x}(t_k)) \right. \\ &\quad \times \frac{a_k(\mathbf{x}(t_k)) + \mathcal{V}_{t_k}[\hat{\Pi}_{k+1}]}{N(\mathbf{x}(t_k))} \\ &\quad \left. + \mathcal{I}_k(\mathbf{x}(t_k)) \cdot \sum_{j=k}^m \frac{b_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} \right] \end{aligned} \quad (5)$$

In this form, it seems that we need to know the conditional value $\mathcal{V}_{t_k}[\hat{\Pi}_{k+1}]$ in order to value Π_0 (which is, by construction, equal to $\hat{\Pi}_0$, since no cash flows occur before t_1). However, since this conditional expectation appears *inside an expectation over its conditioning filtration*, by virtue of the *tower law*, we can replace it by the sequence of (numéraire-deflated) contingent cash flow values:

$$\begin{aligned} \mathcal{V}_{t_0}[\hat{\Pi}_k] &= N(\mathbf{x}(t_0)) \cdot \mathbb{E}_{t_0}^{\mathcal{M}(N)} \left[\tilde{\mathcal{I}}_k(\mathbf{x}(t_k)) \cdot \left(\sum_{j=k}^{\tau_{k+1}^* - 1} \frac{a_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} \right. \right. \\ &\quad \left. \left. + \sum_{j=\tau_{k+1}^*}^m \frac{b_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} \right) + \mathcal{I}_k(\mathbf{x}(t_k)) \cdot \sum_{j=k}^m \frac{b_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} \right] \end{aligned} \quad (6)$$

In this form, we can view

$$c_k = \sum_{j=k}^{\tau_{k+1}^* - 1} \frac{a_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} + \sum_{j=\tau_{k+1}^*}^m \frac{b_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} \quad (7)$$

as the numéraire-deflated *continuation value*, and

$$q_k = \sum_{j=k}^m \frac{b_j(\mathbf{x}(t_j))}{N(\mathbf{x}(t_j))} \quad (8)$$

as the numéraire-deflated *cancellation value*, to arrive at

$$\begin{aligned} \mathcal{V}_{t_0}[\hat{\Pi}_k] &= N(\mathbf{x}(t_0)) \cdot \mathbb{E}_{t_0}^{\mathcal{M}(N)} \left[\tilde{\mathcal{I}}_k(\mathbf{x}(t_k)) \cdot c_k \right. \\ &\quad \left. + \mathcal{I}_k(\mathbf{x}(t_k)) \cdot q_k \right] \end{aligned} \quad (9)$$

The only trouble now is that we do not know, *a priori*, the optimal exercise indicator function $\mathcal{I}_k(\cdot)$. We can confidently say, though, that given any trial exercise decision function $\mathcal{E}_k(\mathbf{x}; \lambda_k)$ (which we choose to indicate exercise if its value is positive), with parameter vector λ_k , we have

$$\begin{aligned} \mathcal{V}_{t_0}[\hat{\Pi}_k] &\geq N(\mathbf{x}(t_0)) \cdot \max_{\lambda_k} \mathbb{E}_{t_0}^{\mathcal{M}(N)} \left[\mathbf{1}_{\{\mathcal{E}_k(\mathbf{x}(t_k); \lambda_k) \leq 0\}} \cdot c_k \right. \\ &\quad \left. + \mathbf{1}_{\{\mathcal{E}_k(\mathbf{x}(t_k); \lambda_k) > 0\}} \cdot q_k \right] \end{aligned} \quad (10)$$

The key idea of *exercise boundary optimization methods* for the valuation of exercisable financial products in a Monte Carlo simulation framework is to use a suitably chosen exercise decision function $\mathcal{E}_k(\mathbf{x}; \lambda_k)$ and to find the value for λ_k that maximizes the Monte Carlo estimator objective function

$$F_k := \frac{1}{n} \sum_{i=1}^n (\mathbf{1}_{\{\mathcal{E}_k(\mathbf{x}(t_k); \lambda_k) \leq 0\}} \cdot c_{ik} + \mathbf{1}_{\{\mathcal{E}_k(\mathbf{x}(t_k); \lambda_k) > 0\}} \cdot q_{ik}) \quad (11)$$

with c_{ik} and q_{ik} representing the continuation and cancellation values of the i th path at time horizon t_k for a set of n -simulated discrete evolutions of the state vector in the chosen measure. Incidentally, it becomes apparent in this formulation that the exercise boundary optimization method allows readily for the switch product B to be, in principle, a different one at each exercise time horizon since the switch payments enter only in the form of the term q_{ik} as the sum of all numéraire-deflated cash flows that are payable if exercise is made at time t_k . Once the maximizing value λ_k has been established, the procedure continues at t_{k-1} , in analogy to a backward induction method. An important observation in this context is that throughout the entire backward iteration the same set of simulated paths and associated values can be used. This is a key point for the efficiency of this method. An initial simulation only needs to store the

required state variables $\mathbf{x}(t_k)$ and associated continuation and cancellation values for each exercise time horizon. All subsequent optimization calculations can then be done over this precomputed *training set*. For typical training set sizes in the range of 8191–65 535 paths, the evaluation of the objective function (11) is thus very fast indeed.

Choices of Exercise Boundary Specification

The choice of exercise decision function $\mathcal{E}(\mathbf{x}; \lambda)$ is crucial for the performance of exercise boundary optimization methods. This applies to both the actual choice of the functional form and, with it, the number of free parameters, as well as the effective financial variables that are considered the primary arguments of $\mathcal{E}(\cdot)$.

Assessment by Related Financial Contracts

An intuitive approach to the choice of a reduced set of state variables is to monitor related financial contracts. Andersen [1] and Piterbarg [3] describe how swap rate levels and European swaptions values, even if only attainable in an approximate analytical fashion in any one given model, can be used to capture most of the callability value for Bermudan swaptions. They also show that for this family of financial contracts, a one-parameter choice for $\mathcal{E}_k(\mathbf{x}; \lambda)$ is often sufficient. This particularly holds when the used model is itself driven by a single Brownian motion, even if there is no one-dimensional Markovian representation as is the case for Libor market model. In this case, the exercise decision function can be as simple as

$$SR(\mathbf{x}) - \lambda$$

with $SR(\mathbf{x})$ denoting the coterminal swap rate, for a payer's Bermudan swaption. More complicated decision rules for Bermudan swaptions can be found in [1].

Financial Coordinate Transformations

It is not always intuitive and easy to find a related financial contract that can be used as an exercise indicator and whose value is attainable (semi)analytically.

Jäckel [2] discusses the exercise boundary optimization method in more general terms and suggests, when necessary, the use of tree methods and non-linear transformations of $\mathbf{x}$ for the assessment of the suitability of any particular functional form and choice of variables prior to its use in an exercise boundary optimization context. The useful observation is made that a functional form that works well for a given financial contract's exercise domain delineation with one model, even if the contract is simplified to a significant extent, practically always also works very well with other models for the fully fledged product version. This makes it possible, for instance, to visualize exercise domains computed with a nonrecombining tree implementation of a two-factor Libor market model for a short contract life such as 6-noncall-2, and to apply the same functional form with a fully factorized model for very long-dated contracts.

A Useful Generic Functional Form

In practice, the functional form

$$\begin{aligned} \mathcal{E}_{\text{hyperbolic}}(x, y; a, b, c, d, g) \\ = a - y + c(x - b) + g\sqrt{(c(x - b))^2 + d^2} \end{aligned} \quad (12)$$

suits many practical applications where two financial variables are required to unlock most of the callability value.

The typical shapes of its zero-level contour line (which is the exercise boundary) are shown in Figure 1. As an example for the use of this functional form, consider the callability of a payer's Bermudan swaption in a multifactor model, and consider x to represent the front Libor and y as the coterminal swap rate. In the limit of both x and y very large, it is clearly beneficial to exercise as soon as possible, whence $\mathcal{E}$ ought to be large in this limit. In contrast, when both are very low, we should not exercise, and $\mathcal{E}$ must be negative in this limit. When x is small and y is moderate but larger than the fixed rate, exercise should not be done now but is likely to become optimal at a later stage. When y is very small, exercise should be avoided, even if x is large. This simple analysis already suggests that $-\mathcal{E}_{\text{hyperbolic}}$ with $a > 0$,

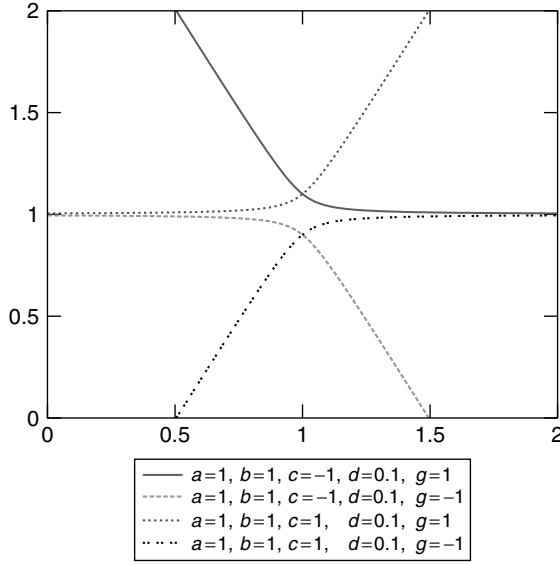

Figure 1 The hyperbolic exercise boundary given by equation (12)

$b > 0$, $c < 0$, $g > 0$ might be a good choice, and empirical tests show that this indeed works very well.

The Full Algorithm

The key stages of the exercise boundary optimization method are as follows:-

- Step 1.* Decide on a functional form for the exercise decision functions $\mathcal{E}$ for all exercise time horizons. Note that different functions may need to be chosen for different time horizons if the product exhibits strong inhomogeneity in its features over time. Also, note that the exercise domain may not be singly connected whence the implicit formulation of the exercise domain in the form of $\mathcal{E}(\mathbf{x}) > 0$ is generally preferable over explicit specifications of the boundary. A simple example for this is a multicallable best-of option paying $(\max(S_1, S_2) - K)_+$.
- Step 2.* Generation of the n -path training set. The only values that need to be stored are each path's continuation values, cancellation values, and exercise decision function argument values for each exercise decision horizon.

Note that for complex models, with contemporary computer's typical memory capacities, this reduction in storage requirements is typically necessary in order to be able to store all data in memory. Also note that the reduction of required memory typically leads to significant speedup since the cache memory access speed and main memory access speed differ considerably.

- Step 3.* In reverse chronological order, optimize the discretely sampled objective function (11) for each exercise time horizon in turn. Note that the objective function, at a high-resolution level, appears to be piecewise constant in its parameters whence an optimization method ought to be used that can cope with the fact that the function appears to change only at scales compatible with the granularity of the Monte Carlo sampling. One of the simplest methods that allows for a scale change during the optimization is the *Downhill-Simplex* algorithm [4]. For the case that λ is one-dimensional, golden section search [4] or outright sorting also works well.

- Step 4.* Using the exercise strategy now defined by the fully specified exercise decision functions established in stage 3, reevaluate the callable financial contract by an independent N -path Monte Carlo simulation with $N \gg n$. In practice, $N \sim 4 \cdot n$ has been found to be a good ratio when low-discrepancy numbers are used throughout.

The final result, by virtue of the inequality (10), is of course biased low since the valuation based on an optimized (implicit) functional approximation can only be as good as the exercise domain boundary is represented in the approximation. It can be shown readily, though, that for a small difference ε (defined in any suitable way) between the truly optimal exercise boundary and the one used in the numerical approximation, the difference between the numerically obtained value and the truly optimal value scales like the second order in ε , that is, like $\mathcal{O}(\varepsilon^2)$ whence small differences tend to have negligible influence on the calculation. Another mitigating factor with respect to the exercise boundary representation is that any mismatches only contribute proportionally to the probability of actually reaching this part of state space, that is, the exercise boundary only need be

matched well where probability densities are high. It is these features of second-order-only exercise domain-matching error propagation and the fact that the boundary only needs to be represented accurately in the center of the state vector distribution that makes this method so effective in practice.

Early Exercise Options: Upper Bounds

Setup and Basic Results

We work, as usual, on a filtered probability space and consider a contingent claim with *early exercise* rights, that is, the right to accelerate payment on the claim at will. Let the claim in question be characterized by an adapted, nonnegative payout process $U(t)$, payable to the option holder at a stopping time (or *exercise policy*) $\tau \leq T$, chosen by the holder. If early exercise can take place at any time in some interval, we say that the derivative security is an *American option*; if exercise can only take place on a discrete set of dates, we say that it is a *Bermudan option*.

Let the allowed set of exercise dates larger than or equal to t be denoted $\mathcal{D}(t)$, and suppose that we are given at time 0 a particular exercise policy τ taking values in $\mathcal{D}(0)$, as well as a pricing numeraire N inducing a unique martingale measure $\mathbb{Q}^N$. Let $C^\tau(0)$ be the time 0 value of a derivative security that pays $U(\tau)$. Under technical conditions on $U(t)$, we can write the value of the derivative security as

$$C^\tau(0) = \mathbb{E}^N \left(\frac{U(\tau)}{N(\tau)} \right) \quad (1)$$

where $\mathbb{E}^N(\cdot)$ denotes expectation in measure $\mathbb{Q}^N$ and where we have assumed, with no loss of generality, that $N(0) = 1$. Let $\mathcal{T}(t)$ be the time t set of (future) stopping times taking value in $\mathcal{D}(t)$. In the absence of arbitrage, the time 0 value $C(0)$ of a security with early exercise into U is then given by the *optimal stopping problem*

$$C(0) = \sup_{\tau \in \mathcal{T}(0)} C^\tau(0) = \sup_{\tau \in \mathcal{T}(0)} \mathbb{E}^N \left(\frac{U(\tau)}{N(\tau)} \right) \quad (2)$$

reflecting the fact that a rational investor would choose an exercise policy to optimize the value of his/her claim.

With $\mathbb{E}_t^N(\cdot)$ denoting expectation conditional on the information (i.e., the filtration) at time t , we can extend equation (2) to future times t

$$C(t) = N(t) \sup_{\tau \in \mathcal{T}(t)} \mathbb{E}_t^N \left(\frac{U(\tau)}{N(\tau)} \right) \quad (3)$$

where $\sup_{\tau} \mathbb{E}_t^N (U(\tau)/N(\tau))$ is known as the *Snell envelope* of U/N under $\mathbb{Q}^N$. Here $C(t)$ must be interpreted as the value of the option with early exercise, *conditional* on exercise not having taken place before time t . To make this explicit, let $\tau^* \in \mathcal{T}(0)$ be the optimal exercise policy, as seen from time 0. We can then write, for $0 < t \leq T$,

$$C(0) = \mathbb{E}^N (1_{\{\tau^* \geq t\}} C(t)/N(t)) + \mathbb{E}^N (1_{\{\tau^* < t\}} U(\tau^*)/N(\tau^*)) \quad (4)$$

where we break the time 0 value into two components: one from the time t value of the option, should it not have been exercised before time t , and other from the right to exercise on $[0, t]$. As we can always elect —possibly suboptimally— to never exercise on $[0, t]$, from equation (4) we see that

$$C(0) \geq \mathbb{E}^N (C(t)/N(t)) \quad (5)$$

which establishes that $C(t)/N(t)$ is a *supermartingale* under $\mathbb{Q}^N$. This result also follows directly from known properties of the Snell envelope; see [13].

In numerical implementations, it is most relevant to consider the discrete-time (i.e., Bermudan) case and assume that $\mathcal{D}(0) = \{T_1, T_2, \dots, T_B\}$, where $T_1 \geq 0$ and $T_B = T$. For $t \in (T_i, T_{i+1})$, define H_i as the time t value of the Bermudan option when exercise is restricted to the dates $\mathcal{D}(T_{i+1}) = \{T_{i+1}, T_{i+2}, \dots, T_B\}$; that is,

$$H_i(t) = N(t) \mathbb{E}_t^N (C(T_{i+1})/N(T_{i+1})), \quad i = 1, \dots, B-1 \quad (6)$$

At time T_i , $H_i(T_i)$ can be interpreted as the *holding value* of the Bermudan option, that is, the value of the Bermudan option if not exercised at time T_i . If an optimal exercise policy is followed, clearly we must have at time T_i

$$C(T_i) = \max (U(T_i), H_i(T_i)), \quad i = 1, \dots, B \quad (7)$$

such that

$$H_i(t) = N(t) \mathbb{E}_t^N (\max (U(T_{i+1}), H_{i+1}(T_{i+1}))), \quad i = 1, \dots, B-1 \quad (8)$$

Starting with the terminal condition $H_B(T) = 0$, equation (8) defines an backward iteration in time for the value $C(0) = H_0(0)$.

Option Pricing Bounds

In a setting where $U(t)$ is a function of a low-dimensional diffusion process, the iteration (8) can often be solved numerically by partial differential equations (PDE) or lattice methods, for example, the finite difference method (*see Finite Difference Methods for Early Exercise Options*). In many cases of practical interest, however, these methods either do not apply or are computationally infeasible. In such situations, we may be interested in at least bounding the value of an option with early exercise rights. Providing a *lower bound* is straightforward: postulate an exercise policy τ and compute the price $C^\tau(0)$ by direct methods, for example, the Monte Carlo method. From equation (2), this clearly provides a lower bound

$$C^\tau(0) \leq C(0) \quad (9)$$

The closer the postulated exercise policy τ is to the optimal exercise policy τ^* , the tighter this bound will be. Two common strategies for approximation of τ^* in a Monte Carlo setting are discussed in **Bermudan Options** and **Exercise Boundary Optimization Methods**, the first based on regression estimates of holding values H in equation (8) and the second on optimization of parametric rules for the exercise strategy.

To produce an *upper bound*, we can rely on duality results established in [9, 14]. To present these results here, let $\mathcal{K}$ denote the space of adapted martingales π for which $\sup_{\tau \in [0, T]} E^N |\pi(\tau)| < \infty$. For a martingale $\pi \in \mathcal{K}$, we then write

$$\begin{aligned} C(0) &= \sup_{\tau \in \mathcal{T}(0)} E^N \left(\frac{U(\tau)}{N(\tau)} \right) \\ &= \sup_{\tau \in \mathcal{T}(0)} E^N \left(\frac{U(\tau)}{N(\tau)} + \pi(\tau) - \pi(\tau) \right) \\ &= \pi(0) + \sup_{\tau \in \mathcal{T}(0)} E^N \left(\frac{U(\tau)}{N(\tau)} - \pi(\tau) \right) \end{aligned} \quad (10)$$

In the second equality, we have relied on the *optional sampling theorem* to tell us that the martingale property is satisfied up to a bounded random stopping time, that is, that $E^N(\pi(\tau)) = \pi(0)$. See [12] for details. We now turn the above result into an upper

bound by forming a pathwise maximum at all possible future exercise dates $\mathcal{D}(0)$:

$$\begin{aligned} C(0) &= \pi(0) + \sup_{\tau \in \mathcal{T}(0)} E^N \left(\frac{U(\tau)}{N(\tau)} - \pi(\tau) \right) \\ &\leq \pi(0) + E^N \left(\max_{t \in \mathcal{D}(0)} \left(\frac{U(t)}{N(t)} - \pi(t) \right) \right) \end{aligned} \quad (11)$$

With equations (9) and (11) we have, as desired, established upper and lower bounds for values of options with early exercise rights. Let us consider how to make these bounds tight. As mentioned earlier, to tighten the lower bound we need to pick exercise strategies close to the optimal one. Tightening the upper bound is a bit more involved and requires usage of the *Doob–Meyer decomposition* (*see Doob–Meyer Decomposition*), which can be used here to show that

$$C(t)/N(t) = M(t) - A(t) \quad (12)$$

where $M(t)$ is a martingale and $A(t)$ an increasing, predictable process with $A(0) = 0$ (such that $C(0) = M(0)$). Given equation (12), consider taking $\pi(t) = M(t)$ in equation (11), to get

$$\begin{aligned} C(0) &\leq C(0) + E^N \left(\max_{t \in \mathcal{D}(0)} \frac{U(t)}{N(t)} - M(t) \right) \\ &= C(0) + E^N \left(\max_{t \in \mathcal{D}(0)} \frac{U(t)}{N(t)} - \frac{C(t)}{N(t)} - A(t) \right) \\ &\leq C(0). \end{aligned} \quad (13)$$

The last inequality follows from the fact that $C(t) \geq U(t)$ and $A(t) \geq 0$. As $M(0) = C(0)$, it follows that the quantity

$$\begin{aligned} M(0) + E^N \left(\max_{t \in \mathcal{D}(0)} \frac{U(t)}{N(t)} - M(t) \right), \\ M(t) = \frac{C(t)}{N(t)} + A(t) \end{aligned} \quad (14)$$

is bounded by $C(0)$ from both above and below, that is, it must equal $C(0)$. We have thereby arrived at a *dual* formulation of the option price

$$C(0) = \inf_{\pi \in \mathcal{K}} \left(\pi(0) + E^N \left(\max_{t \in \mathcal{D}(0)} \frac{U(t)}{N(t)} - \pi(t) \right) \right) \quad (15)$$

and have demonstrated that the infimum is attained when the martingale π is set equal to the martingale component M of the deflated price process $C(t)/N(t)$.

Monte Carlo Upper Bound Methods

Let us consider how we can use the upper bound results (11) and (15) in an actual Monte Carlo application. According to equation (11), to generate an upper bound for the true option price, it evidently suffices to simply pick *any* martingale process adapted to the filtration we work in, and then compute the expectation (11) by Monte Carlo methods. For instance, if the filtration is generated by a vector-valued Brownian motion $W(t)$, we can always set

$$\pi(t) = \int_0^t \sigma(t)^\top dW(t) \quad (16)$$

for some adapted vector-process $\sigma(t)$ satisfying the usual conditions required for the stochastic integral to be a proper martingale. Clearly, however, if $\sigma(t)$ is chosen arbitrarily, the resulting upper bound is likely to be very loose, and probably not very useful. While equation (15) is of little immediate practical use (since we do not know the process $C(t)/N(t)$), it does suggest that for a chosen martingale $\pi(t)$ in equation (11) to produce a tight upper bound, it needs to be “close” to $M(t)$.

Several strategies have been proposed for constructing a good martingale $\pi(t)$. When working on a simple model set up on simple payouts, sometimes one can make inspired guesses for what $\pi(t)$ should be. For instance, in a one-dimensional Black–Scholes model, Rogers [14] shows that using the numeraire-deflated European put option price (which is analytically known) as a guess for $\pi(t)$ generates good bounds for a Bermudan put option price. This approach, however, does not easily generalize to settings with more complicated dynamics and/or more complicated exercise payouts.

The Andersen–Broadie Algorithm

A general strategy for generating upper bounds is proposed in [1], which can start from any approximation to the optimal exercise strategy, perhaps

generated from either of the methods in **Bermudan Options** or **Exercise Boundary Optimization Methods**. Using a straightforward “simulation-within-a-simulation” approach, the authors construct an estimate to the value process $C^\tau(t)$ and use its estimated martingale component as $\pi(t)$ in equation (11). Specifically, working on a discrete timeline, they set

$$\begin{aligned} \pi(T_{i+1}) - \pi(T_i) &= \frac{C^\tau(T_{i+1})}{N(T_{i+1})} - E_{T_i}^N \left(\frac{C^\tau(T_{i+1})}{N(T_{i+1})} \right) \\ &= E_{T_{i+1}}^N \left(\frac{U(\tau)}{N(\tau)} \right) - E_{T_i}^N \left(\frac{U(\tau)}{N(\tau)} \mid \tau \geq T_{i+1} \right) \end{aligned} \quad (17)$$

where nested simulations are used to estimate both expectations on the right-hand side of the equation.^a The resulting Monte Carlo estimate of the upper bound is shown to be biased high always, with the bias being a decreasing function in the number of inner simulation trials. As suggested by equation (15), the upper bound produced by the algorithm in [1] strongly depends on the quality of the exercise strategy: the better the strategy, the tighter the bound.

The need for nested simulations makes the algorithm in [1] expensive: if M is the number of outer simulations and K the number of inner simulations, an option with B exercise opportunities will involve a worst case workload proportional to

$$M \cdot K \cdot B^2 \quad (18)$$

For comparison, a lower bound simulation has a workload proportional to $M \cdot B$, plus whatever work is required to estimate the exercise rule in a presimulation. In many cases the inner simulations can be stopped quickly (due to early exercise); thus, in practice the dependence on B in equation (18) is often less than quadratic and sometimes close to linear. In addition, in [3] it is shown—along with other ideas for efficiency improvements—that inner simulations are not needed on dates where it is suboptimal to exercise the option, which can lead to considerable time savings, especially for out-of-the-money options. Finally, K can often be set to a number much smaller than M without significantly affecting the quality of the upper bound, and even very small values of K (e.g., 50–100 or less) may yield informative results. With the computational improvements suggested in [3], upper bound computations on a range of different option payouts take on the order of 1–10 CPU minutes compared with 0.1–2 CPU minutes for the lower

bound. Of course, the CPU times depend on the speed of the processor, but it is safe to say that relatively tight confidence intervals for most option types can be obtained in times measured in minutes, not in hours as is commonly believed.

The strategy in [1] is generic, in that it can handle virtually any type of multidimensional process dynamics and security payouts. Despite the computational drawbacks, the use of nested simulation guarantees that the choice of π induces an upper bound estimate that is biased high. Importantly, this key property is *not* shared by many alternative estimators, such as regression, of the expectations in equation (17). One exception is discussed in [8] where a special martingale-preserving regression approach is introduced. This algorithm, however, requires strong conditions on regression basis functions that may be hard to check in practice.

The Belomestny–Bender–Schoenmakers Algorithm

In the special case where dynamics are driven only by Brownian motions, the usual martingale representation theorems show that the optimal strategy $\pi^*(t)$ must be an Ito integral, that is, of the form in equation (16). Starting again from a postulated exercise strategy, Belomestny *et al.* [2] use this observation to construct a regression on a set of basis functions to uncover an estimate for the function $\sigma(t)$. By applying regression techniques this way—rather than to directly compute expectations of $U(\tau)/N(\tau)$ —the authors are able to construct a true martingale process $\pi(t)$, which can be turned into a valid upper bound through equation (11). The resulting nonnested simulation algorithm requires careful implementation to yield stable results, in part, because the optimal integrand $\sigma(t)$ can be expected to be considerably less regular than $\pi^*(t)$ itself; this, in turn, requires additional thought in the selection of appropriate basis functions for the regression. One possibility advocated in [2] is to include, whenever available, exact or approximate expressions for the diffusion term in dynamics of several still-alive European options underlying the Bermudan option. This strategy is akin to that of [14], and its feasibility depends on the pricing problem at hand. In cases where it does apply, the authors of [2] demonstrate that their method gives good results, with the upper bound often being nearly as tight as that of the nested algorithm in [1]. They

also show how to use their technique to develop a variance-reduced version of the algorithm in [1].

Confidence Intervals and Practical Usage

Assume that we have estimated an exercise strategy using either of the approaches in **Bermudan Options** or **Exercise Boundary Optimization Methods**. Suppose that the Monte Carlo estimate for the lower bound price is $\hat{C}_{lo}(0)$ with a sample standard deviation of $\hat{s}_{lo}$ based on M_{lo} Monte Carlo trials. Using, say, the algorithm in [1], we also estimate an upper bound $\hat{C}_{hi}(0)$ with a sample standard deviation $\hat{s}_{hi}$ computed from M_{hi} (outer) simulation trials. With z_x denoting the x th percentile of a standard Gaussian distribution, asymptotically a $100(1 - \alpha)\%$ confidence interval for the true price $C(0)$ must be tighter^b than

$$\left[\hat{C}_{lo}(0) - z_{1-\alpha/2} \frac{\hat{s}_{lo}}{\sqrt{M_{lo}}}; \hat{C}_{hi}(0) - z_{1-\alpha/2} \frac{\hat{s}_{hi}}{\sqrt{M_{hi}}} \right] \quad (19)$$

Most often, upper bound simulation algorithms can be expected to be both more involved and/or more expensive than lower bound simulation methods. In many cases, the role of the upper bound simulation algorithm will therefore be to test whether postulated lower bound exercise strategies are tight or not. Specifically, starting from some guess for the exercise strategy, we can produce confidence intervals using equation (19) to test whether the lower bound estimate is of good quality, in which case the confidence interval can be made tight by using large values of M_{lo} and M_{hi} (as well as the number of inner simulation trials). In case the lower bound estimator is deemed unsatisfactory, we can iteratively refine it, by altering the choice of basis functions, say, until the confidence interval is tight. Importantly, such tests can often be done at a high level, covering entire classes of payouts and/or models. Once an exercise strategy has been validated for a particular product or model, day-to-day pricing of Bermudan securities can be done by the lower bound method, with only occasional runs of the upper bound method needed (e.g., if market conditions change markedly). If upper bound methods are predominantly used in this manner, the fact that they may sometimes be computationally intensive^c becomes less punitive.

Extensions and Related Work

The results (11) and (15) are sometimes known as *additive* duality results. Jamshidian [10] has introduced alternative *multiplicative* results. A comparative study of additive and multiplicative duality was undertaken in [7], with the authors concluding that the additive duality results are preferable in applications.

Earlier methods for producing lower and upper bounds were proposed in [5, 6]. Both methods [5, 6] have the significant feature of producing automatically convergent bounds. However, [5] is only practical when the number of exercise dates is a small finite number (e.g., less than five). The method proposed in [6] does not suffer this drawback, but is more challenging to implement and is substantially slower than most lower bounds methods.

Finally, let us note that computation of upper bounds by Monte Carlo simulation theoretically extends to option sensitivities (Greeks), as demonstrated in [11] where duality is applied to the likelihood ratio method (see [4]). As the proposed algorithm is very computationally intensive, the practical value of this result remains to be seen.

End Notes

^aIn cases where $U(t)$ is not known in closed form—as may be the case for complicated callable securities (see **Bermudan Swaptions and Callable Libor Exotics**)—nested simulation can also be used to establish estimates for $U(t)$.

^bThe confidence interval is conservative because of the low bias in $\hat{C}_{lo}(0)$ (i.e., $E^N(\hat{C}_{lo}) \leq C(0)$) and the high bias in $\hat{C}_{hi}(0)$ which originates in part from the nature of the upper bound, and in part from the earlier mentioned additional high bias introduced by the inner simulations.

^cNote, though, that in testing the viability of a class of exercise rules through an upper bound simulation, it is often acceptable to work with a reduced set of exercise opportunities—for example change a quarterly exercise schedule to an annual one—in order to save computation time (see equation (18)).

Monte Carlo Simulation

The History of the Monte Carlo Method

The history of Monte Carlo methods goes back a long time. The generic idea of random, or “stochastic”, sampling is straightforward and appealing in its elegance and has been used for centuries. Possibly, the first systematic application of statistical sampling techniques in science and engineering was by Enrico Fermi in the early 1930s to predict the results of experiments related to the properties of the neutron [11], which had recently been discovered by James Chadwick in 1932. In 1947, Stanislaw Ulam suggested to John von Neumann that the newly developed ENIAC computer would give them the means to carry out calculations based on statistical sampling with hitherto unattained efficiency and comparative ease [17]. Their coworker Nicholas Metropolis dubbed the numerical technique the *Monte Carlo method* partly inspired by Ulam’s anecdotes of his gambling uncle who “just had to go to Monte Carlo”.

Since the deployment of the ENIAC, which could do about 5000 additions or 400 multiplications per second and which occupied the size of a large room, computing power has grown dramatically. In the early 1970s, a computer design was introduced that had at its heart an electronic component first introduced in 1958, a so-called “integrated circuit”. All of a sudden, a computer’s *central processing unit* (CPU) shrank from the size of a domestic refrigerator to that of a fingernail. The number of transistors in a single integrated circuit kept growing at an almost constant exponential rate since then,^a and with it grew the computing power of the computer. In addition to that, miniaturization and the introduction of new materials allowed for equally dramatic increases in the clock speeds of computers. At the time of this writing, on a CPU that trades for £ 25 to retail customers, over 2 billion double-precision floating-point multiplications can be carried out per second,^b which means that the kind of hardware used these days as a wordprocessor can do in one second what used to take the ENIAC over two months.

It is no surprise, then, that by now the use of Monte Carlo methods has become ubiquitous in science, technology, and business. Simulation techniques are used in oil well exploration; stellar evolution; electronic chip design; reactor design; quantum

chromo dynamics; material sciences; physical chemistry; nanostructure, protein, and polymer research; operations research, for example, when designing the relationships and control mechanisms between raw materials input, manufacturing, and delivery; ground and air traffic control systems design; communication and computer system design and testing, for example, network theory; biomolecular research, for example, cancer drug design; all areas of finance and insurance; weather forecasting (where it is referred to as *ensemble forecasting*^c); and local authorities planning and commissioning.^d

Today, the comparative ease of implementation, in combination with the readily available required computer power, makes the use of Monte Carlo techniques more often than not the method of choice. This has gone to the extent where it is deployed (almost) as a black-box tool. As an example for this, we give a quote from the local authority planning and commissioning site mentioned above:

This spreadsheet based tool gives local authorities access to Monte Carlo statistical modelling techniques. The technique allows local authorities to take account of the different factors which may affect spend levels. This will give authorities the ability to more accurately estimate expenditure to take account of uncertainty.

Monte Carlo is a recognised statistical technique, which is recommended by the Treasury.

Basic Ideas

The key defining feature of a Monte Carlo simulation may be stated as follows.

Definition 1 *A Monte Carlo method is any technique whose purpose it is to approximate a specific measure defined on a given domain by the aid of sampling according to a predetermined distributional law.*

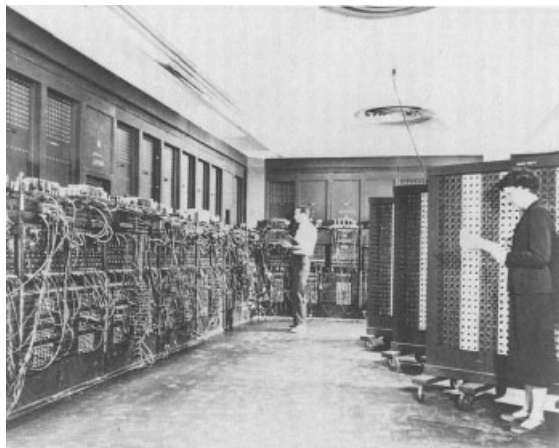

Note that this definition does *not* involve any of the following:

1. randomness
2. expectations or moments
3. stochastic processes.

It may come as a surprise that randomness is not included. It is true that randomness of some of the

input numbers is often associated with Monte Carlo methods. In truth, however, and this was already known to the pioneers of Monte Carlo methods, all that is really needed for a Monte Carlo method to succeed is *asymptotic adherence* to the desired predetermined distributional law on the given domain that is sampled upon. For the sake of explanation, but without loss of generality, we shall assume in the following that the domain is a hypercube $H_m = (0, 1)^m$ for some $m \in \mathbb{N}$ and that the desired distribution is uniform in H_m . Any “draw” in the simulation sequence is thus naturally best to be seen as an m -tuple, or a vector $\mathbf{u} \in H_m$.

Randomness is predominantly used in conceptual considerations for its convenience of guaranteeing uniform coverage as a consequence of *serial independence of draws* (Figure 1). Obviously, if one vector-valued sample drawn from H_m is, in a statistical sense, completely independent from the next draw, and so on, then, asymptotically, the set of all draws will cover H_m uniformly. However, it is both intuitive, as well as readily demonstrable, that it is fairly easy to achieve a more uniform coverage with a deliberate strategy that takes into account all the points that are already part of the simulation. It is, in fact, possible to prove that at least asymptotically (i.e., in the limit of large numbers of draws), by any self-consistent measure, any strategy (algorithm) to generate numbers that attempts to “avoid”

The ENIAC. Smithsonian Institution Photo No. 53192 reproduced from [4] with kind permission by Paul Ceruzzi

points already drawn gives more uniform coverage of the sampling domain than random numbers. In this asymptotic sense, among all number sequences one can construct, random numbers are the worst possible category of numbers one could use for Monte Carlo simulation purposes. In practical applications, though, a Monte Carlo simulation is hardly ever carried out with the intent to determine some kind of asymptotic behavior. What matters for real calculations is to have

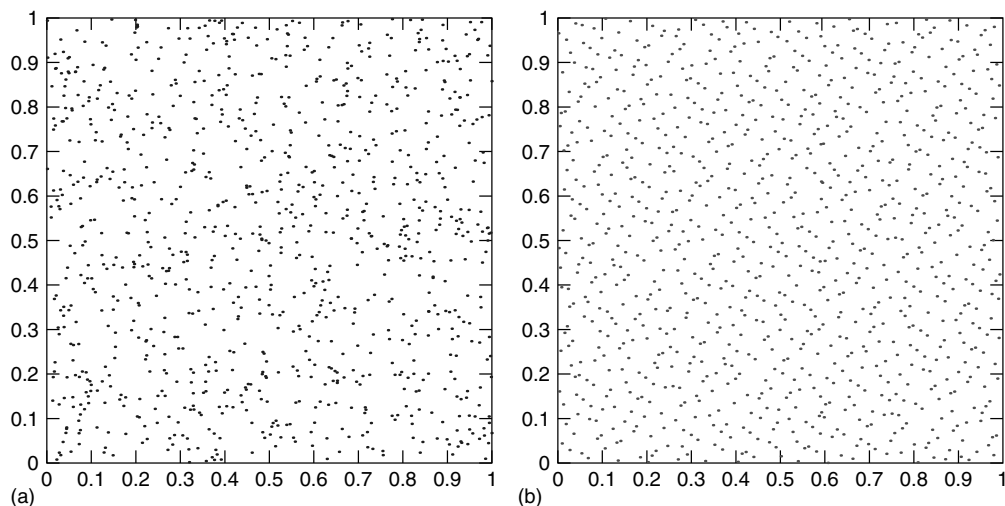

Figure 1 One thousand (a) random and (b) strategic draws from $(0, 1)^2$. Note the significantly more uniform coverage of the unit square in (b)

a result as accurate as possible with the fewest necessary iterations, and it is this latter part that makes the use of nonrandom numbers (also known as *low-discrepancy* or *quasi-random* numbers) slightly more delicate, and this is discussed in article **Quasi-Monte Carlo Methods** by one of the most accomplished researchers in this field, H. Niederreiter. Unfortunately, in the 1940s, no algorithms for the generation of usable nonrandom numbers were available when Monte Carlo simulations on the ENIAC commenced, despite the fact that the theoretical foundations for such number sequences had already been laid in 1916 by Hermann Weyl [18]. As a consequence, practically used Monte Carlo simulations relied on the generation of pseudorandom numbers for the first few decades. The term *pseudorandom* is commonly used to indicate that these are computer-generated numbers, as opposed to random numbers as we assume them to occur in natural phenomena such as radioactive decay. The distinction is somewhat philosophical, but noteworthy nevertheless, since it is, after all, not actually possible to generate randomness on a machine that is designed to give *deterministic* results. This is summarized in John von Neumann's famous words [9]:

Anyone who considers arithmetical methods of producing random numbers is, of course, in a state of sin.

As it turns out, algorithms for the generation of number sequences that can be considered *random enough* for practical use, in some sense, can be devised, though, by the aid of modern number theory, and this is the subject of article **Pseudorandom Number Generators** by P. L'Ecuyer.

At a mathematical level, Monte Carlo methods have a wide range of applicability. Of course, they can be used simply to compute an approximation for the expectation of a given function, say, $E[f(\mathbf{u})]$, and in finance, this is probably the most common application: draw N vectors $\mathbf{u}_1$ to $\mathbf{u}_N$, and evaluate the equally weighted N -iteration estimator:

$$\hat{E}_N[f(\mathbf{u})] := \frac{1}{N} \sum_{i=1}^N f(\mathbf{u}_i) \quad (1)$$

They can, however, also be used for calculations that do not fit well into the format $E[f(\mathbf{u})]$. A common use of Monte Carlo methods is to find a local or global extremum of a given function. Examples

for this application are the so-called *Metropolis* algorithm, and the related *simulated annealing* procedure, which, in finance, is sometimes used for model calibration. Another frequent application of Monte Carlo methods in finance is the calculation of a *quantile level*, that is, to find f_q such that the probability that $f(\mathbf{u}) < f_q$ is q , or, in other words, f_q is implicitly defined by:

$$E[\mathbf{1}_{\{f(\mathbf{u}) < f_q\}}] = q \quad (2)$$

The simplest algorithm to estimate f_q given q is to draw a number of, say N , iterations for $\mathbf{u}$, evaluate $f(\cdot)$ for all the drawn vectors, order the so generated f values by decreasing size, and pick the value at position $\lfloor q \cdot N \rfloor$. The quantile level is only one of various measures for *extreme events*, which are discussed in article **Rare-event Simulation**.

The Monte Carlo method is widely accepted as the designated method of choice for the following two types of calculations:

- **Mathematical problems that are not posed as a set of concise equations, but instead are only described as a procedure, or algorithm, or process.**

An example is the estimation of statistics for traffic-flow problems where the reaction of individual traffic constituents (e.g., cars) on ambient conditions is known, but, because of their nonlinearity, the net effect of many such constituents reacting to the (re-)actions of all other constituents is hard to predict. Some of the problems Fermi, von Neumann, Metropolis, and Ulam originally worked on also belong to this category: they investigated the statistics of neutrons passing through matter by simulating repeated impacts with and deflections by atoms. Some problems are given in the form of stochastic differential equations (SDEs) for which we have no analytical solutions but which can be integrated numerically. Numerical integration of an SDE is mathematically the design of a numerical algorithm that has starting values and an iterative procedure involving numbers to be sampled from a certain domain. Standard Euler integration, for instance, of a simple SDE, over k time steps, typically becomes a sampling problem on $\mathbb{R}^k$, which is usually transformed to $(0, 1)^k$. Note that the numerical integration is composed only by the step that is the conversion of the SDE into a sampling problem. Numerical integration of SDEs is technically not a Monte Carlo technique. It is, in principle, possible, though rarely done, to evaluate the

resulting sampling problem with other means such as multidimensional quadratures, and so on. In practice, however, numerical integration of SDEs is usually combined with a Monte Carlo simulation of the integration procedure. Articles **Monte Carlo Simulation for Stochastic Differential Equations** and **Stochastic Differential Equations: Scenario Simulation** by Platen are dedicated to the subject of numerical integration of SDEs, and how it interacts with the embedding Monte Carlo simulation. The mathematical background behind the design of many of these numerical integration schemes is the equivalent to Taylor's expansion for SDEs, and these *stochastic Taylor expansions* are explained in article **Stochastic Taylor Expansions**.

- **Mathematical problems that require the evaluation of an expectation on a high-dimensional domain.**

The alternative to a Monte Carlo simulation for such problems is to employ lattice methods. The commonly used error measure for lattice techniques is a term proportional to the square of the lattice discretization, say, h^2 . The number of nodes (i.e., sampling points) in a lattice scales like $N = h^{-d}$ with the dimensionality d . Putting this together shows that the error of a lattice algorithm relates to the number of evaluated points like $\sim 1/N^{(2/d)}$. As d increases, the relationship between a lattice method error and N becomes hopelessly inefficient, and this fact is sometimes referred to as the *curse of dimensionality*. When using random numbers, the commonly used error measure of a Monte Carlo estimator for N iterations scales like $1/\sqrt{N}$, irrespective of the dimensionality of the domain. A straightforward scale comparison indicates that the Monte Carlo error estimator is asymptotically superior in its behavior as a function of N as soon as $d > 4$. For low-discrepancy numbers, as explained in detail in article **Quasi-Monte Carlo Methods**, the error measure scales closer to $1/N$, which indicates that lattice methods are (asymptotically) superior to those (used within a Monte Carlo simulation) only when the dimensionality d is 1.

Beyond these two categories, there are many other applications of Monte Carlo techniques, often associated with bespoke Monte Carlo algorithms. Many of these algorithms belong to the family of *Monte Carlo Markov Chain* methods [3, 5, 10]. These methods are, to date, less commonly used in

finance. An exception is perhaps the Robbins–Monro algorithm [1] whose basic purpose is to find the root of a function that is defined as an expectation (and can practically be evaluated only by the aid of a Monte Carlo simulation itself). The Robbins–Monro algorithm is designed to avoid having to nest a Monte Carlo simulation as an objective function inside a numerical root finding procedure. It has been used in the context of variance reduction methods which are discussed in article **Variance Reduction**.

Monte Carlo Methods in Quantitative Finance

The starting point of the use of the Monte Carlo method in quantitative finance, or specifically, in financial engineering, was probably the suggestion by P. Boyle to use it for the valuation of options [2]. Despite the fact that Monte Carlo methods, initially, had the reputation of being *slow*, they started to become popular rather quickly, probably primarily owing to the enormous ease with which they could be implemented. For the valuation of exotic financial contracts, especially in the world of equity and foreign exchange derivatives, and particularly when multiple underlyings were involved, a Monte Carlo method could be implemented directly from the contract's term sheet, without the need for any further mathematics other than a model for the dynamics of the financial underlyings. This made it possible to combine multipurpose financial models, which only describe the (stochastic) dynamics of the financial underlyings, with *product description language* engines, that allowed any trader, or even structurer, to price, and risk-manage, entirely new financial products within minutes, without any new model development or any code recompilation. The use of Monte Carlo simulations is made particularly easy in this context by the fact that most financial contracts' term sheets are written in a language close to an investor's perception of the evolution of the financial contract *forward in time*, making term sheet definitions intrinsically well compatible with the Monte Carlo method's forward looking nature: *if you can describe it on a term sheet, you can probably implement it as a payoff*. Over time, computers became faster, reducing concerns some people may have had with respect to Monte Carlo methods. Eventually, multicore computers became commonplace in the financial industry,

and since Monte Carlo methods are so extremely easily amenable to multithreading, possibly more so than any other numerical technique, they could readily be adapted to take advantage of the extra computing power.

The adoption of Monte Carlo methods as a standard technique was helped not only by pure technological progress of computers, though. A whole range of mathematical developments and discoveries provided improvements both in terms of robustness and relative speed that made it possible to carry out Monte Carlo simulations much faster than before. Many of these methods are known as *variance reduction methods*, which is the subject of article **Variance Reduction**. A very important generic relative speedup technique is the use of low-discrepancy, as opposed to pseudorandom, numbers, such as the Niederreiter'88 [12], Niederreiter-Xing [13], and Sobol' [7, 14–16] numbers, and article **Quasi-Monte Carlo Methods** is dedicated to the theory behind these number sequences. We say *relative* speedup to indicate that the use of these numbers does not necessarily make the execution of N iterations actually faster (albeit that these numbers are usually faster to generate than pseudorandom numbers). They provide a relative speedup due to the fact that, for approximately the same residual numerical error, one may need only of the order $\sqrt{N}$ iterations in comparison to the use of pseudorandom numbers. Another type of speedup is associated with bespoke simulation algorithms for specific mathematical problems such as the numerical integration and simulation of square root processes described by SDEs such as

$$dX = \sigma\sqrt{X} \cdot dW \quad (3)$$

which is discussed in article **Simulation of Square-root Processes**. Simulations of numerical integrations of SDEs with jumps are described in article **Stochastic Differential Equations with Jumps: Simulation**. The simulations required for the important LIBOR market model for interest rate derivative valuation are particularly challenging because of their intrinsic high dimensionality, and are elaborated in article **LIBOR Market Models: Simulation**.

As Monte Carlo methods started being used with financial models, practitioners invented further techniques for specific purposes that are nowadays considered part of the standard toolbox. The handling

of sensitivity calculations, in the context of Monte Carlo simulations, can be tricky, owing to the inherent nature of a numerical sensitivity calculation to amplify noise. In the article **Monte Carlo Greeks**, the most common techniques to deal with this issue are covered. A mathematically elegant, though, in practice, perhaps less frequently used, framework that can help address the same issues is the method known as *integration by parts for stochastic functionals* and is presented in the article **Sensitivity Computations: Integration by Parts**. A particularly interesting development is the family of *weighted Monte Carlo* methods, which provide means for noise-reduced sensitivity calculation and noise-reduced model calibration. This framework gives a generic mathematical analysis that encompasses a proof that the popular *control variates* technique for variance reduction is, in fact, just a special case of a weighted Monte Carlo method, as discussed in article **Weighted Monte Carlo**.

Finally, we should mention that a lot has been done with respect to the handling of early exercise opportunities that may be given within financial contracts. Apart from simple one-dimensional American equity or FX options, these are very common among exotic fixed income derivatives. Since most of these exotic contracts require rather complex and high-dimensional models for realistic risk-management and hedging, it became desirable to find techniques that can be used to evaluate early exercise rights within a simulation setting. In this section of the encyclopedia, we present four articles on the most important techniques for Bermudan options: **Bermudan Options** deals with basis function regression methods for Bermudan options; in **Stochastic Mesh Method**, the Broadie–Glasserman stochastic mesh technique is discussed; article **Exercise Boundary Optimization Methods** explains Bermudan Monte Carlo methods based on exercise boundary optimization; and article **Early Exercise Options: Upper Bounds** is on upper bound methods for callable products.

There is much more one could say about Monte Carlo methods in finance, some of it highly applicable in many situations, some of it bespoke for specific applications, and some of it merely for the sake of its mathematical elegance. We believe, though, that all of the most important aspects of Monte Carlo methods in quantitative finance are covered in this section of the encyclopedia. For further details beyond this, we recommend the books [7, 8] and [6].

End Notes

^aThis phenomenon was surprisingly accurately predicted by Gordon Moore in 1965, whence it is often referred to as *Moore's law*.

^bThis figure is *per se*, of course, misleading since any realistic calculation involves more than the multiplication of the same two numbers over and over again. It does help, though, to highlight the scale of speed improvements in hardware since the days of the ENIAC.

^cAccording to the UK Meteorological Office (www.metoffice.gov.uk/science/creating/daysahead/ensembles), “an ensemble forecasting system samples the uncertainty inherent in weather prediction to provide more information about possible future weather conditions.” In other words, it is a mini Monte Carlo simulation consisting of a comparatively small number (~ 24) of individually deterministic weather forecast calculations, each primed with slightly differing input scenarios based on the currently known weather system status.

PETER JÄCKEL & ECKHARD PLATEN

Mutual Funds

After a major financial crisis in 1773–1774, a Dutch broker founded an investment company that would buy bonds from issuers located in different countries. (For a detailed history of mutual funds, see [1].) Shareholders received an annual report and could periodically check assets and company books. This first example of a mutual fund contains all the elements of the modern collective investment vehicle: a professional manager, a pool of assets, diversification, and governance.

While modern mutual funds can take several legal shapes, such as partnerships and limited-liability corporations, they all perform two important functions: (i) asset management carried out by an expert and (ii) diversified exposure to investment assets.

Mutual funds are beneficial for people who lack the time or expertise necessary to select individual securities. By buying shares in a mutual fund, investors can capitalize on a professional fund manager's expertise and experience. The manager is responsible for building a portfolio consistent with her mandate.

In addition to expert management, mutual funds give investors, of all skill levels, the benefit of higher diversification. For example, Person A has \$1000 to invest, and one share of Company B costs \$1000. To invest in Company B, Person A would have to invest his entire portfolio in that single stock. If Company B were to go bankrupt, the investor would lose everything. However, if Person A were to pool his money with 10 other investors with \$1000 each, they could purchase shares of several different companies. The resulting portfolio's returns would reflect the average return of several stocks rather than just one. Since stocks can move differently from one another (i.e., one stock may gain as another loses), this pooling will reduce the portfolio's risk overall. Mutual funds provide these benefits on a large scale (see **Diversification; Modern Portfolio Theory**).

Mutual funds manage tens of trillions of dollars worldwide. Morningstar, an investment analysis and rating company, had over 54 000 different mutual fund portfolios in its worldwide database in February 2008. There were 7054 open-end mutual funds in the Morningstar database for the United States, 287 of which (4%) were pure index funds. According to

Morningstar, in February 2008, index funds had about 10% of the US open-end mutual fund assets—not including “enhanced index” and similar hybrid strategies (the Morningstar data cited in this paragraph do not include money market funds).

Legal Types of Mutual Fund

Mutual funds have different legal forms. Open-end mutual funds are investment companies that sell a variable number of shares of a pool of assets. In this type of fund, when an investor wants to buy shares, she contacts the investment company, which issues new shares of the fund. If the investor needs to liquidate her position, the company liquidates some of the fund's assets and pays the investor the share's current market price, called *net asset value* (NAV).

Closed-end mutual funds are just like holding companies. The number of shares is predetermined, and shares are bought and sold on the stock market. No contact between issuer and investors occurs after the initial public offering.

Exchange-traded funds (ETFs) are a special type of closed-end funds (see **Exchange-traded Funds (ETFs)**). The peculiarity of ETFs is that their number of shares is variable, and can be increased when an institutional investor, called *authorized participant*, presents the issuer a bundle of assets replicating the ETF's portfolio. The bundle is exchanged for new shares of the ETF. Similarly, authorized participants can redeem ETF shares in kind, receiving portfolio assets from the issuer. As a result, ETF prices reflect the prices of the underlying assets exactly.

Since they are sold to the public, both open- and closed-end funds are regulated in most countries and have strict standards regarding their mandates and disclosures. In contrast, hedge funds are a kind of fund that is not available to most investors; therefore, it is generally unregulated. This allows hedge funds to have more flexible mandates. As a result, hedge funds often are both potentially lucrative and risky (see **Hedge Funds**).

Investment-based Classification

Mutual funds differ by investment mandate. The first type of mandate specifies whether the manager must strictly reproduce the returns of a given index (see **Electricity Markets**). As explained in [2], an

index is a market average. By definition, about half of the investors will have returns exceeding the market average and half will have returns that fall short. Therefore, a reasonable strategy is to pursue the market average. A fund that adopts this strategy is called an *index fund*. Index funds have several advantages. First, because the market is diversified, an index fund's portfolio will have limited idiosyncratic risk. Second, since replicating a market index is rather inexpensive, index funds' management fees are low. Third, in countries taxing realized capital gains, index funds trigger limited capital gains because indexes turn over their portfolios relatively rarely.

The opposite of an index (or passive) fund is an actively managed fund. In an actively managed fund, the index's returns act as a benchmark rather than a target. The fund manager aims to exceed the benchmark, and he/she is free to choose different assets within his/her mandate to meet this goal (*see Capital Asset Pricing Model*).

ETFs started as passive investments, that is, index-based products. More recently, ETFs have branched out into direct investment in commodities such as gold bullion as well as in indexes based on complex trading strategies. While this increases the choices for investors, it often increases fees, too.

Index funds and passive ETFs initially tracked very broad indexes to provide diversified market exposure at low cost. It is now possible to find index funds and ETFs tracking very specialized indexes such as single countries, sectors, or currencies. In this way, an investor can overweight a narrow segment of the market. With ETFs, it is possible to also short market sectors that the investor considers overvalued (*see Hedging*).

A second mandate classification categorizes funds in terms of the kinds of securities that the fund manager can purchase. Equity funds invest in stocks, bond funds invest in debt instruments, and money market funds invest in short-term bonds. In some countries, including the United States, money market funds have legal limits on the credit risk of the bonds they can purchase.

Hybrid funds, also called *balanced* or *asset allocation funds*, invest in a mix of stocks, bonds, and money market instruments. Hybrid funds are often intended to be the only fund in a portfolio, because they contain a balanced exposure to several asset classes.

Funds in each of these broad categories—equity, bond, money market, and hybrid—can be further subdivided according to their specialization. For example, a fund manager may invest exclusively in US large-cap equity, Australian Dollar money market instruments, or Euro Zone high-yield bonds; another fund manager may have a different mandate and run a conservative balanced fund. Management style (*see Style Analysis*) is another common asset-based categorization of equity portfolios.

Expense-based Classification

Open-end funds are called *no-load* if they only charge an annual management fee, which is a percentage of assets. A load is a commission charged either when the investor buys (front load) or sells (back load) the shares. Loads compensate brokers and management companies. In general, a front-load fund has lower annual management fees. Many back-load funds waive loads for investors who have kept their shares for several years.

Closed-end funds do not have loads, but they do have annual management fees. Also, they may have a bid–ask spread and brokerage commission just like a regular stock.

Hedge funds generally have a management fee as well as a performance fee. For example, a hedge fund charging “2 and 20” has an annual management fee of 2% of its assets and a performance fee of 20% of all profits exceeding a certain threshold (called the *hurdle*).

Performance Evaluation

Specialized companies, such as Morningstar and Lipper, collect information about mutual funds' returns, fees, investment styles, and costs. They also provide peer comparisons, which rely on proprietary measures (e.g., the Morningstar Rating™) or on risk-adjusted measures envisioned by academics (*see Sharpe Ratio; Performance Measures*). The purpose of these comparisons is to help investors select skilled managers and avoid those who do not add value.

Modern portfolio theory suggests that the riskier assets should, on average, have higher returns. Hence, it is appropriate to use risk-adjusted measures to avoid confusing managers who have higher long-term returns because they take more risk (*see Capital*

Asset Pricing Model) from managers who add value without adding risk.

MICHELE GAMBERA

Style Analysis

Asset allocation is a major determinant of the return variation in fund portfolios. Hence, an investor who delegates portfolio management to a fund manager is particularly interested in the exposure to different types of asset classes. These exposures characterize the *style* of a fund. Fund names and self-declared fund objectives stated in the prospectus are typically not very informative about the style of mutual funds. Moreover, funds often change their style over time (see, e.g., [2]). Investors therefore turn to alternative ways to infer fund style. Return-based style analysis, introduced by Nobel Prize laureate William F. Sharpe ([5, 6]), determines the style of a fund by regressing the fund returns against the returns of a set of benchmark indices. These benchmark indices typically include style indices for large and small capitalization stocks, value and growth stocks, and bond indices. The coefficients on the style benchmark indices measure the exposures to the risks of these asset classes. Holdings-based style analysis infers the style of a fund directly from the characteristics of the individual positions of the fund portfolio. Style analysis can help characterize the asset allocation, evaluate the performance, and monitor the style consistency of a fund.

Return-based Style Analysis

Methodology

Factor models are a common way in finance to decompose the forces that drive security returns into common and firm-specific influences. A factor model differs from a simple regression exercise in that the residual firm-specific influence for one asset is assumed to be uncorrelated with the residual of all other assets. Hence, the correlation of asset returns is due to their exposure to common factors. Return-based style analysis is a special case of a *linear factor model*. The factors are returns on different asset classes, such as returns on stocks of different style or bond-market indices, which are also called *style benchmark indices*. Owing to this property, return-based style analysis belongs to the category of *asset class factor models*. The return of a fund, $r_{i,t}$, is decomposed into two parts: the fraction that can be

explained by a linear combination of the factors, and a residual term that is uncorrelated with the factors. The residual of fund i , $e_{i,t}$, is uncorrelated with the residual of any other fund j , $e_{j,t}$. Sharpe's ([5, 6]) return-based style analysis differs in a few ways from a standard factor model: (i) There is no intercept; (ii) the loadings on asset classes sum up to 1 to provide an intuitive interpretation as allocations to the asset classes; (iii) in its original form, and when applied to mutual funds, the coefficients are required to be nonnegative to capture short-selling constraints. This last constraint (2) to nonnegative exposures can be relaxed for hedge funds (see, e.g., [4]). The coefficients $b_{i,n}$ of equation (1) are estimated by minimizing the variance of the error terms $e_{i,t}$ subject to these constraints.

$$r_{i,t} = b_{i,1}f_{1,t} + b_{i,2}f_{2,t} + \cdots + b_{i,N}f_{N,t} + e_{i,t} \quad (1)$$

$$\text{s.t. } b_{i,n} \geq 0 \text{ for } n = 1, 2, \dots, N \quad (2)$$

$$\sum_{n=1}^N b_{i,n} = 1 \quad (3)$$

The coefficients $b_{i,n}$ measure the exposure to the n th factor, $f_{n,t}$. These coefficients help the investor to identify the *effective style* of an active portfolio manager. Return-based style analysis extends easily to a multimanager portfolio.

The R^2 from the constrained regression (1–3) measures the fraction of the variation in fund returns that can be explained by the variation of the style benchmark indices.

$$R^2 = 1 - \frac{\text{Var}(e_i)}{\text{Var}(r_i)} \quad (4)$$

When the set of style benchmarks is accurately defined, the difference $(1 - R^2)$ serves as a measure of active management. Stock picking, sector bets, and timing the exposure to different style benchmark indices results in lower R^2 . To penalize the inclusion of additional style benchmarks and to favor a parsimonious specification, the adjusted R^2 or Akaike information criterion can be used as a maximization criterion instead of R^2 (see, e.g., [1]).

Selection of Style Benchmark Indices

The choice of asset classes determines the quality of any asset class factor model:

1. Sharpe [5] recommends using a set of asset classes that are (i) mutually exclusive, (ii) comprehensive; and (iii) where correlations between different asset classes are preferably low.
2. When return-based style analysis is used to evaluate fund performance, a few more properties are desirable: asset classes should represent strategies that can be implemented (i) at low cost and (ii) by a passive, value-weighted, and investable portfolio, that is, the strategy can be implemented *ex ante*.

As an example, average returns on peer groups violate this last property since the median fund manager is not known at the beginning of the evaluation period.

Common choices for equity mutual funds include style indices along the two dimensions size and value/growth. Value (growth) stocks are defined by high (low) book-to-market ratios. Chan *et al.* [3] show that the two dimensions size and book-to-market capture the essential style of mutual funds. The key is a parsimonious set of asset classes that explains the time-series variation of different fund returns, not necessarily their average returns. A larger number of asset classes increases coverage, but, at the same time, reduces the reliability of the estimated exposures.

Use as a Performance Measure

A style-consistent portfolio manager allocates constant fractions $b_{i,n}$ of his or her investments to a given asset class n . The portfolio manager's performance can thus be evaluated against a passive portfolio with the same fractions invested in the N benchmark indices. The difference

$$e_{i,t} = r_{i,t} - b_{i,1}f_{1,t} + b_{i,2}f_{2,t} + \cdots + b_{i,N}f_{N,t} \quad (5)$$

using the optimal weights for the factors, measures the *selection* skills of a manager. The part of the return that is explained by the manager's effective style, $b_{i,1}f_{1,t} + b_{i,2}f_{2,t} + \cdots + b_{i,N}f_{N,t}$, is called the *style benchmark return*. The standard deviation of the selection component $e_{i,t}$ measures the *style benchmark tracking error*.

In a return-based style analysis, the nonfactor residuals $e_{i,t}$ are determined in-sample. To evaluate the performance of a fund manager, we need to determine his or her style and then compare the fund's

out-of-sample return to a passive style benchmark. This requires estimating first the coefficients $\tilde{b}_{i,t-1}$ in equation (1) using the returns from $t - 1 - k$ through $t - 1$, where k is the length of the estimation window. Then, the fund's *selection return* for period t is measured by the difference

$$r_{i,t} - [\tilde{b}_{1,t-1}f_{1,t} + \tilde{b}_{2,t-1}f_{2,t} + \cdots + \tilde{b}_{N,t-1}f_{N,t}] \quad (6)$$

A common approach to monitor style changes of a fund is to apply a rolling window. Typical choices are a 36-month or 60-month window.

Holdings-based Style Analysis

A critique of return-based style analysis is that it does not necessarily uncover what the fund actually holds but rather how it behaves, as expressed by Sharpe's often quoted words "if it walks like a duck and quacks like a duck, it is a duck." Take a position in a hybrid security such as convertible bonds. It likely shows up simultaneously in the loadings of a bond and equity style benchmark index. Furthermore, return-based style analysis reflects the average style over the estimation window and for funds with style drift the coefficient estimates become noisy and less meaningful.

Alternatively, investors may scrutinize fund portfolio holdings. Prominent data providers in the mutual fund industry, such as Morningstar and Lipper, use portfolio holdings to classify funds along the two dimensions size and value/growth. A holdings-based style analysis provides a snapshot of the current asset allocation. Information on portfolio positions is more difficult to collect in a timely manner than that on returns on funds and style benchmark indices, it often lacks uniformity, and processing the information is not an easy task. Holdings may also be affected by window dressing, a behavior of fund managers to adjust their portfolio positions before disclosure at the end of a quarter in an attempt to mimic stock picking skills.

Hedge Funds

A *hedge fund* is a private investment fund that pools money from a limited number of qualified investors and may use leverage to take long and short positions in various financial instruments. The first hedge fund was created by Alfred Winslow Jones in 1949, which was designed to invest in equity long positions hedged through short positions.^a

Owing to flexible trading strategies, incentive-aligned structures, low correlations with traditional asset classes, and loose regulatory oversight, hedge funds have gained popularity in the past decade. In 2007, it has been estimated that there were more than 9000 hedge funds worldwide with assets of about \$2.0 trillion under management, compared with only \$39 billion in 1990.^b Initially, most investments in hedge funds were made by high-net-worth individuals. Of late, institutional investors are increasingly investing in hedge funds.

Structure

Hedge funds are normally organized as limited partnerships for onshore funds in a country like the United States. Under the limited partnership, the investment manager acts as the general partner while investors are limited partners; offshore hedge funds are organized as corporations without a limit on the number of investors.

Offshore hedge funds are often registered in offshore tax havens such as Cayman Island, the British Virgin Island, Bermuda, and Bahamas [31].

Fees

Hedge funds usually charge both asset management fees, and incentive fees. The management fee is typically 1–2% of assets under management, while the incentive fee is typically 20% of the profit. The incentive fee feature makes hedge funds different from mutual funds and offers better incentive alignment between the managers and investors (see [25]).

The minimum rate above which the incentive fee can be charged is called the *hurdle rate*. It could be zero, the T-Bill rate, London Interbank Offered Rate (LIBOR), or some fixed benchmark.

High Watermark

This is a provision under which a manager has to recoup the previous losses before the incentive fee can be charged, that is, the cumulative returns have to be above the hurdle rate in order to collect an incentive fee. Further, it is possible that the manager could “owe” the investors a rebate of fees charged in previous years.

Strategy

Hedge funds follow dynamic trading strategies that are different from buy-and-hold strategies:

- **Global macro**

Follow a “top-down” approach to analyze the world economy and financial markets, and invest in corresponding stock, bond, and currency markets. George Soros’ Quantum Fund is a typical global macro fund.

- **Convertible arbitrage**

Purchase the convertible securities and simultaneously short sell the same issuer’s common stock.

- **Merger arbitrage/risk arbitrage**

Short sell the acquirer’s stock and buy the target’s stock to make arbitrage profit.

- **Fixed income arbitrage**

Purchase undervalued fixed income securities and short sell overvalued fixed income securities.

- **Long/short equity**

Combine long and short positions in equity securities. It could be long biased, short biased, or equity market neutral.

- **Event driven**

Aim to profit from some special events like merger and acquisition, reorganizations, or distressed companies.

- **Equity market neutral**

Take long and short position in equities with the goal of having no net exposure to equity markets.

- **Multistrategy**

A single hedge fund that is managed by multiple managers each following a separate strategy.

• Fund of hedge funds

Invest in a basket of underlying hedge fund managers for the purpose of diversification and operational due diligence. Investors in a fund of hedge funds pay two layers of fees: one at the underlying hedge fund level and one at the fund of hedge funds level.

Minimum Investment

Since hedge funds are designed for accredited/qualified investors, the minimum initial investment can be very high. For example, Eton Park Capital Management LLC has an initial investment of \$5 million.^c

Lockup Period

It is a time period during which an investor's money cannot be redeemed. An advance notice period is typically accompanied by the lockup period for redemption. Hedge funds usually impose a shorter lockup period of less than two years, which is typically the minimum lockup period for private equity funds.

Leverage

In addition to investors' own money, a hedge fund can borrow additional money from prime brokers or other institutions for investment. This can increase both the return and risk. The exact amount of leverage used depends on the investment strategy. For example, at the end of 1997, Long Term Capital Management had a leverage ratio of 28 to 1 for its fixed income arbitrage fund.^d

US Regulation

Unlike heavily regulated vehicles like mutual funds, hedge funds are largely exempt from the US Securities and Exchange Commission (SEC) regulation (at the time of writing). Hedge funds issue securities in "private offerings" and are not required to be registered with the SEC under the Securities Act of 1933. Furthermore, hedge funds are not required to make periodic reports under the Securities Exchange Act of 1934.

Like mutual funds and other securities market participants, hedge funds are subject to prohibitions against fraud, and their managers have the same fiduciary duties as other investment advisers. Depending upon their activities, in addition to complying with the federal securities laws, hedge funds and their advisers may have to comply with other laws including the Commodity Exchange Act or register with the US Commodity Futures Trading Commission (CFTC).

Performance and Risk*Performance Measures*

Unlike traditional investment vehicles, hedge funds are not required to report their performance to any database or regulatory organization. This leads to the question of the accuracy of the reported figures and whether the resulting selection bias prevents investors from having a complete picture of hedge fund industry. To date, three databases have been collecting data for longer than 10 years. They are CISDM (Center for International Securities and Derivatives Markets, University of Massachusetts, Amherst), HFR (Hedge Fund Research), and Lipper-TASS.

Return Distribution

Table 1 presents certain statistical properties of the CISDM indices. First, hedge fund indices provide mean returns that are similar to those provided by traditional stock and bond indices but at lower volatility. Second, hedge fund indices tend to display large negative skewness and large positive excess kurtosis. These two indicate that hedge fund indices are likely to experience extreme negative returns. Hence, traditional measures such as standard deviation and Sharpe ratio may not be suitable for hedge funds. Alternative measures such as the downside deviation, VaR, expected short fall, and maximum drawdown have been proposed [30]. Finally, certain strategies display significant positive autocorrelation, which may indicate that hedge funds representing these strategies carry illiquid and infrequently traded securities.

Data Biases

Returns reported by the public databases are subject to the following biases [1, 16, 29]:

Table 1 Statistical properties of CISDM indices (January 1990–November 2007)

Index provider	Launch date	Base date	Index weighting	Number of funds in the database	Number of funds in the indices	Rebalancing frequency
Altvest/Morningstar	2000	1993	Equal weighted	+4000	+2000	Monthly
Barclay Group	2003	1997	Equal weighted	+4000	+2000	Monthly
CISDM	1994	1990	Median	+4000	+2000	Monthly
CS/Lipper/TASS	1999	1994	Value weighted	+4000	+500	Quarterly
Hennessee	1987	1987	Equal weighted	+4000	+700	Annual
HF Net	1998	1976–1995	Equal weighted	+4000	+3000	Continual
HFR	1994	1990	Equal weighted	+4000	+2000	Monthly
MSCI	2002	2002	Equal and value weighted	+2000	+1500	Quarterly
Van Hedge	1994	1988	Equal weighted	+5000	+1500	Monthly

• Selection bias

Bias resulting from managers reporting their returns on a voluntary basis. This bias arises if the hedge funds that report to databases are systematically different from the universe. The size of this bias is not known since the hedge fund universe is not reported. It is argued that better performing funds may be closed to new investors and therefore do not need to report to public databases. This indicates that reported returns underestimate the true returns. On the other hand, poor performing hedge funds may decide not to report to any database. In this case, the reported returns may overestimate returns to the hedge fund universe.

• Survivorship bias

Databases drop hedge funds that do not survive (i.e., stop reporting). Those that survive tend to have better performance.^c The bias can be measured as the average return of the survived funds in excess of the average return of all funds. It must be noted that not all hedge funds that stop reporting to a database are doing so because of poor performance.^f Some databases maintain records of those funds who decided to stop reporting to them. Using these databases, survivorship bias is estimated to be around 0.16–3.4% per year [1, 11, 16, 17, 29].

• Backfill bias

When a manager decides to report his or her performance to a database, typically after obtaining a reasonable track record, the entire history of the manager may be added to the database (i.e., returns are backfilled). These backfilled returns are estimated to be about 1.3% per year higher than the returns

reported to the database after the manager is added to the database [8, 14, 16, 17].

Liquidity Risk

This refers to risk originating from restrictions on money withdrawal or illiquid assets. It can be estimated by examining share restriction parameters such as lockup as well as return autocorrelations. Returns on certain hedge fund strategies tend to display significant autocorrelation. This estimated autocorrelation may be caused by the presence of illiquid assets in hedge fund portfolios or could be due to return smoothing performed by managers in order to reduce their estimated risk [7, 9, 22]. Estimates of volatility and other risk measures should be adjusted to account for the presence of autocorrelation in reported returns.^g

Operational Risk

It is estimated that one of the main reasons for hedge fund failures is operational risk. Owing to their private nature, hedge funds have low degree of transparency, which may further contribute to operational risk. A recent study by Brown *et al.* [12] proposed to use the public filing information to build a numerical measure for operational risk. A further study shows that operational due diligence is an important source of fund of hedge funds alpha [10].

Risk Exposures

Hedge funds are called *absolute return investments* because they are supposed to provide positive returns

Table 2 Uninvestible indices

Convertible Arbitrage: January 1992–November 2007. Fixed Income Arbitrage: January 1998–November 2007

regardless of market conditions. Several recent studies have examined factor exposures of hedge funds with the goal of determining whether hedge funds are able to earn positive risk-adjusted excess returns (or alpha). The biases discussed above generally do not have significant impact on the estimates of factor exposures of hedge funds. Rather, they are likely to affect the estimates of alphas.

Using linear multifactor models, available research shows that, depending on strategy, hedge funds have exposures to both equity and fixed income factors.^h Though earlier studies reported significant exposures to these risk factors, the resulting R-squares were relatively small. Lack of explanatory power of traditional risk factors can be due to several reasons. First, most hedge fund returns are reported on monthly basis, while hedge fund managers change their factor exposures more often. This will reduce the explanatory power of linear factor models and may create nonlinear exposures in monthly returns.ⁱ Second, the multifactor models may be missing certain factors that are traded by hedge fund managers leading to low explanatory power. Third, the option-like incentive fee structure and investing in derivative securities can cause nonlinearity in risk exposures. Studies of factor exposures of hedge funds are generally conducted in order to determine if hedge funds offer positive excess risk-adjusted return. These studies generally show that top managers are able to generate risk-adjusted abnormal returns.^j Fung *et al.* [21] find that fund-of-funds alphas are shrinking over time as the markets become more competitive.

Hedge Fund Indices

Active Indices

Similar to traditional assets, there also exist a number of manager-based indices for hedge funds. These indices are not directly investible.

• Uninvestible indices

Traditionally, hedge fund indices have been based on a particular database. For example, CISDM hedge fund indices represent equally weighted average performance of managers who report to CISDM. In general, most indices do not impose restrictions on the managers that are added to these databases.^k Also, most indices do not impose a minimum track record and new hedge funds are allowed to be included in strategy indices. Not all indices maintain a database of those managers who at one point reported to their database, but decided at some point in the past to stop reporting. CISDM, HFR, and Lipper-TASS databases have maintained such databases of “dead funds” in the past. Depending on when a database becomes public, it may contain a different degree of backfilled bias. Generally, databases created more recently tend to display a higher amount of backfilled bias.^l Table 2 provides a summary of uninvestible indices.

• Investible indices

Since 2000, a number of manager-based hedge fund indices have been created that may be regarded as investible. Unlike their uninvestible counterparts, these investible indices impose several restrictions on hedge funds that are included in these indices. Foremost among these restrictions is that the managers must be open to new investments and must have adequate capacity. These managers then go through a rigorous due diligence process and at the end only a very small number of them are included in these indices.^m Typically, there are between 6 and 12 managers in each strategy investible index. This may indicate that these indices are not representative of the hedge fund universe. Further, since performance figures of these investible indices are typically reported on a daily basis, financial institutions that offer these indices require these managers to carry more liquid positions when compared to other managers. This selection bias

Table 3 Investible indices

Index provider	Launch date	Base date	Fund weighting	Number of funds in the index	Rebalancing frequency
CS-Termont	August, 2003	January, 2000	Value weighted	+70	Semiannually
Dow Jones	November, 2003	January, 2002	Equal weighted	+70	Quarterly
HFRX	March, 2003	January, 2000	NA	NA	Quarterly
MSCI	July, 2003	January, 2000	Equal weighted	+90	Quarterly
S&P	May, 2002	January, 1998	Equal weighted	+40	Annual

may affect the risk-return profiles of these managers. Table 3 provides a summary of investible indices.

Performance Measures

The measurement of performance is the cornerstone of the evaluation of a fund. Since the advent of modern portfolio theory, it has been the focus of extensive practitioner and academic literature. We start by examining the hypothesis underlying the most commonly used measure, namely, the Sharpe ratio. We then present performance measures avoiding normality assumptions. The section on factor models analyzes the addition of multiple benchmarks for performance measurement. Finally, performance measures considering portfolio holdings are discussed.

Sharpe Ratio

The definition of the *ex post* Sharpe ratio (*see also Sharpe Ratio*) is as follows:

$$Sharpe = \frac{\bar{r}}{\sigma} \quad (1)$$

where $\bar{r}$ is the average excess return over the risk-free rate and σ is the standard deviation of the excess return.

From a theoretical point of view, the Sharpe ratio finds its roots in the Capital Market Line, which weighs expected returns against the volatility. As a consequence, measuring performance with the *ex post* Sharpe ratio implicitly assumes that the return time series are normally distributed or that investor preferences can be described by a quadratic utility function. Moreover, the return time series need to be independently and identically distributed (i.i.d.) as shown in [11].

Performance Measures in the Absence of Normality

Many asset classes, for example hedge funds, do not exhibit normally distributed returns. The use of derivatives has increased the potential of asymmetric behavior of investment strategies. The Sharpe ratio may be significantly increased in such circumstances ([18]). Moreover, this ratio does not reflect the preferences of risk-averse investors who tend to dislike negative skewness and high kurtosis (as shown in [14] and [16]).

As a remedy, new performance measures have emerged in order to cope with the absence of normality. The Sortino ratio, proposed by Sortino and Price [17], has been advocated to capture the asymmetry of the return distribution. It replaces the standard deviation in the Sharpe ratio by the downside deviation, which captures only the downside risk. The Sortino ratio is expressed as follows:

$$\text{Sortino} = \frac{\bar{R} - RMAR}{\text{Downside}(R, RMAR)} \quad (2)$$

where $\bar{R}$ is the average return of the fund and $RMAR$ is the minimum acceptable rate of return.

$$\begin{aligned} \text{Downside}(R, RMAR) \\ = \sqrt{\frac{1}{T} \sum_t 1_{R_t < RMAR} (R_t - RMAR)^2} \end{aligned} \quad (3)$$

The Stutzer index ([19]) does not rely explicitly on a utility function but on a behavioral hypothesis related to the “safety-first” principle of Roy [15]. It assumes that investors aim at minimizing the probability that the excess returns over a given threshold will be negative over a long time horizon. When the portfolio has a positive expected excess return, the aforementioned probability will exponentially decay to zero as the time horizon increases without limit irrespective of the threshold. The maximum possible decay is defined as the Stutzer index. More precisely, if the excess return process is i.i.d., the Stutzer index is expressed as follows:

$$I = - \lim_{T \rightarrow \infty} \frac{1}{T} \log (\text{Prob}[\bar{r}_T \leq 0]) > 0 \quad (4)$$

where $\bar{r}_T$ is the average excess return earned over the threshold periods.

It is interesting to note that for normal return distributions, the ranking of investments is exactly the same as with the Sharpe ratio. This is due to the fact that the Stutzer index is equal to half of the square of the Sharpe ratio in this case. In more general cases, higher moments of the distribution will have an impact on the value of the index. For example, a distribution with negative skewness and high kurtosis will result in a lower Stutzer index value than a normal distribution with the same mean and variance.

The Omega measure suggested by Keating and Shadwick [8] incorporates all the moments of the

distribution by a direct transformation of the latter. More specifically, Omega provides a risk-reward measure for which returns are weighted by their probability of occurrence. In practice, the Omega function at a given threshold can be estimated as

$$\Omega(\text{Thres}) = \frac{\frac{1}{T} \sum_t \max(0, R_t - \text{Thres})}{\frac{1}{T} \sum_t \max(0, \text{Thres} - R_t)} \quad (5)$$

where R_t is the return of the fund at time t and Thres is the threshold defined by the investor.

The Omega function encodes the cumulative density function of the returns (see [8] for a proof). As a consequence, all moments are embodied in the function. In practice, investments may be difficult to rank with this performance measure. When the Omega function of a given investment dominates the Omega function of another, the investment second order stochastically dominates the other. All other possibilities lead to unclear results without defining risk preferences of the investors or without defining a specific metric on the Omega function.

Performance Measures versus Factor Models

Factor models are widely used to decompose and analyze the performance of funds. A general model can be expressed as follows:

$$r_t = \alpha + \sum_i \beta_i F_{it} + \varepsilon_t \quad (6)$$

where r_t is the excess return of the fund over the risk-free rate, F_{it} is the excess return of factor i , and α denotes the alpha of the fund.

Guided by the capital asset pricing model, Jensen [6, 7] uses a single market index as a benchmark. Merton's Intertemporal Capital Asset Pricing Model (ICAPM) [12] provides a theoretical framework for the presence of additional factors in equation (6). Fama and French [3] discovered purely empirical support for including a size (market capitalization) factor and a value (book-to-market ratio) factor, while Carhart [1] added a momentum factor. The emergence of hedge funds as an asset class has further refined the use of factor models. Fung and Hsieh [4] document that factor models are much

poorer at decomposing hedge fund returns than at decomposing mutual fund returns. They show that hedge fund returns contain exposure to additional alternative factors.

The estimation of alpha is severely impacted by the length of the track record under consideration. Pastor and Stambaugh [13] propose a new methodology to increase the precision of the estimation and distinguish good managers from lucky ones. This methodology relies on information (returns) extracted from additional "seemingly unrelated" assets not used in the definition of the alpha. The additional non-benchmark assets help estimate alpha if they are priced by the benchmarks or if their return histories are longer than that of the fund. Kosowski *et al.* [10] advocate a robust bootstrap approach for coping with the cross-sectional nonnormal distribution of individual fund alpha. Using both approaches, Kosowski *et al.* [9] show that persistence can be found in the alpha of top hedge fund managers.

Analysis Based on Portfolio Holdings Information

When portfolio holdings are known, the analysis can be enhanced by looking at the relationship between the weights and the future returns of the portfolio components. More specifically, the performance measure is defined as

$$\text{PerfHolding} = \sum_i \text{cov}(w_{it-1}; R_{it}) \quad (7)$$

where w_{it-1} is the weight of underlying i at the end of period $t-1$ and R_{it} is the return of underlying i between $t-1$ and t .

Grinblatt and Titman [5] estimate equation (7) as

$$\text{PerfHolding} = \sum_i \frac{1}{T} \sum_t [w_{it-1} - E(w_{it-1})] R_{it} \quad (8)$$

where $E(w_{it-1})$ refers to the benchmark weight of underlying i . In practice, the benchmark weight may be chosen as a long-run average.

Daniel *et al.* [2] introduce benchmarks to proxy characteristics of stocks in this context. They show that the gross return of an equity fund can be decomposed into three components:

- Characteristic selectivity:

$$CS_t = \sum_i w_{it-1} (R_{it} - R_t^{b_{it-1}}) \quad (9)$$

- Characteristic timing:

$$CT_t = \sum_i (w_{it-1} R_{it}^{b_{it-1}} - w_{it-k-1} R_{it}^{b_{it-k-1}}) \quad (10)$$

- Average style measure:

$$AS_t = \sum_i w_{it-k-1} R_{it}^{b_{it-k-1}} \quad (11)$$

where $R_t^{b_{it-1}}$ is the return of a value weighted portfolio that matches the characteristics of stock i at the end of period $t - 1$. Wermers [20] documents the superiority of this approach *versus* the factor decomposition.

Sharpe Ratio

The Sharpe ratio (SR) is a popular measure of portfolio performance that was introduced as the reward-to-variability ratio in [6]. For a given set of returns during an evaluation period, portfolio p 's *ex post* SR is

$$SR_p = \frac{\bar{R}_p - \bar{R}_f}{s_p} \quad (1)$$

where $\bar{R}_p$ and s_p denote, respectively, the historical average and standard deviation of p 's returns; $\bar{R}_f$ denotes the average risk-free return.^a A portfolio's SR is typically compared to a market index m 's SR:

$$SR_m = \frac{\bar{R}_m - \bar{R}_f}{s_m} \quad (2)$$

Figure 1 shows that SR_p represents the slope of a line originating at the average risk-free rate and extending to point p where the portfolio is located. Similarly, SR_m represents the slope of a line extending to point m where the index is located. This line is a proxy for the *ex post* capital market line (CML) in [5]. Portfolio p has had superior performance relative to m since $SR_p > SR_m$, resulting in it plotting above the CML; if it had plotted below, then $SR_p < SR_m$ and it would have had inferior performance.

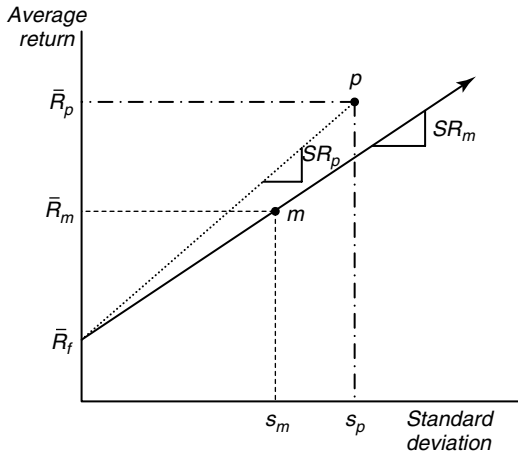

Figure 1 Evaluating the performance of portfolio p with the Sharpe ratio

The SR can also be used to make portfolio construction decisions as in [7]. For a given holding period, portfolio p 's *ex ante* SR is

$$\frac{E[R_p] - R_f}{\sigma[R_p]} \quad (3)$$

where $E[R_p]$ and $\sigma[R_p]$ denote, respectively, the expected value and standard deviation of p 's future return, and R_f denotes the risk-free return. In frictionless markets with a risk-free security, the tangency portfolio in [10] has the highest SR (in absolute value). Optimal portfolios of investors using mean-variance analysis consist of combinations of the risk-free security and the tangency portfolio, which is the market portfolio in [5].

The SR has limitations. First, it assumes that either (i) investors' objective functions are defined solely over the first two moments of portfolio return distributions or (ii) such distributions are characterized by only these moments. Second, proper use of the SR requires knowledge of investors' investment horizons. Levy [4] shows that a bias emerges when using it with a horizon that is different from that of investors. Cvitanic *et al.* [2] find that maximizing the short-term *ex ante* SR is suboptimal for long-term investors. Third, the SR can be manipulated by using derivatives. Ingersoll *et al.* [3] define and characterize a manipulation-proof performance measure. Their measure resembles the average value of a power utility function defined over portfolio returns.

End Notes

^aFor other reward-to-risk ratios of portfolio performance that use VaR and beta instead of standard deviation as risk measures in the denominator of equation (1), see references [1] and [11], respectively. Also see references [8] and [9].

Risk–Return Analysis

Mean–Variance Analysis

While the idea of trade-off curves goes back to, Pareto, the notion of a trade-off curve (later dubbed *efficient frontier*) in finance was introduced by Markowitz [15] in 1952. Markowitz proposed expected return and variance as both a hypothesis about how investors act and as a rule for guiding action in fact. By 1959 [18], he had given up the notion of mean and variance as a hypothesis but continued to propose them as criteria for action.

Tobin [32] said that the use of mean and variance as criteria assumed either a quadratic utility function or a Gaussian probability distribution. This view is sometimes ascribed to Markowitz, but he never justified the use of mean and variance in this way. His views evolved considerably from 1952 to 1959 [15] and [18]. Consequently, his early views [15] should be ignored. In his book published in 1959, Markowitz [18] accepts the views of Von Neumann and Morgenstern [33] when probability distributions are known, and Leonard J. Savage [29] when probabilities are not known. The former asserts that one should maximize expected utility, whereas the latter asserts that when probabilities are not known one should maximize expected utility using probability beliefs when objective probabilities are not known.

A utility function $U(R)$ is any function of return R . If the function is concave, that is,

$$U(aX + (1 - a)Y) \geq aU(X) + (1 - a)U(Y) \quad (1)$$

for $a \in [0, 1]$ then an investor prefers certainty to random returns. If

$$U(aX + (1 - a)Y) \leq aU(X) + (1 - a)U(Y) \quad (2)$$

then the investor prefers gambling to certainty. An intermediate case is when the utility function is linear. In this case, the gambler is neither risk averse as in equation (1) nor risk seeking as in equation (2). Rather, the investor acts to maximize expected return.

Markowitz [18] seeks to serve the cautious investor whose utility function satisfies equation (1). In this respect, Markowitz, assumes a different shape of utility function in [15] from the one in [16]. In the latter, he assumes a utility function that is convex

in some places and concave in others. This was proposed as a hypothesis about human action consistent with gambling and insurance. It builds upon and, the author believes, improves upon [7].

Critical Line Algorithm

The critical line algorithm (CLA) is presented in [17] and again in Appendix A of [18]. The latter shows that the algorithm works even if the matrix of covariances, required by the problem, is singular. This is important since the problem may include short as well as long positions (treated as separate “investments” to represent real-world constraints on the selection of the portfolio when short-sales are permitted), or covariances based on historical returns when there are more securities than observations. In either case, a singular covariance matrix will result.

The CLA makes use of the fact that, in portfolio space, the set of efficient portfolios is piecewise linear. In mean–variance space it is piecewise parabolic; in mean–standard deviation space it is piecewise linear or hyperbolic (see [19] or [22], Chapter 7). The CLA generates, one after the other, all the linear pieces of the portfolio-space set without groping or iterating for the right answer. In this manner, CLA generates the entire mean–variance efficient set almost as quickly as the best methods for finding a single point in this set.

The CLA uses the George Dantzig simplex algorithm [6] of linear programming to determine the first critical line. The portfolio selection constraint may be bounded or unbounded. In the latter case, the first critical line is a ray that proceeds without bounds in the direction of increasing expected return. Again, see [22, Chapter 8], Chapter 9 of [22] discusses the degenerate case in which variables go to zero simultaneously.

Mean–Variance Approximations to Expected Utility

Markowitz [18] accepts the justifications of Von Neumann and Morgenstern [33], and Leonard J. Savage [29] for expected utility using personal probabilities when objective probabilities are not known. He conjectures that a suitably chosen point from the efficient frontier will approximately maximize expected utility for the kinds of utility functions that

are commonly proposed for cautious investors, and for the kinds of probability distributions that are found in practice. Levy and Markowitz [14] expand on this notion considerably. Specifically, Levy and Markowitz show that for such probability distributions and utility functions there is typically a correlation between the actual expected utility and the mean–variance approximation in excess of 0.99. Levy and Markowitz also show that the Pratt [27] and Arrow [1] objections to quadratic utility do not apply to the kind of approximations used by them, or to those in [18]. Specifically, Pratt and Arrow assume that the investor has one fixed-forever utility function and, as her or his wealth changes, the investor moves up and down this utility function. Under this assumption, if the investor becomes wealthy enough, quadratic utility no longer increases with wealth. This is clearly absurd. The Levy and Markowitz [14] and the Markowitz [18] approximations are based on Taylor expansions about current wealth, or expected end-of-period wealth.

Models of Covariance

If covariances are computed from historical returns with more securities than there are observations, for example, 5000 securities and 60 months of observations, then the covariance matrix will be singular. A preferable alternative is to use a linear model of covariance where the return on the i th security is assumed to obey the following relationship:

$$r_i = \alpha_i + \Sigma \beta_{ik} f_k + u_i \quad (3)$$

where u_i are independent of each other and the f_k . The f_k may be either factors or scenarios or some of each. These ideas are carried out in, for example [28, 30], and [20, 21].

Semivariance

In [18, Chapter 9], Markowitz defines two forms of semivariance, namely, about expected value E or about some fixed number a :

$$S_E = E(\min(r, E)^2) \quad (4)$$

or

$$S_a = E(\min(r, a)^2) \quad (5)$$

In [18], Markowitz says that some form of semi-variance seems preferable to mean–variance analysis, but computation is a problem. At present, this computational problem has disappeared. In [18, Chapter 9], he presents a variant of CLA, which traces out the mean–semivariance frontier. Sortino [31] champions the use of semivariance. Mean–variance analysis has been dubbed *modern portfolio theory (MPT)*. Sortino refers to risk–return analysis with semivariance as *postmodern portfolio theory*.

The chief argument in favor of semivariance, as opposed to variance, is that the investor is not concerned with upside deviations; she or he is concerned only with downside deviations. Arguments in favor of mean–variance rather than semivariance are as follows: variance requires only the covariance matrix as input rather than historical returns, or synthetic history generated randomly; and, the mean–variance approximations of expected utility do so well when probability distributions are not spread out “too much”.

Other Measures of Risk

Konno [11] recommends absolute deviation as a criterion for risk in a risk–return trade-off analysis. An advantage of these criteria is that the frontier may be traced out using linear programming.

In [18, Chapter 13], Markowitz objects to these criteria because the function that they imply as the approximation to the utility function does not seem plausible. A similar, but even stronger, objection is raised there to the use of probability of loss as the measure of risk.

Time

In [18, Chapters 11 and 13], Markowitz notes that mean–variance analysis is a single-period analysis, but that does not mean that it is useless in a many-period world. Bellman [2] shows that the optimum strategy for a many-period or infinite-period game consists of maximizing a sequence of single-period utility functions where the utility function is the “derived” utility for the game. If assets are perfectly liquid, the end-of-period derived utility function depends only on end-of-period wealth, and if the Levy–Markowitz approximations to expected utility are good enough, then one may use mean–variance

for a many-period game. If the end-of-period utility function depends on other state variables, and the utility function may be adequately approximated by a quadratic, then the action should depend on mean and variance, and covariance with the other state variables.

If assets are not perfectly liquid, then state variables include the holding of each asset. This results in the problem referred to as the *curse of dimensionality*. Markowitz and van Dijk [19] propose a heuristic for solving this problem. This heuristic approximates the unknown derived utility function by a quadratic in the various state variables. Kritzman [12] report as follows:

Our tests reveal that the quadratic heuristic provides solutions that are remarkably close to the dynamic programming solutions for those cases in which dynamic programming is feasible and far superior to solutions based on standard industry heuristics. In the case of five assets, in fact, it performs better than dynamic programming due to approximations required to implement the dynamic programming algorithm. Moreover, unlike the dynamic programming solution, the quadratic heuristic is scalable to as many as several hundred assets.

Estimation of Parameters

Covariance matrices are sometimes estimated from historical returns and sometimes from factor or scenario models such as the one-factor model of Sharpe [30], the many-factor model of Rosenberg [28], or the scenario models of Markowitz and Perold [20, 21].

Expected returns are estimated in a great variety of ways. It is unlikely that anyone would suggest that the expected returns of individual stocks be estimated from the historical average returns. The Ibbotson [9] series are frequently used to estimate expected returns for asset classes. Black and Litterman [3, 4] propose a very interesting Bayesian approach to the estimation of expected returns. Richard Michaud [25] proposes to use estimates for asset classes based on what he refers to as a *resampled frontier*. Markowitz and Usmen [23] test the resampled frontier idea against a diffuse Bayesian approach. By and large, they find that the Michaud approach outperformed the diffuse Bayesian approach. However, Markowitz and Usmen noted that had they increased the variance estimated by the Bayesian they would have done approximately as well as the Michaud approach. Somehow,

Michaud's patented process, which averages repeated drawings of frontiers generated from a Gaussian distribution with historical covariances, seems to essentially replicate a supercautious Bayesian.

Additional methods for estimating expected return are based on statistical methods for "disentangling" various anomalies [10], or estimates based on factors that [8] might use. See [13, 26], and [5]. The latter paper is based on results obtained by back-testing many alternate hypotheses concerning how to achieve excess returns. When many estimation methods are tested, the expected future return for the best of the lot (assuming that nature will sample from the same population as before) should not be estimated as if this were the only procedure tested (see [24]).

Expected Utility Maximization

The continuous-time portfolio problem consists of maximizing total expected utility of consumption over the trading interval $[0, T]$ and/or of terminal wealth $X(T)$. We look at this problem in the standard continuous-time diffusion market setting. In other words, we consider a security market with $n + 1$ assets, one of which is a money market account with rate of return $r(t)$, and the other n of which are stocks, whose prices are driven by an m -dimensional Brownian motion. More precisely, the prices are given as the unique solutions of the equations

$$dP_0(t) = P_0(t)r(t) dt, \quad P_0(0) = 1 \quad (1)$$

$$dP_i(t) = P_i(t) \left(b_i(t) dt + \sum_{j=1}^m \sigma_{ij}(t) dW_j(t) \right), \quad (2)$$

$$P_i(0) = p_i$$

Here, we assume that the market coefficients r , b , and σ are progressively measurable with respect to the Brownian filtration, component-wise bounded, and that $\sigma\sigma'$ is uniformly positive definite, that is, we have

$$x'\sigma(t)\sigma(t)'x \geq c x'x \quad \text{a.s.} \quad (3)$$

for a positive constant c , and all $0 \neq x \in IR^n$, $t \in [0, T]$. This, in particular, implies

$$m \geq n \quad (4)$$

The investor specifies his/her investment and consumption strategy at time t by choosing the rate $c(t)$ at which he/she consumes and the different fractions $\pi_i(t)$ of his/her wealth that he/she invests in the risky asset i . The remaining fraction of his/her wealth $1 - \sum_{i=1}^n \pi_i(t)$ has to be invested in the money market account. We assume that the investor bases his investment decisions on the observation of past and present security prices. We therefore require both the consumption and the portfolio process to be progressively measurable with respect to the filtration $(f_t)_{t \in [0, T]}$ generated by the security prices. Of course, the consumption should always be nonnegative. We define the investor's wealth process $X^{\pi, c}(t)$ using the strategy (π, c) as the sum of the value of his/her total

holdings at time t . By requiring the investor to act in a self-financing way (i.e., the investor's wealth only changes due to gains/losses from trading and due to consumption), the return of the wealth is given as

$$\frac{dX^{\pi, c}(t)}{X^{\pi, c}(t)} = \left(1 - \sum_{i=1}^n \pi_i(t) \right) \frac{dP_0(t)}{P_0(t)} + \sum_{i=1}^n \pi_i(t) \frac{dP_i(t)}{P_i(t)} - \frac{c(t) dt}{X^{\pi, c}(t)} \quad (5)$$

leading to the stochastic differential equation (the "wealth equation")

$$dX^{\pi, c}(t) = X^{\pi, c}(t) \left(\left(r(t) + \sum_{i=1}^n \pi_i(t)(b_i - r) \right) dt + \sum_{i=1}^n \pi_i(t) \sum_{j=1}^m \sigma_{ij} dW_j(t) \right) - c(t) dt \quad (6)$$

with initial condition

$$X^{\pi, c}(0) = x \quad (7)$$

We call a self-financing pair (π, c) admissible for an initial wealth of x (and write $(\pi, c) \in A(x)$) if the wealth equation (6) has a unique positive solution with $c \geq 0$. By this, we implicitly assume that (π, c) satisfies integrability conditions ensuring that the stochastic integrals in equation (6) are well defined.

To judge the performance of such a pair, we introduce the notion of a utility function:

Definition 1 A strictly concave function $U : (0, \infty) \rightarrow IR$ with $U \in C^2$ satisfying

$$U'(0) := \lim_{x \downarrow 0} U'(x) = +\infty, \quad (8)$$

$$U'(+\infty) := \lim_{x \rightarrow +\infty} U'(x) = 0$$

is called a utility function.

Remarks and Examples

1. Note that the definition implies that a utility function has to be increasing ("more is better than less"), but the advantage of one additional unit decreases with increasing amount x ("decreasing marginal utility"). Popular examples of utility

functions are $U(x) = \frac{1}{\gamma}x^\gamma$ for $\gamma \in (0, 1)$ or $U(x) = \ln(x)$.

2. By slight misuse of the above definition, we will also call a family of functions $U(t, \cdot)$, $t \in [0, T]$ a utility function if for fixed $t \in [0, T]$ $U(t, \cdot)$ is a utility function as a function of the second variable. An obvious example would be the product of a utility function $F(\cdot)$ as in Definition 1 and a discount factor, for example, $U(t, x) = \exp(-\rho t)F(x)$.
3. A utility function is introduced to model the investors attitude toward risk. This can be seen by considering two investment alternatives. One results in the constant payment of A , the other one in a random payment B with $E(B) = A$, both at the same time T . Then by Jensen's inequality, we obtain $U(A) = U(E(B)) > E(U(B))$. Thus, an investor with such a utility function U would automatically go for the less risky alternative, the reason why his behavior (again characterized by the utility function) is called **risk-averse** (read more on this in Chapter 3 of [3]).

Definition 2 *The continuous-time portfolio problem of an investor with an initial wealth of x consists of maximizing his expected utility from final wealth and consumption on $[0, T]$ by choosing the best possible portfolio and consumption process, that is, by solving*

$$\max_{(\pi, c) \in A'(x)} E \left(\int_0^T U_1(t, c(t)) dt + U_2(X^{\pi, c}(T)) \right) \quad (9)$$

Here, U_1 and U_2 are utility functions. The restricted set $A'(x)$ consists of all those elements of $A(x)$ where the expectation over the negative part of the utility functions in equation (9) is finite (ensuring that the expected value in expression (9) is defined).

Remarks

1. Although $U \equiv 0$ is no utility function, we introduce the *pure consumption problem* by setting $U_2 \equiv 0$ and the *pure terminal wealth problem* by setting $U_1 \equiv 0$.
2. In the literature, there are mainly two different classes of methods to solve the continuous-time portfolio problem. The *stochastic control method* pioneered by Merton (see, e.g., [7, 8]) is based on the identification of the expected utility

maximization problem as a stochastic control problem. The optimal solution is then computed by solving the so-called Hamilton–Jacobi–Bellman equation of dynamic programming (see **Stochastic Control** for details on the stochastic control method). The second method, the *martingale method*, is tailored around the specific properties of the market model. We describe it in more details below.

The Martingale Method in the Complete Market Case

The martingale method goes back to [1, 2] and [9]. It relies on decomposing the dynamic portfolio problem (9) into two simpler subproblems, a static optimization problem and a representation problem. We demonstrate the martingale method in a complete market setting (i.e., we assume $m = n$). Here, every contingent claim (i.e., the sum of a nonnegative terminal payment B and a payout process $g(t)$) can be replicated by following a suitable portfolio strategy. Let us introduce the state-dependent discount process

$$H(t) := \exp \left(- \int_0^t (r(s) - 1/2 \|\theta(s)\|^2) ds - \int_0^t \theta(s)' dW(s) \right) \quad (10)$$

with $\theta(t) := \sigma(t)^{-1}(b(t) - r(t)\mathbf{1})$.

The completeness of the market allows to treat the problems of finding the optimal final wealth and finding the corresponding optimal portfolio process separately. More precisely, if a final payment of B and a consumption process $c(t)$ have an initial price satisfying

$$x = E \left(H(T)B + \int_0^T H(t)c(t) dt \right) \quad (11)$$

then a portfolio process $(\pi, c) \in A(x)$ resulting in a final wealth of B always exists.

We demonstrate this in the case of a pure terminal wealth problem (i.e., $U_1 = 0$): we decompose the portfolio problem into a *static optimization problem*

$$\max_{B \in B(x)} E(U(B)) \quad (12)$$

with $B(x) := \{B | B \geq 0, f_T\text{-measurable}, E(H(T)B) = x, E(U(B^-)) < \infty\}$ being the set of all contingent claims B maturing at T and having an initial price of x , and the *representation problem* to find a portfolio process $\pi^* \in A'(x)$ with

$$X^{\pi^*}(T) = B^* \quad a.s. \quad (13)$$

where B^* solves the static optimization problem (12).

Note that the optimization problem (12) is simpler than the original portfolio problem (9) as we only have to optimize over a set of distributions and not over a class of stochastic processes. It can be solved directly with the help of convex optimization and Lagrangian multiplier considerations, even in the general case including consumption. To state the explicit form of the optimal final wealth and consumption we need the following notation:

$$\begin{aligned} I_2(\lambda) &:= (U_2')^{-1}(\lambda), \\ I_1(t, \lambda) &:= \left(\frac{\partial}{\partial x} U_1 \right)^{-1}(t, \lambda) \end{aligned} \quad (14)$$

$$\begin{aligned} G(\lambda) &:= E \left(H(T) I_2(\lambda H(T)) \right. \\ &\quad \left. + \int_0^T H(t) I_1(t, \lambda H(t)) dt \right) \end{aligned} \quad (15)$$

Theorem 1 *Let $x > 0$. Under the assumption of*

$$G(\lambda) < \infty \quad \forall \lambda > 0 \quad (16)$$

the inverse function $\Lambda(x)$ to $G(\lambda)$ exists and the optimal terminal wealth B^ and the optimal consumption process $c^*(t)$, $t \in [0, T]$, are given by*

$$B^* = I_2(\Lambda(x)H(T)), \quad c^*(t) = I_1(t, \Lambda(x)H(t)) \quad (17)$$

Further, there exists a portfolio process $\pi^(t)$, $t \in [0, T]$ with $(\pi^*, c^*) \in A'(x)$,*

$$X^{\pi^*, c^*}(T) = B^*(T) \quad a.s. \quad (18)$$

and (π^, c^*) is the optimal strategy for the portfolio/consumption problem. Moreover, the optimal wealth process is given by*

$$X^{\pi^*, c^*}(t) = E \left(\frac{H(T)}{H(t)} B^* + \int_t^T \frac{H(s)}{H(t)} c^*(s) ds \middle| \mathcal{F}_t \right) \quad (19)$$

Remarks

1. While the optimization problem (12) is now explicitly solved up to the (possibly numerical) determination of the number $\Lambda(x)$, we have only stated existence of an optimal portfolio process π^* . Its explicit determination can be quite complicated and has to rely on very sophisticated methods such as Malliavin derivatives if the market coefficients are not constant and if the utility function is different from the logarithmic one of the example below.
2. We obtain the solution to the pure terminal wealth problem from Theorem 1 by setting U_1 and I_1 equal to zero. Setting U_2 and I_2 equal to zero, we get the optimal solution of the consumption problem.

Example 1 Log-Utility In the case of $U_1(t, x) = U_2(x) = \ln(x)$, we can perform all the calculations explicitly to obtain the optimal final wealth B^* and the optimal consumption c^* as

$$B^* = \frac{x}{T+1} \frac{1}{H(T)}, \quad c^*(t) = \frac{x}{T+1} \frac{1}{H(t)} \quad (20)$$

From this, the optimal wealth process as given in equation (19) can be determined as

$$\begin{aligned} X^{\pi^*, c^*}(t) &= E \left(\frac{H(T)}{H(t)} B^* + \int_t^T \frac{H(s)}{H(t)} c^*(s) ds \middle| \mathcal{F}_t \right) \\ &= \frac{x(T-t+1)}{(T+t)} \frac{1}{H(t)} \end{aligned} \quad (21)$$

By deriving the differential representation for it with the help of Itô's formula and comparing this representation with the general wealth equation (6), we can identify

$$\begin{aligned} c^*(t) &= \frac{1}{T+1-t} X^{\pi^*, c^*}(t), \\ \pi^*(t) &= (\sigma(t)\sigma(t)')^{-1}(b(t) - r(t)\mathbf{1}) \end{aligned} \quad (22)$$

Note that here the optimal consumption is proportional to the current wealth with an increasing proportionality factor ("Increase relative consumption with growing time.") The optimal fractions of wealth invested in the different securities only depend on the market coefficients and not on the wealth process itself. In particular, the fractions remain constant if the market coefficients are also constant.

The Martingale Method and Mean–Variance Optimization

In this section, we mention some possible generalizations of the martingale method. They will, in particular, allow us to treat a continuous-time version of the classical mean–variance problem (see [6] for the one-period model). For simplicity, we concentrate on the pure terminal wealth problem. Let us also relax the requirements on a utility function:

Definition 3 A strictly concave function $U : (0, \infty) \rightarrow \mathbb{R}$ with $U \in C^2$ satisfying

$$\begin{aligned} U'(0) &:= \lim_{x \rightarrow 0} U'(x) > 0, \\ U'(z) &= 0 \text{ for } a \text{ } z \in (0, +\infty] \end{aligned} \quad (23)$$

is called a (weak) utility function.

Remarks

1. The most popular examples of utility functions in the sense of Definition 3, which do not satisfy the conditions of Definition 1, are $U(x) = \alpha - \exp(-\lambda x)$ for $\alpha, \lambda > 0$, the exponential utility function, and $U(x) = -1/2(x - K)^2$ for $K > 0$, the quadratic utility function.
2. One can show (see [3], Chapter 3) that with the generalized inverse function

$$I(\lambda) := \begin{cases} (U')^{-1}(\lambda), & \lambda \in [0, U'(0)] \\ 0, & \lambda \geq U'(0) \end{cases} \quad (24)$$

the results of Theorem 1 remain true in the case that the investor cannot afford to reach the point of maximum utility for sure. This is always the case if we have

$$x < z \cdot E(H(T)) \quad (25)$$

Example 2 Quadratic Utility In the case of $U(x) = -1/2(x - K)^2$ and $x < z \cdot E(H(T))$ using Theorem 1 in the sense of the preceding remark leads to the optimal terminal wealth of

$$B^* = I(\Lambda(x)H(T)) = (K - \Lambda(x)H(T))^+ \quad (26)$$

where the number $\Lambda(x)$ is the unique solution of the equation

$$G(\lambda) = E(H(T)(K - \lambda H(T))^+) = x \quad (27)$$

In the particular case of constant market coefficients and only one stock, that is, $n = m = 1$ we can

calculate $G(\lambda)$ explicitly as

$$\begin{aligned} G(\lambda) &= K e^{-rT} \Phi\left(\frac{\ln(K/\lambda) + (r - 1/2\theta^2)T}{\theta\sqrt{T}}\right) \\ &\quad - \lambda e^{(-2r+\theta^2)T} \Phi\left(\frac{\ln(K/\lambda) + (r - 3/2\theta^2)T}{\theta\sqrt{T}}\right) \end{aligned} \quad (28)$$

with $\theta := (b_1 - r)/\sigma_{11}$. We can then easily solve equation (27) by numerical methods. One can compute the corresponding portfolio process π^* as indicated in [4]. This, however, is quite technical and requires the solution of a partial differential equation.

For dealing with constrained terminal wealth problems of the form

$$\max_{\pi \in A_T^*(x)} E(U(X^\pi(T))) \quad (29)$$

subject to $E(G_i(X^\pi(T))) \leq 0, i = 1, \dots, k$

with the functions G_i being real valued and convex, we introduce the Lagrangian function

$$\begin{aligned} L(\pi, d) &:= E((U - d'G)(X^\pi(T))), \\ \pi &\in A'(x), \quad d \in [0, \infty)^k \end{aligned} \quad (30)$$

Here, the subscript T of the set of admissible portfolio processes indicates that they also have to be admissible for the constrained problem, that is, the expectations in the constraints have to be defined and have to be satisfied (in addition to the usual requirement of a nonnegative wealth process). Then, in [5] under assumption (25) it is proved that—given the existence of a solution to the constrained problem (29)—we obtain a solution to this problem by using the following algorithm:

Step 1. Solve the unconstrained portfolio problem

$$\max_{\pi \in A'(x)} L(\pi, d) \quad (31)$$

by the martingale method for fixed, but arbitrary $d \in [0, \infty)^k$

Step 2. Minimize the function $L(\pi^*(d), d)$ with respect to $d \in [0, \infty)^k$ where $\pi^*(d)$ is an optimal portfolio process for the maximization problem of Step 1.

Example 3 Continuous-Time Mean–Variance Optimization As an application, we solve a continuous-time version of the famous Markowitz mean–

variance problem. The special feature of our solution is that we can guarantee nonnegativity of the final wealth process. This problem is intensively dealt with in the literature starting with [5] and generalized in a series of papers by Zhou *et al.* (see, e.g., [10]). Again, we assume that we are in the setting of constant market coefficients and $n = m = 1$. Then, one can show that under the assumption of

$$x < K e^{-rT} \quad (32)$$

the continuous-time mean–variance problem

$$\begin{aligned} \min_{\pi \in A_T'(y), y \leq x} \quad & \text{Var}(X^\pi(T)) \\ \text{subject to} \quad & E(X^\pi(T)) \geq K \end{aligned} \quad (33)$$

(with $K > 0$ a given constant) is equivalent to solving

$$\begin{aligned} \max_{\pi \in A_T'(x)} \quad & E(-1/2(X^\pi(T) - K)^2) \\ \text{subject to} \quad & K - E(X^\pi(T)) \leq 0 \end{aligned} \quad (34)$$

This, however, is a problem that can be solved by the above two-step algorithm. If in addition one realizes that we have

$$\begin{aligned} L(\pi, d) &= 1/2d^2 \\ &+ \max_{\pi \in A_T'(x)} E(-1/2(X^\pi(T) - (K + d))^2) \end{aligned} \quad (35)$$

we can use the calculations of the quadratic utility case to solve the unconstrained portfolio problems. A deterministic minimization in $d \geq 0$ then yields the solution to the continuous-time mean–variance problem under nonnegativity constraints on the terminal wealth.

The martingale method can also be applied to portfolio problems in incomplete markets. Then, however, convex duality methods have to be used to deal with constraints on the portfolio process or with the fact that the underlying market model is not

complete (see Chapter 4 of [3] for a survey on such constrained problems)

Black–Litterman Approach

The approach by Black and Litterman (BL) [2] blends a reference market distribution with subjective views on the market and yields allocations that smoothly reflect those views.

We present the original BL model and we review the related literature. A longer version of this article with all the proofs and more details is available at www.symmys.com > Research > Working Papers.

The Original Model

Here we follow [4], see also [5, 12] and [13].

The Market Model

We consider a market of N securities or asset classes, whose returns are normally distributed:

$$\mathbf{X} \sim N(\boldsymbol{\mu}, \boldsymbol{\Sigma}) \quad (1)$$

The covariance $\boldsymbol{\Sigma}$ is estimated by exponential smoothing of the past return realizations. Since $\boldsymbol{\mu}$ cannot be known with certainty, BL model it as a normal random variable

$$\boldsymbol{\mu} \sim N(\boldsymbol{\pi}, \tau \boldsymbol{\Sigma}) \quad (2)$$

where $\boldsymbol{\pi}$ represents the best guess for $\boldsymbol{\mu}$ and $\tau \boldsymbol{\Sigma}$ the uncertainty on this guess.

To set $\boldsymbol{\pi}$, BL invoke an equilibrium argument. Assuming there is no estimation error, that is, $\tau \equiv 0$ in equation (2), the reference model (1) becomes

$$\mathbf{X} \sim N(\boldsymbol{\pi}, \boldsymbol{\Sigma}) \quad (3)$$

Assume that, consistent with this normal market, all investors maximize a mean–variance trade-off and that the optimization is unconstrained:

$$\mathbf{w}_\lambda \equiv \underset{\mathbf{w}}{\operatorname{argmax}} \{ \mathbf{w}' \boldsymbol{\pi} - \lambda \mathbf{w}' \boldsymbol{\Sigma} \mathbf{w} \} \quad (4)$$

The solution of this optimization problem yields the relationship between the equilibrium portfolio $\tilde{\mathbf{w}}$, which stems from an average risk-aversion level $\bar{\lambda}$ and the reference expected returns:

$$\boldsymbol{\pi} \equiv 2\bar{\lambda} \boldsymbol{\Sigma} \tilde{\mathbf{w}} \quad (5)$$

Therefore, $\boldsymbol{\pi}$ can be set in terms of $\tilde{\mathbf{w}}$, where BL set exogenously $\bar{\lambda} \approx 1.2$. Giacometti *et al.* [3] generalize this argument to stable-distributed markets. Notice that historical information does not play a direct role in the determination of $\boldsymbol{\pi}$: this is an instance of the shrinkage approach to estimation risk, see more details in the extended online version of this article.

To calibrate the overall uncertainty level τ in equation (2), we can compare this specification with the dispersion of the sample mean in a market where returns are distributed as in equation (3) independently across time: this implies $\tau \approx 1/T$. Satchell and Scowcroft [12] propose an ingenious model where τ is stochastic, but extra parameters need to be calibrated. In practice, a tailor-made calibration that spans the interval $(0, 1)$ is called for in most applications, see also the discussion in [13].

To illustrate, we consider the oversimplified case of an international stock fund that invests in the following six stock market national indexes: Italy, Spain, Switzerland, Canada, United States, and Germany. The covariance matrix of daily returns on the above classes $\boldsymbol{\Sigma}$ is estimated as follows in terms of the (annualized) volatilities $\boldsymbol{\sigma} \approx (21\%, 24\%, 24\%, 25\%, 29\%, 31\%)$ and the correlation matrix

$$\mathbf{C} \approx \begin{pmatrix} 1 & 54\% & 62\% & 25\% & 41\% & 59\% \\ \cdot & 1 & 69\% & 29\% & 36\% & 83\% \\ \cdot & \cdot & 1 & 15\% & 46\% & 65\% \\ \cdot & \cdot & \cdot & 1 & 47\% & 39\% \\ \cdot & \cdot & \cdot & \cdot & 1 & 38\% \\ \cdot & \cdot & \cdot & \cdot & \cdot & 1 \end{pmatrix} \quad (6)$$

To determine the prior expectation $\boldsymbol{\pi}$, we start from the market-weighted portfolio $\tilde{\mathbf{w}} \approx (4\%, 4\%, 5\%, 8\%, 71\%, 8\%)'$ and obtain from equation (5) the annualized expected returns $\boldsymbol{\pi} \approx (6\%, 7\%, 9\%, 8\%, 17\%, 10\%)'$. Finally, we set $\tau \approx 0.4$ in equation (2).

The Views

BL consider views on expectations. In the normal market (1), this corresponds to statements on the parameter $\boldsymbol{\mu}$. Furthermore, BL focus on linear views: K views are represented by a $K \times N$ “pick” matrix $\mathbf{P}$, whose generic k th row determines the relative weight of each expected return in the respective view. To associate uncertainty with the views, BL use a normal model:

$$\mathbf{P}\boldsymbol{\mu} \sim N(\mathbf{v}, \boldsymbol{\Omega}) \quad (7)$$

where the metaparameters $\mathbf{v}$ and $\mathbf{\Omega}$ quantify views and uncertainty thereof, respectively.

If the user has only qualitative views, it is convenient to set the entries of $\mathbf{v}$ in terms of the volatility induced by the market:

$$v_k \equiv (\mathbf{P}\boldsymbol{\pi})_k + \eta_k \sqrt{(\mathbf{P}\boldsymbol{\Sigma}\mathbf{P}')_{k,k}}, \quad k = 1, \dots, K \quad (8)$$

where $\eta_k \in \{-\beta, -\alpha, +\alpha, +\beta\}$ defines “very bearish”, “bearish”, “bullish”, and “very bullish” views, respectively. Typical choices for these parameters are $\alpha \equiv 1$ and $\beta \equiv 2$. Also, it is convenient to set as in [6]

$$\mathbf{\Omega} \equiv \frac{1}{c} \mathbf{P}\boldsymbol{\Sigma}\mathbf{P}' \quad (9)$$

where the scatter structure of uncertainty is inherited from the market volatilities and correlations and c represents an overall level of confidence in the views.

To continue with our example, the manager might assess two views: the Spanish index will rise by 12% on an annualized basis, and the spread United States–Germany will experience a negative annualized change of 10%. Therefore, the pick matrix reads

$$\mathbf{P} \equiv \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 \end{pmatrix} \quad (10)$$

and the annualized views vector becomes $\mathbf{v} \equiv (12\%, -10\%)'$. We set the uncertainty in the views to be of the same order of magnitude as that of the market, that is, $c \equiv 1$ in equation (9).

The Posterior

With the above inputs, we can apply Bayes’ rule to compute the posterior market model:

$$\mathbf{X}|\mathbf{v}; \mathbf{\Omega} \sim \mathcal{N}(\boldsymbol{\mu}_{BL}, \boldsymbol{\Sigma}_{BL}) \quad (11)$$

where

$$\boldsymbol{\mu}_{BL} = \boldsymbol{\pi} + \tau \mathbf{\Sigma} \mathbf{P}' (\tau \mathbf{P} \boldsymbol{\Sigma} \mathbf{P}' + \mathbf{\Omega})^{-1} (\mathbf{v} - \mathbf{P} \boldsymbol{\pi}) \quad (12)$$

$$\boldsymbol{\Sigma}_{BL} = (1 + \tau) \mathbf{\Sigma} - \tau^2 \mathbf{\Sigma} \mathbf{P}' (\tau \mathbf{P} \boldsymbol{\Sigma} \mathbf{P}' + \mathbf{\Omega})^{-1} \mathbf{P} \mathbf{\Sigma} \quad (13)$$

See the proof in the extended online version of this article.

The normal posterior distribution (11) represents the modification of the reference model (3) that incorporates the views (7).

The Allocation

With the posterior distribution, it is now possible to set and solve a mean–variance optimization, possibly under a set of linear constraints, such as boundaries on securities/asset classes, or a budget constraint. This quadratic programming problem can be easily solved numerically. The ensuing efficient frontier represents a gentle twist to equilibrium that reflects the views without extreme corner solutions.

In our example, we assume the standard long-only and budget constraints, that is, $\mathbf{w} \geq \mathbf{0}$ and $\mathbf{w}' \mathbf{1} \equiv 1$. In Figure 1, we plot the efficient frontier from the reference model (3) and from the posterior model (11). Consistently with the views, the exposure to the Spanish market increases for lower risk values; the exposure to Germany increases across all levels of risk aversion; and the exposure to the US market decreases.

Related Literature

The BL posterior distribution (11) presents two puzzles. On one extreme, when the views are uninformative, that is, $\mathbf{\Omega} \rightarrow \infty$ in equation (7), one would expect the posterior to equal the reference model (3). On the other extreme, when the confidence in the views $\mathbf{v}$ is full, that is, $\mathbf{\Omega} \rightarrow \mathbf{0}$, one would expect the posterior to yield scenario analysis: the user inputs deterministic scenarios $\mathbf{v} \equiv (v_1, \dots, v_K)'$ for the factor combinations, resulting in a conditional distribution

$$\mathbf{X}|\mathbf{v} \sim \mathcal{N}(\boldsymbol{\mu}|\mathbf{v}, \boldsymbol{\Sigma}|\mathbf{v}) \quad (14)$$

where

$$\boldsymbol{\mu}|\mathbf{v} \equiv \boldsymbol{\pi} + \mathbf{\Sigma} \mathbf{P}' (\mathbf{P} \boldsymbol{\Sigma} \mathbf{P}')^{-1} (\mathbf{v} - \mathbf{P} \boldsymbol{\pi}) \quad (15)$$

$$\boldsymbol{\Sigma}|\mathbf{v} \equiv \mathbf{\Sigma} - \mathbf{\Sigma} \mathbf{P}' (\mathbf{P} \boldsymbol{\Sigma} \mathbf{P}')^{-1} \mathbf{P} \mathbf{\Sigma} \quad (16)$$

see, for example, [9].

The BL model does not satisfy the above two limit conditions. However, this issue can be fixed as in [6], by rephrasing the model in terms of views on the market $\mathbf{X}$, instead of the parameter $\boldsymbol{\mu}$. As we show in the extended online version of this article, the posterior then reads

$$\mathbf{X}|\mathbf{v}; \mathbf{\Omega} \sim \mathcal{N}(\boldsymbol{\mu}_{BL}, \boldsymbol{\Sigma}_{BL}) \quad (17)$$

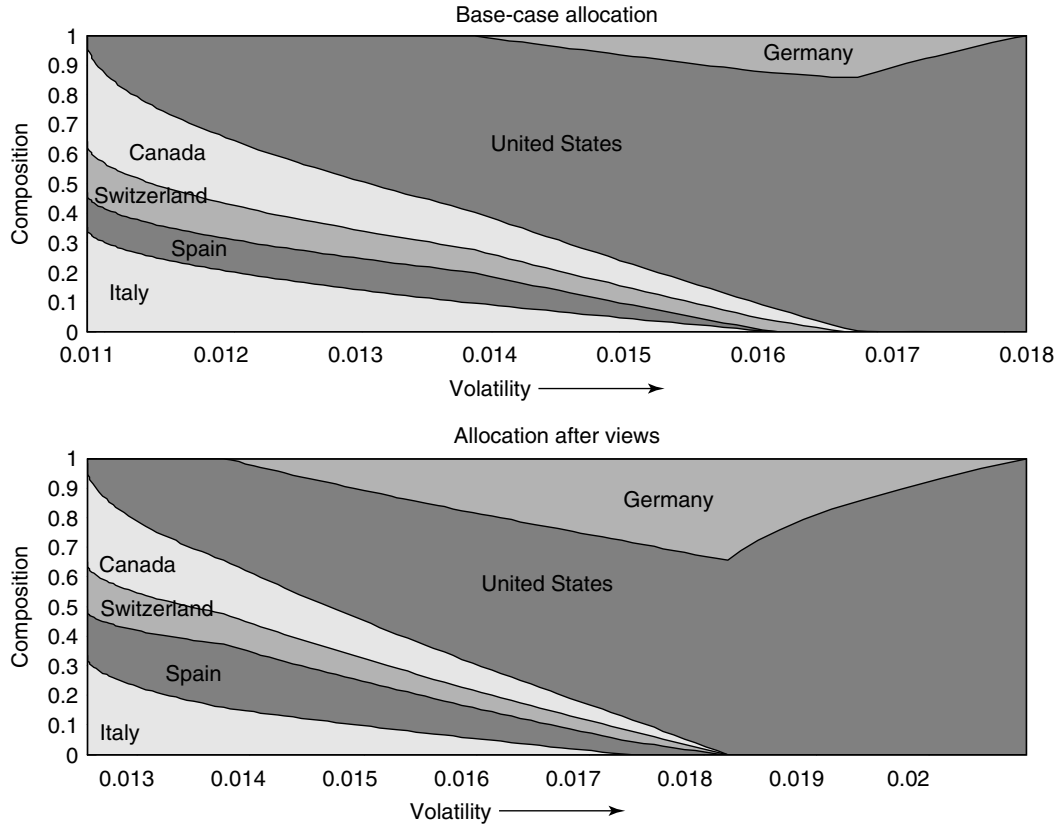

Figure 1 BL: efficient frontier twisted according to the views

where

$$\mu_{BL} \equiv \pi + \Sigma P'(\mathbf{P}\Sigma P' + \Omega)^{-1}(\mathbf{v} - \mathbf{P}\pi) \quad (18)$$

$$\Sigma_{BL} \equiv \Sigma - \Sigma P'(\mathbf{P}\Sigma P' + \Omega)^{-1}\mathbf{P}\Sigma \quad (19)$$

These formulas are very similar to their counterparts (12)–(13) in the original BL model. However, the parameter τ in equation (2) is no longer present and the two limit conditions are now satisfied.

Therefore, scenario analysis processes views on market expectations with infinite confidence and the BL model overlays uncertainty to the views by means of Bayesian formulas. Qian and Gorman [11] use a conditional/marginal factorization to input views on volatilities and correlations in addition to expectations. Pezier [10] processes full and partial views on expectations and covariances by least discrimination. Almgren and Chriss [1] provide a framework to express ranking, “lax” views on expectations.

The posterior formulas (12)–(13), their modified versions (18)–(19), as well as the formulas in the above literature can be applied to any *normal* distribution, not necessarily the equilibrium (5). Accordingly, Meucci [7] applies the above approaches to fully generic risk factors that map nonlinearly into the final P&L, instead of securities returns.

To further extend all the above approaches to nonnormal markets, as well as fully general nonlinear views from possibly multiple users, Meucci [8] uses entropy minimization and opinion pooling: since no costly repricing is ever necessary, this technique covers even the most complex derivatives.

Fixed Mix Strategy

There are a number of advantages of adopting multi-period models over the traditional single-period, static models in portfolio managements [12]. One of the more important benefits, among others, is the improved performance on portfolio investments *via* the fixed mix rule [3–5]. The buy-and-hold rule, which represents single-period models, does not rebalance the portfolio at any intermediate juncture; hence, the weight on each component might change as asset prices fluctuate in different proportions. In contrast, when a portfolio is constructed based on the fixed mix rule, it is rebalanced at every time point so that component weights remain the same as the initial state. To keep the weights unchanged, investors should sell assets whose prices have gone up and buy ones whose prices have dropped. Therefore, in some sense, the fixed mix rule is analogous to the “buy low/sell high” strategy. Possibly because of such an analogy, there seems to be a widely spread misconception regarding the fixed mix strategy and its benefits—it requires mean-reverting processes for assets. Of course, because of its nature, it is not difficult to see that it would be helpful to have such processes to achieve better performance. However, the truth is that mean reversion is *not* necessary for the fixed mix to accomplish superior performance.

Theoretical Background

We first recall performance of the buy-and-hold strategy. Suppose that there are n stocks whose mean return is $r \in \mathbf{R}^n$ and covariance matrix $\Sigma \in \mathbf{R}^{n \times n}$. Assuming that normality, r^{BH} the average buy-and-hold portfolio return with weight $w \in \mathbf{R}^n$, is normally distributed with mean $w^T r$ and variance $\sigma_p^2 = w^T \Sigma w$. That is,

$$r^{\text{BH}} \sim \mathbf{N}(w^T r, \sigma_p^2) \equiv \mathbf{N}(w^T r, w^T \Sigma w) \quad (1)$$

Next, let us consider a fixed mix portfolio constructed from the same stocks with the same weight (w) as the previous buy-and-hold portfolio. Since it is rebalanced at every intermediate juncture, it is required to model stock prices as processes. Thus, we model them as an n -dimensional geometric Brownian motion whose return distribution for a unit time

length would be the same as the previous case. Then, the price process of stock i can be written as the following SDE:

$$\frac{dS_t^i}{S_t^i} = \left(r_i + \frac{\sigma_i^2}{2} \right) dt + dB_t^i \quad (2)$$

where σ_i^2 is the i th diagonal term of Σ (hence, variance of stock i) and for the Cholesky factorization of Σ , L and the standard n -dimensional Wiener process $(W_t^1 - W_t^n)^T$,

$$d(B_t^1 - B_t^n)^T = L d(W_t^1 - W_t^n)^T \quad (3)$$

Since the fixed mix portfolio is rebalanced at each time point to the initial weight (w), its instantaneous growth rate is the same as the weighted sum of instantaneous growth rates of the stocks at any given juncture. Therefore, the SDE for the portfolio wealth can be written as

$$\frac{dP_t^{\text{FM}}}{P_t^{\text{FM}}} = \sum_{i=1}^n w_i \frac{dS_t^i}{S_t^i} = \sum_{i=1}^n w_i \left\{ \left(r_i + \frac{\sigma_i^2}{2} \right) dt + dB_t^i \right\} \quad (4)$$

With simple algebra, one can show that, for the standard one-dimensional Wiener process W_t ,

$$\frac{dP_t^{\text{FM}}}{P_t^{\text{FM}}} = \left(w^T r + \frac{1}{2} \sum_{i=1}^n w_i \sigma_i^2 \right) dt + \sigma_p^2 dW_t \quad (5)$$

Hence, the return of the fixed mix portfolio for a unit time length can be given as

$$\begin{aligned} r^{\text{FM}} &\sim N \left(w^T r + \frac{1}{2} \sum_{i=1}^n w_i \sigma_i^2 - \frac{1}{2} \sigma_p^2, \quad \sigma_p^2 \right) \\ &\equiv N \left(w^T r + \frac{1}{2} \sum_{i=1}^n w_i \sigma_i^2 - \frac{1}{2} w^T \Sigma w, w^T \Sigma w \right) \end{aligned} \quad (6)$$

Therefore, returns of both buy-and-hold (r^{BH}) and fixed mix (r^{FM}) are normally distributed with the same variance (σ_p^2), whereas the mean of the latter contains extra terms ($\sum_{i=1}^n w_i \sigma_i^2 - \sigma_p^2/2$). These extra terms, which are often referred to as *rebalancing gains* or *volatility pumping*, represent the value of having an option to constantly rebalance the portfolio to initial weights.

To observe its effects more closely, let us consider the following simple example: suppose that we have n stocks where the expected return and the volatility of each are r and σ , and the correlation is given as ρ . Assuming the portfolio is equally weighted, the amount of the rebalancing gain

$$RG = \frac{1}{2} \left\{ \sum_{i=1}^n \frac{1}{n} \sigma^2 - \left(\frac{1}{n} - \frac{1}{n} \right) \Sigma \left(\frac{1}{n} - \frac{1}{n} \right)^T \right\} \\ = \frac{(n-1)\sigma^2(1-\rho)}{2n} \quad (7)$$

Now it is evident that the fixed mix strategy has benefit over the static buy-and-hold rule, *even without mean-reversion*; the rebalancing gain is always positive, except the case that all stock returns are perfectly correlated, in which it becomes 0. Note that the rebalancing gain is an increasing function of the number of stocks (n) and the volatility (σ) and is a decreasing function of the correlation (ρ). See Figure 1 for the illustrations of simulation results for the effects of σ and ρ to rebalancing gains. Therefore, with the wisdom from the portfolio theory, one can see that volatile stocks should *not* be penalized when a portfolio is constructed with the fixed mix rule, as long as their correlations to other stocks are low and they possess reasonable expected returns; they can serve as good sources of rebalancing gains. The portfolio risks can be effectively reduced *via* dynamic diversification. For more complete discussion, see [3–5, 10, 15].

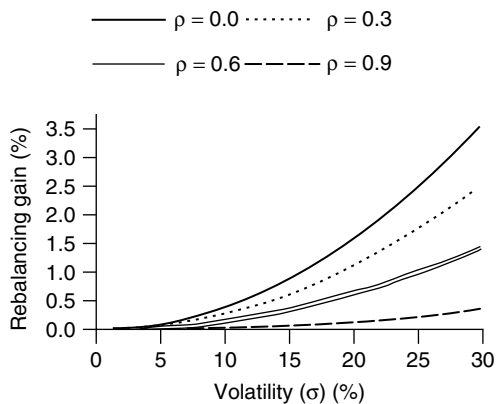

Figure 1 Effects of volatility (σ) and correlation (ρ) to rebalancing gains ($n = 5$)

Practical Examples

Under certain conditions, the fixed mix rule has been proved to be optimal in multiperiod settings. Early on, Mossin [7] showed that it is the optimal strategy when an investor maximizes the expected power utility of her terminal wealth, assuming IID asset returns and no intermediate consumption. Samuleson [17] analyzed the problem in more generalized settings: using an additive intertemporal power utility function of consumption over time, he proved that it is still optimal to adopt the fixed mix rule when the investor is allowed to consume at intermediate junctures. Merton [6] also concluded the same in the continuous time setting model.

Indeed, there are many practical applications that are successfully taking advantage of rebalancing gains by employing fixed mix rules. Among others [9, 14, 16], one of good examples is the S&P 500 equal-weighted index (S&P EWI) by Rydex Investments (Figure 2) [8]. Unlike traditional cap-weighted S&P 500 index, it applies the fixed mix rule to the same stocks as S&P 500, rebalancing them every six month to maintain the equally weighted portfolio. During 1994–2005, S&P Equal Weighted Index earned 2% excess return with mere 0.6% extra volatility over S&P 500. This added profit is partially due to superior performance of small/mid-sized stocks and also can be accounted for by rebalancing gains.

Implementations of the fixed mix rule could also lead to successful leverage. Figure 3 illustrates levered portfolios of buy-and-hold and fixed

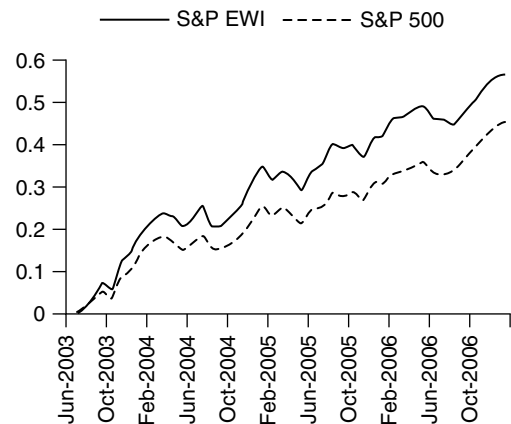

Figure 2 Log prices of S&P 500 and S&P EWI during July 2003 to December 2006

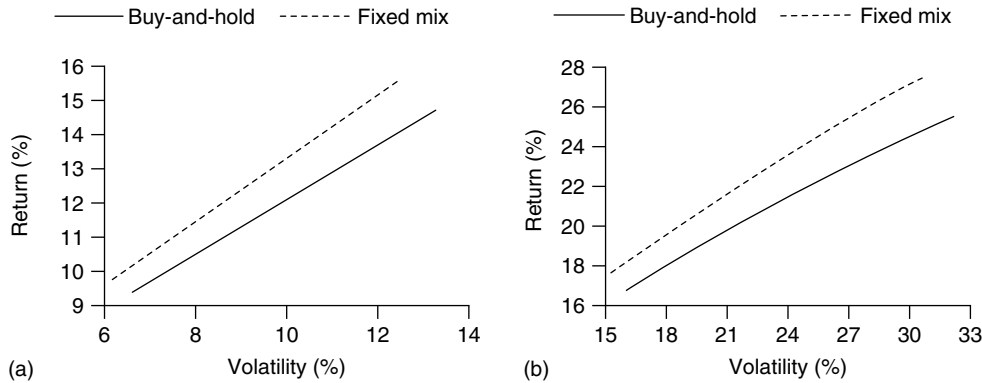

Figure 3 Efficient frontiers of levered buy-and-hold and fixed mix portfolios: (a) mix of traditional and alternative assets (1994–2005) and (b) mix of momentum strategies of five regions (1980–2006)

mix portfolios constructed in two different domains. Figure 3(a) compares efficient frontiers of buy-and-hold and fixed mix portfolios, which are constructed with six traditional assets (S&P 500, EAFE, Lehman long-term bond index, Strips, NAREIT, and Goldman Sachs commodity index) and four alternative assets (hedge fund index, managed futures index, Tremont long-short equity index, and currency index) [11]. Both are equally weighted and levered up to 100% *via* t-bill rate. Although the buy-and-hold portfolio is not rebalanced, monthly rebalancing rule is adopted for the fixed mix for the entire sample period (1994–2005). In addition, Figure 3(b) depicts results from portfolios of industry-level momentum strategies across international stock markets for 27-year sample period (1980–2006) [10]. Momentum strategies are constructed in five nonoverlapping regions (US, EU, Europe except EU, Japan, and Asia except Japan) and aggregated into equally weighted portfolios with leverage up to 100%. Similar to the previous case, the fixed mix portfolio is rebalanced monthly. In both the cases, the efficient frontiers from the fixed mix dominate ones from the buy-and-hold.

Implementation Issues

The fixed mix rule is now becoming a norm in various financial domains. For instance, it is now commonplace for large pension plans, such as TIAA-CREF, to automatically rebalance client-selected portfolios back to client-selected weights, at the client's requests. Given the circumstances, it is imperative to address issues regarding practical implementations.

First, since the best sources of rebalancing gains are volatile financial instruments with low intracorrelations, it is crucial to find a set of relatively independent assets. However, the task is very unlikely to be perfectly achieved in the real world. Second, even such a set exists at certain time point, correlations could change over time. For instance, it is well known that stock indices across international markets become highly correlated upon serious market distress. In addition, one should consider transaction costs such as capital gain taxes upon deciding the rebalancing intervals. Although frequent rebalancing could lead to investment performance close to the theoretical values, it may deteriorate performance due to transaction costs. Careful analysis on this trade-off is required. Good references regarding practical implementations of the fixed mix rules include [1, 2, 13, 18].

Stochastic Control

The theory of stochastic optimal control concerns the control of a dynamical system in the presence of random noises so as to optimize a certain performance criterion. The early development of stochastic optimal control theory began in the period between the late 1950s and early 1960s. The earlier stage of the development focused on the quadratic performance criterion. Around the same period, the classic work of Bellman [1] first introduced one of the main approaches in stochastic optimal control theory, namely, the dynamic programming principle. The dynamic programming approach plays a significant role in modern finance, in particular, continuous-time finance. The key idea of the dynamic programming principle is to consider a family of stochastic optimal control problems with different starting times and states and to relate the problems through the Hamilton–Jacobi–Bellman (HJB) equation. An HJB equation is a nonlinear second-order partial differential equation (*see Partial Differential Equations*) that describes the local behavior of the performance criterion evaluated at the optimal control. For detailed discussion of the dynamic programming approach, we refer to [11, 12, 21].

Together with the HJB approach, the stochastic maximum principle provides the second main approach to stochastic control. The key idea of the stochastic maximum principle is to derive a set of necessary conditions satisfied by any optimal control. The stochastic maximum principle basically states that any optimal control must satisfy forward–backward stochastic differential equations (SDEs), called the *optimality system*, and a maximum condition of a functional, called the *Hamiltonian*. The novelty of the stochastic maximum principle is to make the stochastic optimal control problem, which is infinite dimensional, more tractable. It leads to explicit solutions for the optimal controls in some cases. References [2] and [21] provided excellent discussions on the stochastic maximum principle.

Merton [16, 17] pioneered the study of an optimal consumption–investment problem in a continuous-time economy. He first explored the state of the art of the stochastic optimal control theory to develop an elegant (closed-form) solution to the problem (*see Merton Problem*). The stochastic control approach adopted by Merton uses the HJB equation. Another

approach is the martingale approach, which uses the martingale method for risk-neutral valuation of options to provide an elegant solution to the optimal consumption–investment problem. The martingale approach was pioneered by the important contributions of Cox and Huang [4] and Karatzas *et al.* [13]. It was then extended by a number of authors, (*see, e.g., [14]*).

Each of the three main approaches in stochastic optimal control has its own merits. For example, dynamic programming works well in the case when (i) the state processes and optimal controls are Markov (*see Markov Processes*), (ii) the state processes have deterministic coefficients, and (iii) state constraints are absent. The stochastic maximum principle can deal with the situations when the state processes have random coefficients and state constraints are present. The martingale approach is applicable when one considers a general state process, for example, when the state process is not Markov. It works well when the market is complete though there are some works that consider the case when the market is incomplete (*see [14]*). The martingale approach is suitable for the situations when there are nonnegative constraints on consumption and wealth. It is difficult to say which one is uniformly better or more general than the other two. However, the three approaches are related to each other in some way. For example, the relationship between the dynamic programming approach and the stochastic maximum principle can be established by relating the solutions of the forward–backward SDEs associated with the stochastic maximum principle to those of the HJB equation from the dynamic programming ([21], Chapter 5). The relationship between the martingale approach and the stochastic maximum principle stems from two facts. Firstly, the solutions of the adjoint equations can be related to the density process for the change of measures in the martingale approach. Secondly, the first-order condition of the constrained maximization problem in the martingale approach is related to that of the first-order condition of the Hamiltonian in the stochastic maximum principle [3]. It is interesting to note that the three approaches end up with the same result of the optimal consumption–investment problem in some cases.

We discuss three methods, namely, the martingale method, the HJB Method, and the stochastic maximum principle to solve the optimal consumption–investment problem. Here, we focus on the case

of a power utility function. For general cases, refer to [10, 14].

The Martingale Approach

The development here is based on the contributions of Karatzas, Lehoczky, Sethi, Shreve, and Xu [13]. Here, we just present some main results and highlight some key steps. For a more comprehensive discussion, we refer to [10; Chapter 10].

We consider a popular model for a financial market consisting of one risk-free asset and n risky assets. These assets are tradable over a finite time horizon $[0, T^*]$, where $T^* < \infty$. Fix a complete probability space $(\Omega, \mathcal{F}, \mathcal{P})$, where $\mathcal{P}$ is a real-world probability measure.

The dynamics of the risk-free asset or bond, B , and the risky assets $S_1, S_2, \dots, S_n$, under $\mathcal{P}$, are governed by

$$dB(t) = r(t)B(t) dt, \quad B(0) = 1 \quad (1)$$

$$dS_i(t) = S_i(t) \left(\mu_i(t) dt + \sum_{j=1}^n \sigma_{ij}(t) dW_j(t) \right) \quad (2)$$

$$S_i(0) = s_i, \quad i = 1, 2, \dots, n \quad (3)$$

Here $W(t) := (W_1(t), W_2(t), \dots, W_n(t))^T$ is an n -dimensional Brownian motion defined on $(\Omega, \mathcal{F}, \mathcal{P})$, where y^T is the transpose of a vector y . Write $\{\mathcal{F}(t)\}$ for the right-continuous and complete filtration generated by $\{W(t)\}$. For a treatment of SDEs, see [8].

The market interest rate $r(t)$, the vector of appreciation rates $\mu(t) := (\mu_1(t), \mu_2(t), \dots, \mu_n(t))^T$, and the volatility matrix $\sigma(t) := [\sigma_{ij}(t)]_{i,j=1,2,\dots,n}$ of the risky assets are supposed to be measurable, $\{\mathcal{F}(t)\}$ -adapted, and bounded processes. The market is complete.

Let $a(t) := \sigma(t)\sigma^T(t)$. Suppose there is an $\epsilon > 0$ such that

$$\xi^T a(t) \xi \geq \epsilon |\xi|^2, \quad \forall \xi \in \mathbb{R}^n, \quad (t, \omega) \in [0, T^*] \times \Omega,$$

where $|\cdot|$ denotes the Euclidean norm in $\mathbb{R}^n$.

Then, the inverses of σ and σ^T exist and are bounded, and the market is complete. The filtration $\{\mathcal{F}(t)\}$ is equivalent to the $\mathcal{P}$ -completion of the filtration generated by the price process $\{S(t)\}$.

We define the market price of risk by

$$\theta(t) := \sigma^{-1}(t)(\mu(t) - r(t)\mathbf{1}) \quad (4)$$

where $\mathbf{1} := (1, 1, \dots, 1)^T \in \mathbb{R}^n$; θ is bounded and $\{\mathcal{F}(t)\}$ -progressively measurable.

Now, we introduce an exponential process:

$$\Lambda(t) := \exp \left(- \int_0^t \theta^T(s) dW(s) - \frac{1}{2} \int_0^t |\theta^T(s)|^2 ds \right) \quad (5)$$

Define a new probability measure $\mathcal{P}^\theta \sim \mathcal{P}$ on $\mathcal{F}(T^*)$ by setting

$$\frac{d\mathcal{P}^\theta}{d\mathcal{P}} := \Lambda(T^*) \quad (6)$$

By Girsanov's theorem,

$$W^\theta(t) := W(t) + \int_0^t \theta(s) ds \quad (7)$$

is an n -dimensional standard Brownian motion under $\mathcal{P}^\theta$.

Also, under $\mathcal{P}^\theta$,

$$dS_i(t) = S_i(t) \left(r(t) dt + \sum_{j=1}^n \sigma_{ij}(t) dW_j^\theta(t) \right) \quad (8)$$

Here $\mathcal{P}^\theta$ is called the *risk-neutral* or *equivalent martingale measure*.

Consider a power utility as below:

$$U(c) = \frac{c^\gamma}{\gamma}, \quad 0 < \gamma < 1 \quad (9)$$

where γ represents the risk-aversion parameter. The relative degree of risk aversion is $1 - \gamma$, which indicates how risk averse the investor is. The higher $1 - \gamma$ is, the more risk averse the investor is.

Let U' denote the first derivative of $U(c)$ with respect to c . Write $I(\cdot)$ for the inverse of $U'(\cdot)$. Then, for any $y \in (0, \infty)$,

$$I(y) = y^{1/(\gamma-1)} \quad (10)$$

Consider a measurable $\mathbb{R}^n$ -valued, $\{\mathcal{F}(t)\}$ -adapted process $\pi := (\pi_1, \pi_2, \dots, \pi_n)^T$ and a consumption

process $\{c(t)\}$ as a nonnegative, measurable, $\{\mathcal{F}(t)\}$ -adapted process such that

$$\int_0^{T^*} (c(t) + |\pi(t)|^2) dt < \infty, \quad \mathcal{P} \text{ a.s.} \quad (11)$$

Here $\pi_i(t)S_i(t)$ represents the amount invested in the i th risky asset, for $i = 1, 2, \dots, n$. So, π is called a *portfolio process* or a *trading strategy*. Note that the adapted condition of (π, c) implies that the investor cannot anticipate the future. One financial implication is that “insider trading” is not allowed.

We assume that π is self-financing. A trading strategy is said to be self-financing if the changes in the value of the wealth result entirely from net gains or losses from the investments in the risk-free asset and the risky assets. In other words, there is no net inflow or outflow of funds. Let $\{V(t)\}$ denote the wealth process of the investor, where $V(t) := \sum_{i=1}^n \pi_i(t)S_i(t) + (1 - \sum_{i=1}^n \pi_i(t))B(t) - \int_0^t c(s) ds$. Then, under $\mathcal{P}$, the evolution of $\{V(t)\}$ is governed by

$$dV(t) = \sum_{i=1}^n \pi_i(t) dS_i(t) + \left(1 - \sum_{i=1}^n \pi_i(t)\right) dB(t) - c(t) dt \quad (12)$$

Let $\beta(t) := B^{-1}(t) = \exp\left(-\int_0^t r(u) du\right)$. Then, under $\mathcal{P}^\theta$, the evolution of the discounted wealth process $\{\beta(t)V(t)\}$ is governed by

$$\begin{aligned} \beta(t)V(t) &= v - \int_0^t \beta(s)c(s) ds \\ &\quad + \int_0^t \beta(s)\pi^T(s)\sigma(s) dW^\theta(t) \end{aligned} \quad (13)$$

where $v = V(0)$ represents the initial wealth of the investor.

Let $\mathcal{A}(v)$ denote the class of control processes (π, c) , for the initial wealth v , with wealth process satisfying equation (13) and that the wealth process $\{V(t)\}$ is nonnegative at all times in $[0, T^*]$.

It can be shown that for any $(\pi, c) \in \mathcal{A}(v)$,

$$E^\theta \left[\int_0^{T^*} \beta(t)c(t) dt \right] \leq v \quad (14)$$

The utility maximization problem is to select $(\pi, c) \in \mathcal{A}(v)$ so as to maximize the expected discounted utility *see Expected Utility Maximization, Expected Utility Maximization: Duality Methods* from consumption over $[0, T^*]$:

$$J(v, \pi, c) := E \left[\int_0^{T^*} \frac{(c(t))^\gamma}{\gamma} dt \right] \quad (15)$$

Note that the utility only depends on the consumption level. So, in order to maximize the utility from consumption, we should increase the consumption level up to a certain bound. In other words, we only consider the consumption processes c such that $E^\theta \left[\int_0^{T^*} \beta(t)c(t) dt \right] = v$. The utility maximization problem is to solve the following maximization problem:

$$J(v, \hat{\pi}, \hat{c}) = \sup_{(\pi, c) \in \mathcal{A}(v)} J(v, \pi, c) \quad (16)$$

subject to the budget constraint

$$E \left[\int_0^{T^*} \Lambda(t)\beta(t)c(t) dt \right] = v \quad (17)$$

To solve the problem, we need to find the optimal portfolio process $\hat{\pi}$, the optimal consumption process $\hat{c}$, and the value function defined by $\Phi(v) := J(v, \hat{\pi}, \hat{c})$.

Let λ denote the Lagrange multiplier of the constrained maximization problem (3). Then, the first-order conditions of the maximization problem imply that the optimal consumption rate $c^*(t)$ satisfy

$$c^*(t) = (\lambda \Lambda(t)\beta(t))^{1/(\gamma-1)} \quad (18)$$

$$E \left[\int_0^{T^*} \Lambda(t)\beta(t)c^*(t) dt \right] = v \quad (19)$$

So, the optimal consumption process is

$$c^*(t) = (\lambda \Lambda(t)\beta(t))^{1/(\gamma-1)}, \quad \forall t \in [0, T^*] \quad (20)$$

with the Lagrange multiplier λ determined by

$$\lambda = \left(\frac{v}{E \left[\int_0^{T^*} (\Lambda(t)\beta(t))^{\gamma/(\gamma-1)} dt \right]} \right)^{\gamma-1} \quad (21)$$

Since the market is complete, the optimal wealth process $\{V^*(t)\}$ is given by

$$\begin{aligned} V^*(t) &= E^\theta \left[\int_0^{T^*} c^*(s) \beta(s) ds | \mathcal{F}(t) \right] \\ &= \frac{1}{\Lambda(t)} E \left[\int_0^{T^*} \Lambda(s) c^*(s) \beta(s) ds | \mathcal{F}(t) \right] \end{aligned} \quad (22)$$

The HJB Method

In this section, we illustrate the use of the dynamic programming approach, also called the *HJB method*, to solve the optimal consumption–investment problem described in the section The Martingale Approach. We consider the asset price dynamics in the section The Martingale Approach with time-dependent coefficients replaced by constant coefficients. We impose the same assumptions and notation for control policies, utility function, and probability measures as those in the section The Martingale Approach, unless otherwise stated.

We consider the same problem as that in the last section on the interval $[t, T^*]$ instead of $[0, T^*]$. For any $t \in [0, T^*]$, we consider admissible policies $(\pi, c) \in \mathcal{A}(t, v)$ for which the wealth process $\{V(t)\}$ satisfies

$$\begin{aligned} &e^{-ru} V(u) \\ &= ve^{-rt} - \int_t^u e^{-rs} c(s) ds \\ &\quad + \int_t^u e^{-rs} \pi^T(s) \sigma dW^\theta(s) \quad \forall u \in [t, T^*] \end{aligned} \quad (23)$$

Here we require that the wealth process $\{V(t)\}$ is nonnegative at all times in $[0, T^*]$.

The value function, which is an indirect utility *see Expected Utility Maximization, Expected Utility Maximization: Duality Methods* function, is defined by

$$\Phi(t, v) := \sup_{(\pi, c) \in \mathcal{A}(t, v)} E \left[\int_t^{T^*} \frac{(c(s))^\gamma}{\gamma} ds | \mathcal{F}(t) \right] \quad (24)$$

Let Φ_t , Φ_v , and Φ_{vv} denote the derivative of Φ with respect to t , the first and second derivatives of Φ with

respect to v respectively. Then, the value function satisfies the following HJB equation:

$$\begin{aligned} 0 &= \Phi_t + \sup_{\pi \in \mathfrak{M}^u, c \in [0, \infty)} \left[\frac{1}{2} |\pi^T \sigma|^2 \Phi_{vv} \right. \\ &\quad \left. + [(rv - c) + \pi^T (\mu - r\mathbf{1})] \Phi_v + \frac{c^\gamma}{\gamma} \right] \end{aligned} \quad (25)$$

with the boundary and terminal conditions

$$\Phi(t, 0+) = 0, \quad \forall t \in [0, T^*] \quad (26)$$

$$\Phi(T^*, v) = 0, \quad \forall v \in (0, \infty) \quad (27)$$

With the power utility, the solution of the HJB equation is

$$\Phi(t, v) = \frac{(g(t))^{1-\gamma}}{\gamma} v^\gamma \quad (28)$$

where

$$g(t) = \frac{1}{K} (1 - e^{-K(T-t)}) \quad (29)$$

with

$$K = -\frac{\gamma}{1-\gamma} \left(r + \frac{|\theta|^2}{2(1-\gamma)} \right) \quad (30)$$

$$\theta = \sigma^{-1}(\mu - r\mathbf{1}) \quad (31)$$

In this case, the optimal consumption and portfolio processes are, respectively, given by

$$c^*(t, v) = \frac{v}{g(t)} \quad (32)$$

and

$$\pi^*(t, v) = (\sigma^T)^{-1} \left(\frac{v}{1-\gamma} \right) \theta \quad (33)$$

The HJB method for the optimal consumption–investment problem is discussed in different monographs, such as [6, 15, 18, 19], and others. These monographs focus on discussing the verification theorem for the HJB solution to the problem. Loosely speaking, if a bounded, continuous, and smooth enough function satisfies the HJB equation with associated boundary conditions, the function

is identical to the value function. The verification theorem also provides a sufficient condition for an optimal control. For detailed discussion on the verification theorem, we refer to [18] for the diffusion case and [19] for the jump-diffusion case.

One fundamental result behind the HJB method is called the *principle of optimality*. Informally speaking, the principle of optimality states that if you do not know the optimal expected reward at the current time t , but have knowledge of how well you can achieve at some later time, say $t + h$, you can evaluate the expected reward associated with the policy of adopting the control u during $(t, t + h)$, acting optimally from $t + h$ onward and minimizing over the set of controls. Indeed, the HJB equation for a stochastic control problem follows “in principle” from the principle of optimality for dynamic programming. By the principle of optimality and Itô’s differentiation rule, it can be shown that the value function of a stochastic optimal control problem satisfies the HJB equation if the value function satisfies certain differentiability or smoothness conditions *see Monotone Schemes*. However, the principle of optimality and its derivation are often overlooked in some recent literature on the stochastic optimal control theory and its financial applications, but they are certainly important. Some fundamental contributions to these aspects were due to Davis and Varaiya [5] and Elliott [7], (see also [8]). In these works, the martingale method was used to deduce the principle of optimality.

The Stochastic Maximum Principle

Firstly, we suppose that the state $X(t) := X^{(u)}(t)$ of a controlled diffusion in $\mathbb{R}^n$ is

$$\begin{aligned} dX(t) = & b(t, X(t), u(t)) dt \\ & + \sigma(t, X(t), u(t)) dW(t) \end{aligned} \quad (34)$$

where the coefficients b and σ satisfy some regularity conditions.

Here, the control u enters both the drift coefficient b and the diffusion coefficient σ . We assume that (i) the control $u(t) := u(t, \omega)$ takes value in $U \subset \mathbb{R}^k$, for some positive integer k ; (ii) u is $\{\mathcal{F}(t)\}$ -progressively measurable and right continuous with left-hand limit (RCLL); and (iii) the controlled diffusion has a unique solution $\{X^{(u)}(t)\}$. These controls are called

admissible and we write $\mathcal{U}$ for the set of admissible controls.

We consider the same performance criterion as the one in the principle of optimality in the section The HJB Method and impose the same set of assumptions for the performance criterion as those in that section.

Let $H : [0, T^*] \times \mathbb{R}^n \times U \times \mathbb{R}^n \times \mathcal{L}(\mathbb{R}^n, \mathbb{R}^n) \rightarrow \mathbb{R}$ denote the Hamiltonian given by

$$\begin{aligned} H(t, X, u, p, q) \\ := g(t, X, u) + b^T(t, X, u)p + \text{tr}(\sigma^T(t, X, u)q) \end{aligned} \quad (35)$$

where $\text{tr}(M)$ represents the trace of a square matrix M ; we suppose that H is differentiable in X .

The adjoint equation corresponding to u and $X^{(u)}$ for the unknown processes $\{p(t)\}$ and $\{q(t)\}$ is given by the following backward stochastic differential equation:

$$\begin{aligned} dp(t) = & -\nabla H(t, X(t), u(t), p(t), q^T(t)) dt \\ & + q^T(t) dW(t) \end{aligned} \quad (36)$$

$$p(T^*) = \nabla h(X(T^*)) \quad (37)$$

where ∇G is the gradient of a function G with respect to X . h is a concave function of X .

Then, we present a sufficient maximum principle in the following proposition.

Proposition 1 *Let $u^* \in \mathcal{U}$ and the corresponding controlled state process be $X^* := X^{(u^*)}$. Suppose there exists a solution $(p^*(t), q^*(t))$ of the corresponding adjoint equation, (36) and (37) satisfying*

$$E \left[\int_0^{T^*} q^*(t)(q^*(t))^T dt \right] < \infty \quad (38)$$

Suppose, further, that

1. *for each $t \in [0, T^*]$,*

$$\begin{aligned} & H(t, X^*(t), u^*(t), p^*(t), q^*(t)) \\ & = \sup_{u \in U} H(t, X^*(t), u, p^*(t), q^*(t)) \end{aligned} \quad (39)$$

2. *$h(X)$ is a concave function of X ,*

3. for each $t \in [0, T^*]$,

$$H^*(X) := \max_{u \in U} H(t, X, u, p^*(t), q^*(t)) \quad (40)$$

exists and is a concave function of X .

Then, u^* is an optimal control.

For the necessary condition of the stochastic maximum principle, we refer to [2, 3, 7–9, 20].

Now, we illustrate the application of the stochastic maximum principle to the optimal consumption–investment problem presented. Here, we just present some heuristic arguments. For detailed discussions and proofs, we refer to The Martingale Approach [3]. We assume the same asset price dynamics and adopt the same notation as those in the section. As in that section, the market is complete here, so the market price of risk is uniquely determined. We consider the following utility maximization problem for both consumption and terminal wealth:

$$J_1(v) := \sup_{(\pi, c) \in \mathcal{A}(v)} E \left[\int_0^{T^*} \frac{(c(t))^{\gamma_1}}{\gamma_1} dt + \frac{(V(T^*))^{\gamma_2}}{\gamma_2} \right] \quad (41)$$

In this case, the Hamiltonian is

$$\begin{aligned} H(t, V, (\pi, c), p, q) \\ = \frac{c^{\gamma_1}}{\gamma_1} + p[r(t)V - c + \pi^T(\mu(t) - r(t)\mathbf{1})] \\ + q^T \sigma^T(t) \pi \end{aligned} \quad (42)$$

and the adjoint equation has the following form:

$$dp(t) = -r(t)p(t)dt + q^T(t)dW(t) \quad (43)$$

$$p(T) = (V^*(T))^{\gamma_2-1} \quad (44)$$

Define an exponential process $\{Z_{\bar{\theta}}(t)\}$ by

$$Z_{\bar{\theta}}(t) := \exp \left(- \int_0^t \bar{\theta}^T(s) dW(s) - \frac{1}{2} \int_0^t |\bar{\theta}(s)|^2 ds \right) \quad (45)$$

where $\{\bar{\theta}(t)\}$ is a measurable, $\{\mathcal{F}(t)\}$ -adapted process, which is uniformly bounded in $(t, \omega) \in [0, T^*] \times \Omega$. Write $\xi_{\bar{\theta}}(t) := \beta(t)Z_{\bar{\theta}}(t)$, for each $t \in [0, T^*]$.

It can be shown that an adapted solution to the adjoint equation (42) and (43) is given by the processes

$$p(t) = p(0)\xi_{\bar{\theta}}(t), \quad q(t) = -p(0)\xi_{\bar{\theta}}(t)\theta(t) \quad (46)$$

From the first-order conditions of maximizing the Hamiltonian (5), one obtains

$$c^*(t) = (p(0)\xi_{\bar{\theta}}(t))^{1/(\gamma_1-1)} \quad (47)$$

$$\bar{\theta}(t) = \sigma^{-1}(\mu(t) - r(t)\mathbf{1}) = \theta(t) \quad (48)$$

To simplify the notation, write $\xi(t) := \xi_{\bar{\theta}}(t)$, for each $t \in [0, T^*]$. Define a function $\mathcal{X}: (0, \infty) \rightarrow (0, \infty)$ by

$$\begin{aligned} \mathcal{X}(y) \\ := E \left[\int_0^{T^*} \xi(s)(y\xi(s))^{\frac{1}{\gamma_1-1}} ds + \xi(T^*)(y\xi(T^*))^{\frac{1}{\gamma_2-1}} \right] \end{aligned} \quad (49)$$

Since $\mathcal{X}$ is strictly decreasing and surjective, its inverse $\mathcal{Y} := \mathcal{X}^{-1}: (0, \infty) \rightarrow (0, \infty)$ exists and is strictly decreasing. We then conjecture that the optimal controls (π^*, c^*) satisfy

$$E \left[\int_0^{T^*} \xi(s)c^*(s) ds + \xi(T^*)V^*(T^*) \right] = v \quad (50)$$

Under this conjecture, $p(0) = \mathcal{Y}(v)$.

By the martingale representation theorem, there exists a progressively measurable process $\eta: [0, T^*] \times \Omega \rightarrow \mathbb{R}^n$ with $\int_0^{T^*} |\eta(s)|^2 ds < \infty$, $\mathcal{P}$ a.s. such that

$$\begin{aligned} E \left[\int_0^{T^*} \xi(s)(\mathcal{Y}(v)\xi(s))^{\frac{1}{\gamma_1-1}} ds \right. \\ \left. + \xi(T^*)(\mathcal{Y}(v)\xi(T^*))^{\frac{1}{\gamma_2-1}} | \mathcal{F}(t) \right] \\ = v + \int_0^t \eta^T(s) dW(s) \end{aligned} \quad (51)$$

Then, it can be shown that

$$\pi^*(t) = \sigma^{-1}(t) \left[\frac{\eta(t)}{\xi(t)} + V^*(t)\theta(t) \right] \quad (52)$$

$$c^*(t) = (\mathcal{V}(v)\xi(t))^{\frac{1}{\gamma_1-1}} \quad (53)$$

where the optimal wealth process $\{V^*(t)\}$ is given by

$$V^*(t) = \frac{1}{\xi(t)} E \left[\int_t^{T^*} \xi(s) (\mathcal{V}(v)\xi(s))^{\frac{1}{\gamma_1-1}} ds + \xi(T^*) (\mathcal{V}(v)\xi(T^*))^{\frac{1}{\gamma_2-1}} | \mathcal{F}(t) \right] \quad (54)$$

Transaction Costs

Standard models for financial markets are based on the simplifying assumption that trading orders can be given and executed in continuous time with no friction. This assumption is clearly a strong idealization of the reality. In particular, securities should not be described by a single price but by a bid and ask curve. As a first approximation, one may assume that the bid and ask prices do not depend on the traded quantities, which leads to models with proportional transaction costs. These models have attracted a lot of attentions these last years, mostly because their linear structure allows to develop a nice duality theory as in frictionless models.

No Arbitrage with Proportional Costs

The Fictitious Markets Approach in the One-dimensional Case

The study of models with proportional transaction costs starts with the paper of Jouini and Kallal [22] who considered a financial market with one nonrisky asset S^1 , taken as a numéraire and normalized to 1, and one risky asset called S^2 .

To be consistent with the developments below, we use a different (but equivalent) presentation than the one used in [22]. In particular, we denote by π^{ij} the number of physical units of asset i for which an agent can buy 1 unit of asset j . With these notations, the bid and ask prices of S^2 in terms of S^1 are given by $1/\pi^{21}$ and π^{12} . They are assumed to be right-continuous and adapted to the underlying (right-continuous) filtration $(\mathcal{F}_t)_{t \leq T}$.

In this model, simple self-financing trading strategies are defined as finite sequences of trading times $(t_n)_{n \leq N}$, for some $N \geq 1$, and random vectors of traded quantities $(\xi_{t_n})_{n \leq N}$ such that ξ_{t_n} is $\mathcal{F}_{t_n}$ -measurable. The i -th component $\xi_{t_n}^i$ of ξ_{t_n} stands for the number of physical units of S^i bought at the times t_n . In this framework, the usual self-financing condition reads $\xi_{t_n}^1 - (\xi_{t_n}^2)^+ \pi_{t_n}^{12} + (\xi_{t_n}^2)^- / \pi_{t_n}^{21} \leq 0$ for each $n \leq N$. The associated portfolio starting with a zero initial holding is described as a two-dimensional process $V_t^\xi = \sum_{t_n \leq t} \xi_{t_n}$ whose i -th component is the numbers of units of S^i held.

The key observation of Jouini and Kallal [22] is the following: if $\tilde{Z}^2$ is a process such that $\tilde{Z}_t^2 \in [1/\pi_t^{21}, \pi_t^{12}]$ a.s. (almost surely for all $t \leq T$), then the liquidation value at time T of the portfolio, $\ell(V_T^\xi) := V_T^{\xi,1} - (V_T^{\xi,2})^- \pi_T^{12} + (V_T^{\xi,2})^+ / \pi_T^{21}$, is a.s. lower than the terminal value $\tilde{V}_T^\xi := \sum_{t_n \leq T} \xi_{t_n}^2 (\tilde{Z}_{t_{n+1} \wedge T}^2 - \tilde{Z}_{t_n}^2)$ associated to the same strategy in a *fictitious market* in which the risky asset has the dynamics $\tilde{Z}^2$ and where there is no transaction costs. In particular, if there is an equivalent measure $\mathbb{Q}$ such that $\tilde{Z}^2$ is a martingale, then no arbitrage (NA) is possible: $\ell(V_T^\xi) \in L^0(\mathbb{R}_+) \Rightarrow \tilde{V}_T^\xi \in L^0(\mathbb{R}_+) \Rightarrow \tilde{V}_T^\xi = 0 \Rightarrow \ell(V_T^\xi) = 0$. Thus, the existence of such a process $\tilde{Z}^2$, called *fictitious price process*, admitting an equivalent martingale measure is a sufficient condition for the absence of arbitrage in this model.

The fundamental result in [22] is that this condition is actually also necessary, whenever we replace the notion of NA by that of *no free lunch*; see the above paper for a precise definition.

As an example, let us consider the case where $1/\pi^{21} = (1 - \lambda)S^2$ and $\pi^{12} = (1 + \lambda)S^2$ where S^2 is now viewed as a right-continuous adapted process and $\lambda \in (0, 1)$. Then, a necessary and sufficient condition for the absence of *free lunch* for simple strategies is that there exists a process $\tilde{Z}^2$ such that $\tilde{Z}_t^2 \in [(1 - \lambda)S_t^2, (1 + \lambda)S_t^2]$ a.s. for all $t \leq T$ and which is a martingale under some equivalent measure $\mathbb{Q}$. An important consequence of this result is that S^2 itself need not admit a martingale measure nor be a semimartingale under the original probability measure. One could, for instance, allow S^2 to be a fractional Brownian motion as in [16].

The Multivariate Case: The Solvency Region and Its Polar

In the multivariate setting where direct exchanges between many assets is possible, which is typically the case on currency markets, a similar reasoning can be used, and the geometric structure of the problem is more apparent. In particular, the notion of *solvency region*, introduced by Kabanov [29], and its positive polar play an important role.

The *solvency region* at time t is the set $K_t(\omega)$ formed by all vectors x such that we can find nonnegative numbers a^{ij} satisfying $x^i + \sum_j (a^{ji} - a^{ij} \pi_t^{ij}(\omega)) \geq 0$. It corresponds to positions, which can be transformed into nonnegative holdings after

suitable exchanges. A portfolio process, in units of physical quantities, is defined in [29] as a cadlag bounded variation process V satisfying $dV_t \in -K_t$. This means that there is a matrix-valued cadlag adapted process L , with nondecreasing components, such that $dV_t = \sum_j (dL_t^{ji} - dL_t^{ij} \pi_t^{ij})$, that is, dL_t^{ij} is the number of units of asset j obtained by selling $dL_t^{ij} \pi_t^{ij}$ units of asset i .

In this model, a strategy is said to be admissible if the following *no-bankruptcy* condition holds: $V_t - a\mathbf{1} \in K_t$ a.s. for some real number a with $\mathbf{1} := (1, \dots, 1)$. This means that the *liquidation value* of the portfolio is bounded from below by a .

The counterpart of the key observation of Jouini and Kallal [22] is the following. Let Z be a continuous martingale with positive components such that Z_t takes values in the positive polar K_t^* of K_t : $K_t^*(\omega) := \{z \in \mathbb{R}^d : 0 \leq z^i \leq z^j \pi_t^{ji}(\omega)\}$. Then, by the integration by parts formula, $Z_t \cdot V_t = \sum_i Z_t^i dV_t^i + V_t^i dZ_t^i$. The first part is nonpositive because $Z_t \in K_t^*$ and $dV_t \in -K_t$, the second part is a local martingale, and $Z \cdot V$ is bounded from below by the martingale aZ . This implies that $Z \cdot V$ is a supermartingale, which rules out any arbitrage opportunities: $V_T \in L^0(K_T) \Rightarrow Z_T \cdot V_T \in L^0(\mathbb{R}_+) \Rightarrow Z_T \cdot V_T = 0 \Rightarrow V_T \in L^0(\partial K_T)$. Otherwise stated, if the liquidation value of the portfolio is nonnegative a.s., then it must be equal to 0.

As in [22], the process Z has a nice interpretation in terms of *fictitious price process*. Indeed, if we set $\tilde{Z}^i = Z^i / (Z^1 / \mathbb{E}[Z_T^1])$, we see that the above conditions imply that the *fictitious market*, without transaction costs and where the dynamics of the i -th asset is given $\tilde{Z}^i$, is *cheaper* than the original one ($\tilde{Z}^i / \tilde{Z}^j \in [1/\pi^{ij}, \pi^{ji}]$) and admits no arbitrage (there is at least one martingale measure $\mathbb{Q} := Z_T^1 / \mathbb{E}[Z_T^1] \cdot \mathbb{P}$ for $\tilde{Z}$). See [7] for a precise statement.

Note that in this model no asset has been taken explicitly as a numéraire, except in the last interpretation in terms of *fictitious markets*. It turns out that, when working with quantities instead of amounts, as in usual frictionless models, the only important quantity is the bid–ask spread process $\pi = (\pi^{ij})$, which directly expresses the exchange rates between two assets.

No-arbitrage Conditions

Different notions of NA have been proposed for discrete time multivariate models. In the following,

we denote by A_T the set of terminal values of portfolios starting from 0.

1. The usual NA condition can be written as $A_T \cap L^0(K_T) = L^0(\partial K_T)$ (see above). It was studied in [32] and called *weak no arbitrage condition* therein. When the probability space is finite, it is equivalent to the existence of a martingale Z such that Z_t takes values in $K_t^* - \{0\}$ for all $t \leq T$ a.s. We therefore retrieve the process Z required for the NA condition in [29]. Moreover, this condition implies that A_T is closed in probability, a desirable feature to build on a nice duality for the set of superhedgeable claims (see below). Such a process Z was called a *consistent price system* in [36]. The notion of consistency reflects the fact that the exchange rates corresponding to the induced frictionless market (see above) lie within the original bid–ask spreads: $\tilde{Z}^i / \tilde{Z}^j \in [1/\pi^{ij}, \pi^{ji}]$.

However, this condition is not strong enough when Ω is not finite (see [36]). This leads to the introduction of a second notion of NA.

2. The *strict NA condition* (NA^s) introduced in [31] reads as follows: $A_t \cap L^0(K_t) = L^0(K_t^0)$ for all $t \leq T$. Here, $K_t^0 := K_t \cap (-K_t) (= \partial K_t \cap (-\partial K_t))$. The economic interpretation is that, if a wealth process V starting from a zero initial endowment has a nonnegative liquidation value at any time, then it is *equivalent* to 0, that is, its liquidation value is 0 ($V_t \in \partial K_t$) and it can be constructed from a 0 endowment at time t by a suitable immediate exchange on the market ($V_t \in -\partial K_t$). Under the *efficient friction* condition, $1/\pi^{ij} < \pi^{ji}$ for all $i \neq j$, which means that no couple of assets can be exchanged freely and can be written as $K_t^0 = \{0\}$, this condition is equivalent to the existence of a martingale Z which lies in the relative interior $\text{ri} K_t^*$ of K_t^* , that is, $Z^i / Z^j \in \text{ri}[1/\pi^{ij}, \pi^{ji}]$. Moreover, it implies that A_T is closed in probability. Such a process Z is called a *strictly consistent price system*.

This last notion of NA is sufficient to cover the cases where the transaction costs are strictly positive. However, up to the slight (also interesting) extension proposed [35], it does not allow to show that A_T is closed or to construct a *consistent price system* in general without the extra *efficient friction* condition, see the counterexample in [36].

3. The last notion was proposed in [36]. It is based on the idea that if a martingale Z satisfies the condition $Z^i/Z^j \in \text{ri}[1/\pi^{ij}, \pi^{ji}]$, then one can construct a bid–ask spread matrix $\bar{\pi}$ defined by $\bar{\pi}^{ji} := Z^i/Z^j$, which leads to a market without arbitrage, because Z is a martingale, and satisfies $[1/\bar{\pi}^{ij}, \bar{\pi}^{ji}] \subset \text{ri}[1/\pi^{ij}, \pi^{ji}]$ by construction. Thus, the existence of a *strictly consistent price system* implies a strong notion of NA: there exists a market associated to a bid–ask spread matrix $\bar{\pi}$ satisfying $[1/\bar{\pi}^{ij}, \bar{\pi}^{ji}] \subset \text{ri}[1/\pi^{ij}, \pi^{ji}]$ in which there is no arbitrage. Otherwise stated, one can slightly reduce the transaction costs, when they are not already equal to 0, and still preserve the NA condition. This condition was called the *robust NA* condition (NA^r) in [36]. The main result of this article is that this condition is sufficient to ensure that A_T is closed in probability and is actually equivalent to the existence of a *strictly consistent price system*. This is the good condition to impose on a model:

- (a) It is equivalent to the existence of a *strictly consistent price system* without any extra assumption.
- (b) When there is no friction, that is, $1/\pi^{ij} = \pi^{ji}$ for all i, j , it is equivalent to the usual no-arbitrage condition in frictionless markets.
- (c) Similar notions can be used to study models with nonlinear frictions (see [5]).
- (d) It can be extended to continuous-time models in the following form: the absence of arbitrage opportunities for arbitrary small transaction costs is equivalent to the existence of a *strictly consistent price system* for arbitrary small transaction costs. This result was proved in a model with only one risky asset with continuous paths in [17]. The existence of a *strictly consistent price system* for arbitrarily small transaction costs in a multivariate market with continuous price processes is a result of [18].

Superhedging and No-arbitrage Price Intervals

When there are transaction costs, we generally have more than one fictitious price process and more than

one martingale measure $\mathbb{Q}$ satisfying the conditions above. Furthermore, as underlined in [1], even if a contingent claim G can be duplicated by dynamic trading, the duplication strategy does not necessarily correspond to the cheapest way to hedge this claim. They thus introduced the concept of *super-replication price* $\pi(G)$ that corresponds to the minimum amount it costs to hedge the claim G (in terms of the first asset taken as a numéraire).

As first shown in [11] and [22], it can be obtained by taking the (normalized) expected value of $\tilde{Z}_T \cdot G$ with respect to all the *fictitious markets* $\tilde{Z}$ and all measures $\mathbb{Q}$ that characterize the absence of arbitrage opportunities in the corresponding *fictitious market*. Here, G is viewed as the vector of units of the different assets to be delivered. This result can easily be understood in the light of the above discussion. If $V_T - G \in K_T$, then $\tilde{Z}_T \cdot V_T \geq \tilde{Z}_T \cdot G$. Since $\tilde{Z} \cdot V$ is a $\mathbb{Q}$ -supermartingale (see above) it follows that $\tilde{Z}_0 \cdot V_0 \geq \mathbb{E}^{\mathbb{Q}}[\tilde{Z}_T \cdot G]$. The converse implication is obtained by using a standard separation argument, once A_T is known to be closed in a suitable sense.

The no-arbitrage prices interval is then equal to $[-\pi(-G), \pi(G)]$. Using the viability concept for price systems introduced in [20], the paper [23] also proves that these bounds are the tightest bounds that can be inferred at the equilibrium on the price of a contingent claim without knowing the agent's preferences (see also [21]). This is still the case even if we assume that agents have von Neumann–Morgenstern (VNM) preferences [24]. In particular, this means that even if the super-replication price seems too high (see below) it is always possible to construct VNM agents that are willing to pay amounts arbitrarily close to this super-replication price in order to hedge the considered asset (see also [4]).

Since endowments in different assets are not equivalent in the presence of transaction costs, it is also of interest to extend the notion of *superhedging price* to that of *initial endowments* $x \in \mathbb{R}^d$ that *allow to superhedge*. In this case, the above dual formulation reads $\tilde{Z}_0 \cdot x \geq \mathbb{E}^{\mathbb{Q}}[\tilde{Z}_T \cdot G]$ for all the *fictitious markets* $\tilde{Z}$ and all associated martingale measures $\mathbb{Q}$ (see [32] and [8]). It can be restated in terms of consistent price systems: $Z_0 \cdot x \geq \mathbb{E}[Z_T \cdot G]$ for all *consistence price systems* Z .

The case of American options can be treated similarly. However, it is not sufficient to impose the above condition at any stopping time lower than T as in frictionless markets. This is due to the absence of

total order on $\mathbb{R}^d$. To overcome this problem, one has to relax the notion of stopping times and consider the more general notion of *randomized* stopping times. See [6] and [10] for discrete time models, and, [3] and [15] for a continuous-time extension.

The notion that *superhedging* typically leads to much too high prices to be useful in the market (it usually corresponds to a buy-and-hold strategy) was first conjectured in [13] for call options and then proved by different authors at different level of generality; see [7] and the reference therein.

Utility Maximization

Thanks to the above-mentioned duality between superhedgeable claims and consistence price systems, existence of optimal strategies can be obtained for general models with transaction costs. The first general result was derived by Cvitanic and Karatzas [11] in a Brownian diffusion model and then extended by Cvitanic and Wang [12] to the semimartingale case. The general multivariate case was studied in [2] and [14] under *Asymptotic Elasticity* conditions similar to the one introduced in [33]; see [19] for the necessity of this condition in models with proportional transaction costs. All these papers show that the usual duality holds once we replace the notion of *equivalent local martingale measures* by that of *consistent price systems*.

In Markovian diffusion models, the partial differential equation (PDE) approach has also attracted a lot of attention. It leads to the Hamilton–Jacobi–Bellman (HJB) equations involving constraints on the gradients of the value function. It allows to show that the optimal strategy typically consists in maintaining the dotations in a given *no-trading region*. See, for example, [30, 37] and the references therein.

Extensions

In order to take a large set of possible frictions including multivariate transaction costs into account, one can follow the approach of [9] (in discrete time) and [26] and [28] (in continuous time), where it is proposed to deal directly with the space of possible cash flows, instead of the space of terminal payoffs, and provide a characterization of the no free-lunch assumption in terms of the existence of

a separating functional. In particular, Napp [34] develops an arbitrage pricing theory and a super-replication concept in this cash-flow space.

The case of fixed transaction costs is analyzed in [25] and [27]. The conclusion drawn is that the absence of free lunch is characterized by the existence of a (family of) martingale measure(s) for the frictionless price processes. The unique difference with the frictionless case consists in the fact that these martingale measures are not necessarily equivalent to the initial probability but only absolutely continuous with respect to it.

Behavioral Portfolio Selection

Behavioral portfolio selection is the study of how psychology impacts investors' portfolio choices. These choices pertain to the manner in which investors structure the risk-return composition of their portfolios and modify their portfolios over time through the buying and selling of securities.

The key behavioral features about portfolios include a dual emphasis on very safe and very risky securities, a lack of full diversification, excessive trading, the salience of securities that are purchased for the portfolio, and the disposition to sell winners too early but ride losers too long.

The theoretical framework underlying behavioral portfolio selection draws on the following four elements in the literature in behavioral decision making: (i) *SP/A* theory; (ii) prospect theory; (iii) regret and self-control; and (iv) heuristics and biases. Notably, the first three elements pertain to risk preferences, while the fourth deals with erroneous judgments about risk.

All four elements involve departures from the neo-classical mean-variance approach to portfolio selection. In the neoclassical approach, investors are rational in two senses. First, their preferences conform to the axioms of expected utility, where utility is defined over total return (or wealth) and risk is measured in terms of return standard deviation. Second, their judgments about risk and return are free of error. By way of contrast, in the behavioral approach, preferences typically violate the axioms of expected utility, investors attach importance to other variables besides total return (or wealth), investors do not measure risk in terms of return standard deviation, and investors make erroneous judgments about the risks they face.

In the mean-variance approach, investors hold well-diversified portfolios that feature risk and return being rationally balanced against each other. In the behavioral approach, investors are imperfectly rational, and in the course of attempting to make the best portfolio decisions they can, they adopt piecemeal approaches to portfolio selection that leave them holding undiversified portfolios.

Theoretical Foundations

SP/A Theory

Lopes [9] developed a psychologically based approach known as *SP/A theory* to explain choice among risky alternatives. She titled her 1987 article "The Psychology of Risk: Between Hope and Fear" to capture the idea that the emotions of hope and fear play key roles in choice among risky alternatives. In this respect, the letters that make up *SP/A* refer to specific concepts that measure or impact the degree of fear or hope experienced by a decision maker. Notably, *S* stands for security, *P* stands for potential, and *A* stands for aspiration.

In order to describe Lopes' formal framework, consider some notation. Denote the set of possible outcomes by a finite set of real numbers $X = \{x_1, \dots, x_n\}$, ordered from the lowest outcome x_1 to the highest x_n . Formally, a risky alternative or prospect is a random variable that takes on values in X . One way to describe the probabilities attached to a random variable is to use a decumulative distribution function D , where $D(x)$ is the probability that the outcome payoff is at least x . The same probabilistic information is also conveyed by the cumulative distribution function, which measures the probability that the outcome payoff is no greater than x , or the probability density function, which measures the probability that the outcome payoff is exactly x .

In a typical decision task, a decision maker chooses a best alternative from a menu $\{D\}$ of risky alternatives. The role of the theory is to describe the criteria leading to the choice. In *SP/A* theory, risky alternatives are evaluated using an objective function whose arguments reflect security *S*, potential *P*, and aspiration *A*.

Roughly speaking, increased fear stems from reduced security and reduced security corresponds to an increase in the probability attached to the occurrence of some unfavorable event. Suppose we consider two decision makers who face an identical risk, or prospect D , but experience different degrees of fear. Intuitively, the decision maker who experiences more fear attaches greater importance to the probability associated with unfavorable events than the decision maker who experiences less fear.

Formally, Lopes uses rank-dependent utility to capture the effects of fear. In rank-dependent utility, a decision maker who faces a risky prospect D

acts as if the decumulative density function is the transform $h(D)$ rather than D itself. In *SP/A* theory, fear operates on the probabilities associated with unfavorable events. Because D is a decumulative distribution function, the probability attached to the least favorable event x_1 is given by $\text{Prob}\{x_1\} = D(x_1) - D(x_2)$.

Under the transform $h(D)$, the probability attached to the least favorable event x_1 is given by $\text{Prob}\{x_1\} = h(D(x_1)) - h(D(x_2))$. In Lopes' framework, a decision maker who is fearful about exposure to event x_1 overweights the probability attached to x_1 . That is, the fearful decision maker employs a transform h that satisfies

$$h(D(x_1)) - h(D(x_2)) > D(x_1) - D(x_2) \quad (1)$$

Because x_1 is the least favorable outcome, the probability that the actual outcome turns out to be x_1 or higher is 1. In other words, $D(x_1) = 1$. What equation (3) effectively states is that increased fear leads to an increase in the slope of the h -function in the neighborhood of 1.

Rank-dependent utility also captures the manner in which the decision maker experiences hope. Hope is associated with upside potential, or potential for short. Hope induces a decision maker to attach greater weight to the most favorable events. Because D is a decumulative distribution function, the probability attached to the most favorable event x_n is given by $\text{Prob}\{x_n\} = D(x_n)$. Therefore, the emotion of hope leads a decision maker to employ a transform h that satisfies $h(D(x_n)) > D(x_n)$. For the second most favorable outcome, the corresponding inequality would read as

$$h(D(x_n)) - h(D(x_{n-1})) > D(x_n) - D(x_{n-1}) \quad (2)$$

This inequality indicates that increased hope leads to an increase in the slope of the h -function in the neighborhood of 0.

In Lopes' framework, a person who neither experiences fear nor hope is associated with an h -function that is the identity function: $h(D) = D$. A decision maker who experiences only fear, but not hope, is associated with an h -function that is strictly convex in D : it is steep in the neighborhood of 1 and flat in the neighborhood of 0. Formally, Lopes uses a power function $h_S(D) = D^q$, $q > 1$ for this case. A decision maker who experiences only hope is associated with an h -function that is strictly concave in D . Formally,

Lopes uses a power function $h_P(D) = 1 - (1 - D)^p$, $p > 1$ for this case. A person who experiences both fear and hope is associated with an h -function that has an inverse-S shape. It is concave in the neighborhood of the origin and convex in the neighborhood of 1. Formally, Lopes uses a convex combination of the power functions h_S and h_P to capture this case.

In *SP/A* theory, the degree to which fear and hope are experienced depends on the degree to which risky prospects offer security S and potential P . To capture the impact of both security and potential, Lopes uses an expected utility function with probabilities derived from the h -transform. She calls the function SP for security–potential, and it has the form

$$SP = \sum_{i=1}^n (h(D_i) - h(D_{i+1}))u(X_i) \quad (3)$$

In equation (1), u is a utility function whose argument is outcome x . Although Lopes uses the assumption $u(x) = x$ in most of her analysis, Lopes and Oden [10] comment that, in practice, u might display a bit of concavity.

The A in *SP/A* denotes aspiration. Aspiration pertains to a target value α (or range) to which the decision maker aspires. Aspiration points reflect different types of goals. For example, a decision maker might wish to generate an outcome that would allow the purchase of a particular good or service. Alternatively, the aspiration point might reflect a status quo position that corresponds to the notion of no gain or loss. In Lopes' framework, aspiration risk is measured as the probability 1- A where $A = \text{Prob}\{x \geq \alpha\}$ that the random outcome x meets or exceeds the aspiration level α .

In *SP/A* theory, the decision maker maximizes an objective function $V(SP, A)$ in deciding which alternative D to choose from the menu of available prospects. V is strictly monotone increasing in both of its arguments. Therefore, there are situations in which a decision maker is willing to trade off some SP in exchange for a higher value of A .

Prospect Theory

Prospect theory is a theory of choice developed by psychologists Kahneman and Tversky [5]. Prospect theory has four distinctive features.

First, the carriers of utility are changes, meaning gains and losses relative to a reference point, not the final position.

Second, the utility function (known as a *value function* in prospect theory) is concave in gains and convex in losses, with a point of nondifferentiability at the origin so that the function is more steeply sloped for losses (to the left of the origin) than for gains (to the right of the origin). Hence, the utility function is S-shaped with a kink at the origin. Tversky and Kahneman [16] suggest using a utility function $u(x)$ with the form x^α in the domain of gains ($x \geq 0$) and $-\lambda(-x)^\beta$ in the domain of losses ($x \leq 0$).

Third, probabilities are weighted (or distorted) when prospects are evaluated. In the original 1979 version of prospect theory (original prospect theory OPT), the weighting function π has probability density p as its argument. The π -function in OPT is convex, with $\pi(p) > p$ for small positive values of p and $\pi(p) < p$ for high values of p less than 1. In 1992, Tversky and Kahneman [16] proposed a cumulative version of prospect theory (cumulative prospect theory CPT) that uses rank-dependent utility. Unlike OPT, where probability weights depend only on probability density, the weights in CPT depend on outcome rank.

Tversky and Kahneman [16] use two weighting functions, one function for gains and one function for losses. Both functions take decumulative probabilities as their arguments, where the decumulative distribution pertains to the absolute value of the gain or loss, respectively. The weighting function is similar to the h -transform used by Lopes. It features an inverse S-shape, which Tversky–Kahneman generate using the ratio of a power function to a Hölder average; that is, $p^\gamma / (p^\gamma + (1-p)^\gamma)^{1/\gamma}$. As a result, in CPT, it is the probabilities of extreme outcomes that are overweighted (very large losses and very large gains).

Both the S-shape of the utility function and the inverse S-shape of the weighting functions reflect psychophysics, meaning the diminished sensitivity to successive changes. For the utility function, the changes pertain to differences relative to the reference point. For the weighting function, the changes pertain to differences relative to the endpoints 0 and 1.

Fourth, decision makers engage in editing or framing before formally evaluating risky prospects. There are several types of editing issues. Perhaps the simplest editing issue is the choice of reference point. Kahneman and Tversky illustrate this issue by describing a medical task in which the data can be presented, or framed, in one of two ways. The first

way is in terms of lives saved, while the second way is in terms of lives lost. The “lives saved” frame implicitly sets the reference point at 100% fatalities. The “lives lost” frame implicitly sets the reference point at 0% fatalities. Although the data underlying the two frames is identical, physicians tend to act as if they are more risk averse when presented with the data framed in terms of “lives saved” than when the data is framed in terms of “lives lost”. This choice pattern is consistent with the S-shaped utility function.

A more complex framing issue is the segmentation of a complicated decision task into a series of subtasks. The structure of each subtask is called a *mental account* and the segmentation process is known as *narrow framing*. Because narrow framing tends to overlook interdependencies between mental accounting structures, the segmentation process is often suboptimal. Tversky and Kahneman present examples in which narrow framing leads to the selection of stochastically dominated choices.

Prospect theory is a descriptive framework, not a normative framework. People who choose stochastically dominated alternatives do so because they do not always grasp the complete structure of the decision tasks they confront. The complete structure is typically opaque, not transparent, and people lack the ability to frame complex decision tasks transparently.

Regret and Self-control

In the early development of prospect theory, Kahneman and Tversky focused on the role of regret. Regret is the psychological pain associated with recognizing after the fact that taking a different decision would have produced a better outcome. Kahneman *et al.* [7] eventually built prospect theory using the S-shaped value function, but in their 1982 work they continued to emphasize the importance of regret. They pointed out that regret will be magnified by the ease with which a person can imagine taking a different decision.

Self-control refers to situations when a person is conflicted, and *thinks* he or she should take one decision, but emotionally *feels* like taking a different decision. Studies of self-control in financial economics tend to emphasize the difficulty in delaying gratification. However, self-control applies more broadly,

and in particular applies when the emotion of regret prevents a person from taking a decision that he or she “thinks” is appropriate.

Heuristics and Biases

The weighting functions in *SP/A* theory and prospect theory reflect the way that people process known probabilistic information. In these theories, people weight probabilities as they do because of emotion (as in *SP/A* theory) or psychophysics (as in prospect theory). In contrast, heuristics and biases involve errors in judgments about the probabilities themselves. A person might know the true probability of winning the lottery but because of hope overweights its value psychologically when deciding whether or not to purchase a lottery ticket. On the other hand, a person who is unrealistically optimistic would tend to overestimate the probability of winning the lottery.

The volume edited by Kahneman *et al.* [6] contains the foundation contributions to the heuristics and biases literature. A heuristic is a crude rule of thumb for making judgments about probabilities, statistics, future outcomes, and so on. A bias is a predisposition toward making a particular judgmental error. The heuristics and biases approach studies the heuristics upon which people rely to form judgments, and the associated biases in those judgments.

Some biases are associated with specific heuristics. Examples of these biases relate to such heuristic principles as availability, anchoring, and representativeness.

Availability is the tendency to form judgments based on information that is readily available, but to underweight information because it is not readily available. For example, a person might underestimate the danger from riptides and overestimate the danger from shark attacks because media stories tend to report most shark attacks but rarely report less dramatic incidents involving riptides. Heuristics and biases associated with availability reflect the importance of salience and attention.

Anchoring is the tendency to formulate an estimate by using a process that begins with an initial number (the anchor) and then making adjustments relative to the anchor. Anchoring bias is the tendency for the associated adjustments to be too small.

Representativeness is the tendency to rely on stereotypes to make a judgment. For example, a person who relies on representativeness might be

especially bold in predicting that the future return of a particular stock will be very favorable because its past long-term performance has been very favorable. This is because they form the judgment that favorable past performance is representative of good stocks. However, representativeness leads such predictions to be overly bold, because of insufficient attention to factors that induce regression to the mean.

Although some biases relate directly to specific heuristics, other biases stem from a variety of factors. For example, people tend to be overconfident about both their abilities and their knowledge. People who are overconfident about their abilities overestimate those abilities. People who are overconfident about their knowledge tend to think they know more than they actually do. In particular, people who are overconfident about their knowledge tend to set confidence intervals around their estimates that are too narrow. As a result, they wind up being surprised at their mistakes more often than they anticipate.

Other examples of biases that do not stem directly from specific heuristics are unrealistic optimism and the illusion of control. Unrealistic optimism involves overestimating the probabilities of favorable events and underestimating the probabilities of unfavorable events. The illusion of control is overestimating the role of skill relative to luck in the determination of outcomes.

Implications for Portfolio Selection

SP/A Theory and Portfolio Selection

Shefrin and Statman [15] use the *SP/A* framework as the basis of behavioral portfolio theory. They develop a model with two dates, $t = 0$ and $t = 1$, in which an investor with initial wealth $W = 1$ chooses a portfolio at $t = 0$. The model is structured so that at $t = 1$ one of n possible states will occur, and the subjective probability (density) associated with the occurrence of state i is p_i . The model also features a complete market, meaning that securities are priced in accordance with state prices $v_1, \dots, v_n$, where v_i is the price associated with the delivery of 1 unit of consumption in state i .

A portfolio return configuration is given by $x_1, \dots, x_n$ where x_i denotes the number of units of consumption paid if state i occurs. Notice that

because $W = 1$, $x_1, \dots, x_n$ are indeed gross rates of return, which are assumed to be nonnegative.

The decision task for investor with SP/A preferences is to choose a portfolio return configuration $x_1, \dots, x_n$ to maximize the objective function $V(SP, A)$ subject to the constraint

$$\sum_{i=1}^n v_i x_i = 1 \quad (4)$$

The maximization of $V(SP, A)$ for fixed A is formally equivalent to a constrained expected utility maximization problem, where the decision weights derived from the h -transform are treated like probabilities. The associated constraint is $A = \text{Prob}\{x \geq \alpha\}$. The effect of this constraint, when active, is to introduce a flat region $i_L \leq i \leq i_U$ for which $x_i = \alpha$. Notably, the investor meets the A -constraint by fulfilling this constraint from the favorable states down. This can result in three regions: $x_n > \alpha$, $x_i = \alpha$ for $i_L \leq i \leq i_U$, and $x_i < \alpha$ for $i < i_L$, and when u is linear $x_i = 0$ for $i < i_L$. In effect, an SP/A portfolio can be thought of as the combination of a risky bond and a call option on a neoclassical portfolio with a high exercise price.

There are two key questions associated with SP/A portfolios. First, how do the h -function and curvature of the utility function $u(x)$ impact the choice of portfolio payoff configuration? Second, how is the return configuration impacted by the values of α and A ?

Lopes suggests that the utility function $u(x)$ is mildly concave, although for purposes of exposition she treats it as linear in her discussions. Notably, linearity encourages an investor to concentrate as much wealth as possible on purchasing claims associated with the state featuring the lowest state price per unit probability. This will lead to a lottery property, meaning the small probability of a very large payoff. Concavity in the utility function will dampen the lottery property.

The impact of fear and hope occurs through the SP function, where the probabilities associated with the least favorable states and the most favorable states are overweighted. Such overweighting leads to higher returns in extreme states than would occur otherwise, and therefore lower returns in intermediate states.

It is the impact of the A variable that makes SP/A theory distinct from other psychologically based

theories of risk. It should be kept in mind that the investor tends to fulfill the A -constraint from the most favorable state down. Increasing the value of A leads to a shift in returns from both the most unfavorable states and the most favorable states, where $x_i \neq \alpha$, to expand the middle region where $x_i = \alpha$. If an investor increases the value of α , then she also shifts return from the extremes to the middle, but with the purpose of raising the level of the middle region.

SP/A theory implies that investors will choose portfolios whose return patterns can be generated by combining a risky bond and a call option on a neoclassical portfolio associated with unconstrained SP -maximization.

Prospect Theory and Portfolio Selection

Two features of prospect theory are particularly germane to portfolio selection, and both involve the manner in which the information underlying the selection task is framed. The first feature is the simplification of the selection task through the use of mental accounts. The second feature is the reference point used to define gains and losses.

The use of mental accounting leads investors to evaluate decisions about securities with little or no reference to other securities in the portfolio. This is in sharp contrast to neoclassical theory, where the value of a security to an investor very much depends on the return covariance of that security with other securities in the portfolio. Mental accounting implies that investors make little if any direct use of the return variance–covariance matrix.

Shefrin and Statman [14] suggest that the most natural reference point for the mental account associated with an individual security is original purchase price. As discussed earlier, the location of a reference point is important because people's attitude toward risk depends critically on whether they view the set of possible outcomes as gains, losses, or a mixture of gains and losses. This feature was first highlighted by Kahneman and Tversky [5], and is shared by SP/A theory.

Mental accounting is also associated with investors having a multitude of different goals. In this case, the investor associates a mental account or portfolio layer to a specific goal α and associated probability A . Downside protection is associated with a low α and high probability A . Upside potential is associated

with a high α and associated probability A that is as high as feasibility allows.

Regret, Self-control, and Portfolio Selection

People experience regret when they admit to having made a decision that turned out poorly. When an investor purchases a stock that subsequently performs poorly, the investor is prone to experiencing regret. Shefrin and Statman [14] suggest that the degree of regret is especially high when an investor sells a stock at a loss.

Because there are tax benefits from selling stocks at a loss, many investors who delay tax-loss selling forego potential benefits. In doing so, they pay a price to defer the pain of regret, hoping that the stock will bounce back so that they can avoid selling at a loss. On the flip side, selling a stock for a gain can be a source of pride, even if there is a tax penalty for doing so. In this respect, imperfect self-control can lead investors to sell stocks before their gains become long-term, thereby leading to a higher tax liability. Therefore, regret and imperfect self-control predispose investors to sell winners too early and ride losers too long, a phenomenon that Shefrin and Statman [14] call *the disposition effect*.

The S-shaped utility function in prospect theory implies that decision makers are prone to be risk averse in the domain of gains but risk seeking in the domain of losses. For this reason, prospect theory is the natural starting point for discussing the disposition effect. However, prospect theory does not explain why an investor would knowingly incur an unnecessary tax penalty.

Heuristics, Biases, and Portfolio Selection

Few, if any, investors have objectively correct knowledge of return distributions. Most investors formulate their beliefs by applying heuristics to the information at their disposal. As such, they are vulnerable to forming biased beliefs.

Biases take many forms. Barber and Odean [2] point out that because of reliance on the availability heuristic, investors tend to place undue stress on stocks that have attracted their attention. They call this phenomenon *the attention hypothesis*. De Bondt and Thaler [3] suggest that individual investors who rely on representativeness are prone to extrapolate past performance with undue weight on the

recent past. They call this phenomenon *the overreaction effect*. Shefrin [13] suggests that professional investors who rely on representativeness apply it differently than individual investors and are prone to attach too high a probability to reversals. Odean [11] suggests that overconfidence leads all investors to be overconfident in their beliefs, thereby trading with excessive frequency on unwarranted convictions.

Empirical Evidence

Much of the literature pertaining to behavioral portfolio selection involves the development of hypotheses in theoretical papers followed by other papers which tested these hypotheses.

Polkovnichenko [12] and Kumar [8] provide evidence that supports hypotheses stemming from *SP/A*-based portfolio theory. Kumar's work documents that the portfolios of individual investors overweight high-risk stocks, which he calls *lottery stocks*, while the portfolios of professional investors underweight lottery stocks. Polkovnichenko's work characterizes the degree to which the portfolios of individual investors are driven by fear, as reflected in their unwillingness to hold equities. His work also highlights the lack of diversification in most investors' portfolios. Odean [11] documents the degree to which individual investors are prone to the disposition effect, and Frazzini [4] shows that professional investors are also prone. Barber and Odean [2] provide evidence that individual investors purchase stocks by relying on the availability heuristic more so than professional investors. Barber and Odean [1] provide evidence that excessive trading by individual investors harms performance.

HERSH SHEFRIN

Kelly Problem

Consider a financial market with K assets whose prices $P_i(t), i = 1, \dots, K$ are stochastic, dynamic processes, and a risk-free asset whose price is $P_0(t)$. The vector of prices at time t is

$$\mathbf{P}(t) = (P_0(t), P_1(t), \dots, P_K(t))' \quad (1)$$

If the prices are given at points in time t_1 and t_2 , with $t_1 < t_2$, then the rate of return over that time on a unit of capital invested in asset i is

$$R_i(t_1, t_2) = \frac{P_i(t_2)}{P_i(t_1)} = 1 + r_i(t_1, t_2), i = 0, \dots, K \quad (2)$$

When there are dividends D_i accrued in the time interval, then the return is $R_i(t_1, t_2) = (P_i(t_2) + D_i(t_2 - t_1))/P_i(t_1)$.

Suppose an investor has w_t units of capital at time t , and that capital is fully invested in the assets, with the proportions invested in each asset given by $x_i(t), i = 0, \dots, K$, where $\sum_{i=0}^K x_i(t) = 1$. Then an investment or trading strategy at time t is the vector process

$$\mathbf{X}(t) = (x_0(t), x_1(t), \dots, x_K(t))' \quad (3)$$

Given the investments $w_{t_1} \mathbf{X}(t_1)$ at time t_1 , the accumulated capital at time t_2 is

$$W(t_2) = w_{t_1} R'(t_1, t_2) \mathbf{X}(t_1) = w_{t_1} \sum_{i=0}^K R_i(t_1, t_2) x_i(t_1) \quad (4)$$

The trajectory of returns between time t_1 and time t_2 depends on the asset, and is typically nonlinear. So changing the investment strategy at points in time between t_1 and t_2 will possibly improve capital accumulation. If trades could be timed to correspond to highs and lows in prices, then greater capital would be accumulated. To consider the effect of changes in strategy, partition the time interval into n segments, with $d = \frac{t_2 - t_1}{n}$, so that the accumulated capital is monitored, and the investment strategy is possibly revised at times $t_1, t_1 + d, \dots, t_1 + nd = t_2$. Then

wealth at time t_2 is

$$W_n(t_2) = w_{t_1} \prod_{i=0}^{n-1} R'(t_1 + id, t_1 + (i+1)d) \times X(t_1 + id) \quad (5)$$

Alternatively, wealth is

$$W_n(t_2) = w_{t_1} \left(\exp \left[\frac{1}{n} \sum_{i=0}^{n-1} \ln(R'(t_1 + id, t_1 + (i+1)d) X(t_1 + id)) \right] \right)^n \quad (6)$$

The exponential form highlights the *growth rate* with the strategy $\mathbf{X} = (X(t_1), \dots, X(t_1 + (n-1)d))$,

$$G_n(\mathbf{X}) = \frac{1}{n} \sum_{i=0}^{n-1} \ln(R'(t_1 + id, t_1 + (i+1)d) \times X(t_1 + id)) \quad (7)$$

As the partitioning of the interval gets finer, so that $d \rightarrow 0$, then monitoring and trading are continuous. If d is fixed and the random variables $V_i = \ln(R'(t_1 + id, t_1 + (i+1)d) X(t_1 + id)), i = 0, \dots, n-1$ are independent and identically distributed (i.i.d.) with mean μ_d and variance σ_d^2 , then $S_n(t_2) = (1/(\sigma_d \sqrt{n})) \sum (V_i - \mu_d)$ converges as n increases (i.e., as t_2 increases) to a standard normal variable. The simplest continuous time process with normally distributed accumulations is the Brownian motion model. In the continuous case, therefore, it is usually assumed that the instantaneous returns $dP_i(t)/P_i(t)$ are approximated by Brownian motion.

If the distribution of accumulated capital (wealth) at the horizon is the criterion for deciding on an investment strategy, then the rate of growth of capital becomes the determining factor when the horizon is distant. For fixed d and i.i.d V_i , the growth rate converges to the mean growth rate as n increases, so considering the average growth rate between t_1 and t_2 , for strategy $\mathbf{X} = (X(t_1), \dots, X(t_1 + (n-1)d))$,

$$E[G_n(\mathbf{X})] = \frac{1}{n} \sum_{i=0}^{n-1} E[\ln(R'(t_1 + id, t_1 + (i+1)d) \times X(t_1 + id))] \quad (8)$$

2 Kelly Problem

Table 1 Some good and bad properties of the optimal capital growth strategy

Feature	Property	Reference
Good	Maximizes the asymptotic rate of growth	Algeot and Cover [1] and Brieman [3]
	Maximizes median log wealth	Ethier [5]
	Minimizes expected time to asymptotically large goals	Algeot and Cover [1], Brieman [3] and Browne [4]
	Never risks ruin	Hakansson and Miller [8]
	Kelly is the unique evolutionary strategy	Hens and Schenk-Hoppe [9]
Bad	It takes a long time to outperform other strategies with high probability	Aucamp [2]; Browne [4] and Thorp [13]
	The total amount invested swamps the gains	Ethier and Tavaré [6]; Griffin [7]
	The average return converges to half the return from optimal expected wealth	Ethier and Tavaré [6]; Griffin [7]
	Kelly strategy does not optimize the expected nonlogarithmic utility of wealth. Example: Bernoulli trials with $1/2 < p < 1$, and $u(w) = w$. Then $x = 1$ maximizes $u(w)$, but $x = 2p - 1$ maximizes $E[\ln(w)]$.	Samuelson [11]; Thorp [12]

where E denotes the expected value.

The case usually discussed is the one in which the incremental returns are serially independent. So the maximization of $E[G_n(X)]$ is

$$\max \{E[\ln(R'(t_1 + id, t_1 + (i + 1)d)X(t_1 + id))]\} \quad (9)$$

separately for each i . If the distribution of the returns is the same for each i , a fixed strategy holds over time.

The strategy that solves equation (9) subject to the normalization constraint is called the *Kelly* or *optimal capital growth strategy*. This strategy is the unique *evolutionary stable* strategy, in the sense that it asymptotically overwhelms other portfolio rules that may be used within the population of investors with the accumulated wealth criterion. Strategies that survive in the long run must converge to the optimal growth strategy [9]. In the case of a stationary returns distribution, the Kelly or log optimal portfolio is $X^{*'} = (x_0^*, \tilde{X}^{*'})$, where $x_0^* = 1 - \sum_{i=1}^K x_i^*$. This Kelly strategy is a *fixed mix*. In other words, the fraction of wealth invested in assets is determined by X^* , but rebalancing is required to maintain the fractions as wealth varies.

The optimal growth/Kelly strategy has been studied extensively. A list of some of its properties is given in Table 1.

A variation on the Kelly strategy is the fractional Kelly strategy defined as $\tilde{X}_f = f\tilde{X}^*$, $f \geq 0$. The

fractional Kelly strategy has the same distribution of wealth across risky assets as the Kelly, but varies the fraction of wealth invested in those risky assets. Table 2 gives an example of the gain in security and the loss in return from a half-Kelly strategy. The results are from a simulation [15] assuming initial wealth of \$1000 and 700 decision points for investing in five possible assets, each with expected return of 1.14.

Observe that the Kelly strategy has enormous returns most of the time, but it is possible to make 700 independent bets, all with a 14% advantage at differing odds, and lose 98% of one's fortune. So the Kelly strategy, which is used by many great investors (see [14]) is risky in the short term because the absolute Arrow-Pratt risk aversion index is almost zero; it is also risky in the long term and must be used with care.

Table 2 Performance of Kelly and half-Kelly strategies

Final wealth statistic	Kelly	Half-Kelly
Minimum	18	145
Maximum	483 883	111 770
Mean	48 135	13 069
Median	17 269	8043
Probability of exceeding 500	0.916	0.990
Probability of exceeding 1000	0.870	0.945
Probability of exceeding 10 000	0.598	0.480
Probability of exceeding 50 000	0.302	0.03

Drawdown Minimization

Drawdown versus Shortfall

One measure of riskiness of an investment is “drawdown”, defined, most often in the asset management space, as the decline in net asset value from a historic high point. Mathematically, if the net asset value is denoted by $V_t, t \geq 0$, then the current “peak-to-trough” drawdown is given by $D_t = V_t - \max_{0 \leq u \leq t} V_u$. The maximum drawdown, $\max_{0 \leq u \leq t} D_u$, is a statistic that the CFTC forces managed futures advisors to disclose, and so many investment advisors and managers implicitly face drawdown constraints in setting their investment strategies. Hedge funds, for example, implicitly face drawdown constraints in that many multiperiod hedge fund contracts reflect investor preferences related to the maximum drop in a fund’s asset value from the previous peak. These often include a high-water-mark provision that sets the strike price of each period’s incentive fee equal to the all-time high of fund value (see **Hedge Funds**).

Another measure of riskiness that is related but often confused terminologically with drawdown is that of “shortfall”, which is simply the gap, or loss level of the current value from the initial or some other given value. This value could be constant but more often is determined by a stochastic exogenous or endogenous benchmark. For example, the shortfall with respect to the endogenous benchmark of the running maximum is the drawdown.

Since drawdown and shortfall are essentially equivalent in single period models, the research on the topic reviewed in this article is focused on multiperiod and, in particular, on continuous-time models pioneered in [16] and [17] where optimal portfolio rules are derived by solving a multiperiod portfolio optimization problem. The minimization of short-fall probability in a single-period model dates back to [18] and [21]. See **Value-at-Risk; Expected Shortfall** for work on portfolio selection with drawdown constraints in single period mean-variance models.

In the continuous time framework, there is an implicit nonnegativity constraint on wealth, which is one form of a shortfall constraint (see **Merton Problem**).

The models reviewed here differ in their assumptions regarding investment horizons (finite or infinite), constraints (fixed or stochastic benchmark), stochastic processes (diffusion with and without jumps), as well as objective function (purely probabilistic or expected utility based). In general, without transactions costs, the incorporation of drawdown constraints induces a portfolio insurance strategy: specifically, in the stationary stochastic model case, the strategy is that of a constant proportions portfolio insurance (CPPI) with different “floor” levels determined by the horizon and the objective (see **Transaction Costs** for portfolio optimization with transaction costs).

In this case, the risky asset price is assumed to follow a geometric Brownian motion with drift $\mu + r$, and diffusion coefficient σ^2 where r is the rate of return on cash. Hence, as is standard (see **Merton Problem**), the dynamics of the investor’s wealth portfolio are given by

$$dW_t = r W_t dt + x_t [\mu dt + \sigma dZ_t] \quad (1)$$

where Z_t is a standard Brownian motion and where x_t denotes the dollar holdings of stock.

For reference, investment strategies that are of the form

$$x_t = k \times W_t \quad (2)$$

are called a *constant proportion rebalanced portfolio rule* (see **Fixed Mix Strategy**), and are optimal in a variety of settings ([7]). Investment strategies that are of the form

$$x_t = k(W_t - F_t) \quad (3)$$

are referred to as *constant proportion portfolio insurance strategies (CPPI)* with scale multiple k and floor F_t (see **Constant Proportion Portfolio Insurance**).

Such CPPI strategies are, in fact, constant proportional strategies on the *surplus* $W_t - F_t$ and in a pure diffusion setting insure that wealth remains above the floor level F_t at all times, (although it is possible that F_t serves as an absorbing barrier). These strategies effectively synthesize an overlay of a put option on top of the wealth generated by a constant proportional

strategy, and are at the core of many of the strategies that have been discussed here.

Infinite Horizon Drawdown Minimization

In a seminal paper on the subject, Grossman and Zhou [15] show how to extend the Merton framework to encompass a more general drawdown constraint of $W_t \geq \alpha M_t$, where W_t is the wealth level at time t , M_t is the running maximum wealth up to that point, that is, $M_t = \max_{0 \leq u \leq t} W_u$, and α is an exogenous number between 0 and 1.

The motivation for this constraint is that, in practice, a fund manager may implicitly be subject to redemptions that depend on whether the manager's portfolio stays above a (possibly discounted) previous high, M_t .

For an investor with constant relative risk aversion utility, Grossman and Zhou [15] show that the optimal policy implies an investment in the risky asset at time t in proportion to the "surplus" $W_t - \alpha M_t$, that is, a CPPI ([3]) strategy with floor given by a multiple of the running maximum wealth, $F_t = \alpha M_t$. The analysis of Grossman and Zhou [15] is extended in [12] by allowing for intermediate consumption.

Infinite Horizon Shortfall Minimization

There are a variety of approaches and objectives related to shortfall minimization. For example, in a stochastic model where rational investment strategies may enable wealth to hit a given shortfall (e.g., liability driven models), one might choose a strategy that minimizes the *probability* of ever hitting this shortfall level directly ([5, 6, 8, 9, 11, 13, 19, 20]), or one might incorporate a (expected) *shortfall* constraint into other objectives such as a standard utility maximization framework ([1, 2, 4, 20] and [22]).

Directly minimizing the probability of hitting a shortfall level is a relevant objective only in economic settings where there is a possibility that a shortfall level is reached under a rational investment strategy. One such setting is the case of external risk, such as an insurance company, or liabilities as treated in [5], where the investor's total wealth evolves now according to a combination of an uncontrolled

Brownian motion (the "risk" part), and a controlled geometric Brownian motion (the investment possibility). Drawdown and shortfall prevention strategies for deterministic liabilities are treated in [6] where it is shown that if the initial wealth or reserve is below the funding level of the perpetual liability, the optimal strategy is linear in the negative surplus, that is, has an *inverse* CPPI structure, namely $k(F - W)$. For initial wealth above the funding level, various CPPI strategies using the funding level as the floor are optimal for a variety of utility and probabilistic objectives.

Other settings of interest include cases where there is an exogenous and uncontrollable benchmark relative to which the shortfall is measured. Infinite horizon probabilistic objectives are treated in [8] in an incomplete market setting, and connects these results with those obtained from standard utility maximization problems. A risk-constrained problem that yields a CPPI related strategy is treated in [11]. Stutzer [19] treats long-horizon shortfalls and deviations from benchmarks in the context of a large-deviation approach.

Finite Horizon Shortfall Minimization

The structure of the optimal strategy changes significantly when the horizon is finite in that the optimal strategies become *replicating strategies* for various structures of finite term options. Specifically, the strategy that minimizes the *shortfall probability* starting from a wealth process below the target level is given by the replicating strategy for a digital or binary put option on the shortfall level. This is discussed in [9, 10] and in an equivalent hedging framework in [13]. The optimal dynamic policy in the case of multiple risky assets has a time-dependent component (determined by the risk premium and remaining time) and a state-dependent component, which is a function of the current percentage of the distance to the target. The minimization is treated in [13] in the context of determining a partial hedging strategy on a contingent claim that minimizes the hedging cost for a given shortfall probability. This strategy may be considered a dynamic version of the static Value-at-Risk (VaR) concept and the authors label it *quantile hedging*. The potential riskiness of such a strategy is illustrated in [9, 10] via the fact that since it replicates a digital or

binary option, the strategy effectively acts as the delta of the digital option with all the instability of that delta as the term decays if the strike remains unachieved. Strategies that mitigate this fact and therefore minimize the *expected shortfall* are constructed in [14]. These strategies effectively replicate options with standard put payoffs as opposed to digitals or binaries.

Utility Maximization Approaches to the Expected Shortfall

Utility maximization approaches to the expected shortfall problem also lead to optimal strategies that have optionlike features. Basak and Shapiro [1] consider an agent's utility maximization problem in a model with a VaR constraint, which states that the probability of his wealth falling below some "floor" $\underline{W}$ is not allowed to exceed some prespecified level α :

$$\Pr(W(T) \geq \underline{W}) \geq 1 - \alpha \quad (4)$$

and is clearly related to the objectives treated earlier by Browne, Föllmer, and Leukert [9, 13, 14] (*see Value-at-Risk*).

In this framework, the case $\alpha = 1$ corresponds to the standard benchmark agent that does not limit losses and $\alpha = 0$ corresponds to the portfolio insurer (or put option purchaser) who maintains his wealth above the floor in all states [3].

Basak and Shapiro [1] show that the VaR constrained agent's wealth can be expressed as either (i) the portfolio insurer solution plus a short position in binary options or (ii) the benchmark agent's solution plus an appropriate position in "corridor" options (*see Corridor Options*). Similar to the analysis and earlier findings mentioned above they observe that since the VaR constrained agent is only concerned with the probability (and not the magnitude) of a loss, he or she chooses to leave the worst states uninsured because they are the most expensive ones to insure against. Thus, as in [14], Basak and Shapiro [1] examine a so-called LEL-RM (limited-expected-losses-based risk management) strategy, which remedies some of the shortcomings of the VaR constrained solution. Other related papers considering variants of these results are found in [2, 22]

Universal Portfolios

The mainstream mathematical approach to investment portfolio selection involves modeling asset prices as a stochastic process, and deriving asset allocation strategies that are optimal with respect to some statistical criteria, such as the mean and variance of returns, or an expected utility. The application of this approach to real-world markets is complicated by the lack of a fully specified stochastic process. It is, in fact, debatable whether an underlying stochastic process exists at all.

The theory of universal portfolios offers an alternative approach that forgoes stochastic models and associated optimality criteria and instead finds universal portfolio selection strategies that perform well relative to *all* strategies in a target class of allocation strategies, for *all* possible sequences of asset price changes. The term *universal portfolio* was coined in [3], which first put forth this alternative paradigm for the specific target class of constant rebalanced portfolios. This particular target class, which has also been the focus of much of the subsequent related work, seems to strike a favorable balance between the richness of the class and the degree to which the class performance can be tracked. The theory, in its greatest generality, however, can involve any target class, and would be concerned with finding the degree to which it can be tracked universally. The article focuses on universal portfolios for constant rebalanced portfolios, with only a brief mention of what is known beyond this.

Constant rebalanced portfolios [14] are a well-known (though under several aliases) class of allocation strategies that, at designated times, buy and sell assets to restore the fractions of wealth invested in each asset to an initial, fixed allocation. For a given sequence of rebalancing times, constant rebalanced portfolios can thus be parameterized by a vector with real valued, nonnegative components summing to one, specifying the fractions of wealth to which asset allocations are rebalanced. For example, given a pair of assets, the constant rebalanced portfolio corresponding to the vector $(1/3, 2/3)$ initially invests $1/3$ and $2/3$ of starting capital, respectively, in each of the assets. Thereafter, as the asset prices change, it buys and sells the assets at each rebalancing time to restore the fractions of cumulative wealth invested in each asset back to the initial $(1/3, 2/3)$.

One well-known motivating property of constant rebalanced portfolios is that they maximize the expectation of a variety of utility functions when asset price returns between rebalancing times are statistically independent and identically distributed from one interval to the next. In general, the optimal allocation depends on both the underlying probability distribution and the utility function, making the optimal choice, from this point of view, a challenging one for any given real-world setting. The theory of universal portfolios for constant rebalanced portfolios, which seeks to perform well relative to all portfolios, offers a principled way around this difficulty. It is worth reemphasizing, however, that beyond this motivational aspect, the theory makes *no* stochastic assumptions on asset prices.

Given a fixed number of assets and a sequence of asset price changes between n -designated rebalancing times, let S_n^* denote the largest return attained by any constant rebalanced portfolio on that sequence of asset price changes. This will be the benchmark for universal portfolio performance. Note that S_n^* and the (best) constant rebalanced portfolio that achieves it depend on the entire sequence of asset price changes, whereas the allocations of any realizable portfolio selection strategy must be causal, or nonanticipating, depending only on the previously observed price data. As such, the return S_n^* is not directly realizable. Furthermore, depending on the actual asset returns, S_n^* may exceed the return of any fixed constant rebalanced portfolio by an exponentially increasing factor. This means that naively using a seemingly safe choice like the uniform allocation might be exponentially suboptimal.

Nonetheless, nonanticipating universal portfolios have been found with returns $\hat{S}_n$ that approach S_n^* , in the sense that the exponential rates of return per rebalancing interval, $\hat{W}_n = (1/n) \log \hat{S}_n$ and $W_n^* = (1/n) \log S_n^*$, are guaranteed to satisfy $\hat{W}_n - W_n^* \geq -((m-1)/(2n)) \log n - O(1/n)$, uniformly for *all* sequences of asset prices. Since this relative exponential rate of return tends to 0 in n , it follows that if S_n^* is increasing at some exponential rate of growth (as would be hoped for and expected in practice), $\hat{S}_n$ will increase at the same exponential rate, asymptotically. The remainder of the article explains the universal portfolios achieving this benchmark performance.

Formal Definitions and Notation

Investments in m assets are to be adjusted at designated rebalancing times, with the gap between two consecutive such times constituting an investment period. The multiplicative factors by which the respective asset prices change over an investment period (gross returns) are denoted by a price relative vector $\mathbf{x} = (x_1, \dots, x_m)'$, with $x_j \geq 0$ specifying the return factor of asset j , and $\mathbf{v}'$ denoting the transpose of vector $\mathbf{v}$. The entire cumulative wealth is assumed to be reinvested at each rebalancing time and a non-negative portfolio vector $\mathbf{b} = (b_1, \dots, b_m)'$, satisfying $\sum_j b_j = 1$, denotes the fractions of cumulative wealth to invest in each asset (fraction b_j in asset j). If a rebalancing according to the portfolio vector $\mathbf{b}$ is followed by asset returns corresponding to the price relative vector $\mathbf{x}$, the cumulative wealth is multiplied by a factor of $\mathbf{b}'\mathbf{x} = \sum_{j=1}^m b_j x_j$, over that investment period. Consequently, a sequence of n rebalancings according to the portfolios $\mathbf{b}^n = \mathbf{b}_1, \mathbf{b}_2, \dots, \mathbf{b}_n$ and a corresponding sequence of ensuing price relatives $\mathbf{x}^n = \mathbf{x}_1, \dots, \mathbf{x}_n$ result in an overall return factor (cumulative gross return) of

$$S_n(\mathbf{x}^n, \mathbf{b}^n) = \prod_{i=1}^n \mathbf{b}_i' \mathbf{x}_i \quad (1)$$

A constant rebalanced portfolio reinvests according to a fixed $\mathbf{b}$ at each rebalancing time, resulting in a return factor of $S_n(\mathbf{x}^n, \mathbf{b}) = \prod_{i=1}^n \mathbf{b}' \mathbf{x}_i$. The best constant rebalanced portfolio $\mathbf{b}^*(\mathbf{x}^n)$ for a price relative sequence achieves $S_n^*(\mathbf{x}^n) = \max_{\mathbf{b} \in \mathcal{B}} S_n(\mathbf{x}^n, \mathbf{b})$, where $\mathcal{B}$ denotes the set of all valid portfolio vectors. A nonanticipating portfolio selection strategy is a sequence of functions $\hat{\mathbf{b}}_i(\cdot)$ that map previously occurring price relative vectors into portfolio vectors. The corresponding portfolio used at rebalancing time i can thus be expressed as $\hat{\mathbf{b}}_i(\mathbf{x}_1, \dots, \mathbf{x}_{i-1})$. As mentioned, universal portfolio theory for the target class of constant rebalanced portfolios seeks nonanticipating portfolio selection strategies that perform well relative to $S_n^*(\mathbf{x}^n)$ for all $\mathbf{x}^n$.

μ -Weighted Universal Portfolios

For a target class consisting of only two portfolio allocation strategies, a natural corresponding universal portfolio would split the starting capital into two pools and invest each pool according to the respective target portfolios, thereby achieving the average of

the target returns. The class of constant rebalanced portfolios is considerably more complex, since it is a continuum of portfolio selection strategies, but an extension of this idea still works well. Given a measure or distribution μ on the space of valid portfolio vectors $\mathcal{B}$ satisfying $\mu(\mathcal{B}) = 1$, the μ -weighted universal portfolio can be thought of as investing an infinitesimal fraction $d\mu(\mathbf{b})$ of initial capital according to each constant rebalanced portfolio $\mathbf{b}$, where $d\mu(\mathbf{b})$, informally, is the differential measure at $\mathbf{b}$. The return factor $\hat{S}_{n,\mu}(\mathbf{x}^n)$ of such a strategy for a sequence of price relatives $\mathbf{x}^n$, is the average, with respect to μ , of the returns of the underlying constant rebalanced portfolios, or more precisely,

$$\hat{S}_{n,\mu}(\mathbf{x}^n) = \int_{\mathcal{B}} S_n(\mathbf{x}^n, \mathbf{b}) d\mu(\mathbf{b}) \quad (2)$$

A more rigorous formulation of the μ -weighted universal portfolio is that at time i it uses the portfolio function,

$$\hat{\mathbf{b}}_i(\mathbf{x}^{i-1}) = \frac{\int_{\mathcal{B}} S_{i-1}(\mathbf{x}^{i-1}, \mathbf{b}) \mathbf{b} d\mu(\mathbf{b})}{\int_{\mathcal{B}} S_{i-1}(\mathbf{x}^{i-1}, \mathbf{b}) d\mu(\mathbf{b})} \quad (3)$$

which can be interpreted as a past performance weighted average of constant rebalanced portfolios. Setting $S_0(\mathbf{x}^0, \mathbf{b}) = 1$ and incorporating these portfolio vectors into equation (1), results in a telescoping product, with the overall return factor simplifying to equation (2).

The μ -weighted universal portfolio was first proposed in [3] for the special case of μ equal to the uniform distribution, or Lebesgue measure, on the set of valid portfolio vectors $\mathcal{B}$. Later, Cover and Ordentlich [5] refined the performance bounds for the uniform case and found that a different μ corresponding to the Dirichlet($1/2, \dots, 1/2$) distribution with density proportional to $1/\sqrt{b_1 b_2 \dots b_m}$ exhibits a better worst case performance against the benchmark $S_n^*(\mathbf{x}^n)$. Letting $\hat{S}_{n,U}(\mathbf{x}^n)$ and $\hat{S}_{n,D}(\mathbf{x}^n)$, respectively, denote the return factors of the uniform and Dirichlet-weighted universal portfolios, the following performance bounds were derived in [5]:

$$\begin{aligned} \min_{\mathbf{x}^n} \frac{\hat{S}_{n,U}(\mathbf{x}^n)}{S_n^*(\mathbf{x}^n)} &= \left[\binom{n+m-1}{m-1} \right]^{-1}, \\ \min_{\mathbf{x}^n} \frac{\hat{S}_{n,D}(\mathbf{x}^n)}{S_n^*(\mathbf{x}^n)} &= \frac{\Gamma(m/2)\Gamma(n+1/2)}{\Gamma(1/2)\Gamma(n+m/2)} \end{aligned} \quad (4)$$

where the minimizations are over all sequences of price relative vectors. Stirling's approximation of the Gamma function applied to the performance bound for the Dirichlet-weighted universal portfolio shows that it decreases in n as $c_m/n^{(m-1)/2}$, with c_m depending only on the number of assets m (and not n). After taking logarithms and normalizing by n , this gives the worst-case exponential rate of return of $\hat{S}_{n,D}$ relative to S_n^* mentioned in the introduction section of the article. Exact algorithms for computing (3) for the uniform and Dirichlet-weighted universal portfolios are given in [5]. Lower complexity approximate algorithms based on quantization [3] and randomization [2, 11] have also been proposed.

Max-min Universal Portfolios

It was shown in [16] that the maximum over all nonanticipating portfolio strategies of the minimum return relative to the benchmark best constant rebalanced portfolio is given by

$$\begin{aligned} & \max_{\{\hat{\mathbf{b}}_i(\cdot)\}} \min_{\mathbf{x}^n} \frac{\hat{S}_n(\mathbf{x}^n, \{\hat{\mathbf{b}}_i(\cdot)\})}{S_n^*(\mathbf{x}^n)} \\ &= \left[\sum_{n_1+\dots+n_m=n} \left(\frac{n!}{n^m} \prod_{j=1}^m \frac{n_j}{n_j!} \right) \right]^{-1} \end{aligned} \quad (5)$$

where the maximization is over all nonanticipating portfolio strategies, with $\hat{S}_n(\mathbf{x}^n, \{\hat{\mathbf{b}}_i(\cdot)\})$ denoting the return factor of such a strategy, and the summation on the right is over m -tuples of nonnegative integers summing to n . The max-min universal portfolio for horizon n achieves the game theoretic optimum of equation (5). Letting $\hat{S}_{n,\max-\min}(\mathbf{x}^n)$ denote its return factor, the ratio $\hat{S}_{n,\max-\min}(\mathbf{x}^n)/S_n^*(\mathbf{x}^n)$ at time n is, therefore, guaranteed to not fall below the right-hand side of equation (5). As for the Dirichlet-weighted universal portfolio, this relative return factor behaves like $\tilde{c}_m/n^{(m-1)/2}$, where $\tilde{c}_m$ improves on (is larger than) the corresponding constant for the Dirichlet case.

The max-min universal portfolio for horizon n can also be expressed as splitting the pool of starting capital among a collection of constituent strategies. In this case, there are m^n such strategies, identified with the sequences of length n of elements from the set $\{1, \dots, m\}$. The strategy corresponding

to the sequence $j^n = j_1, \dots, j_n$ invests the entire cumulative wealth at time i in asset j_i . The fraction of starting capital allocated to the constituent strategy corresponding to j^n is $V \prod_{j=1}^m (n_j/n)^{n_j}$ where V ensures that the fractions add up to one. It turns out that V equals the right-hand side of equation (5). The portfolio function $\hat{\mathbf{b}}_i(\mathbf{x}^{i-1})$ to use at each time i can be computed efficiently (polynomially in n) using an algorithm similar to that proposed in [5] (see also [16]) for the uniform and Dirichlet-weighted universal portfolios. Note that unlike these universal portfolios, the max-min universal portfolio entails a different sequence of portfolio functions for each horizon n .

The worst case sequences of price relatives that pin the ratio $\hat{S}_{n,\max-\min}(\mathbf{x}^n)/S_n^*(\mathbf{x}^n)$ to the right-hand side of equation (5) are those in which each price relative vector $\mathbf{x}_i$ has exactly one nonzero component.^a These are characteristic of horse race or gambling markets [5]. A conditionally max-min universal portfolio is proposed in [15] that “locks in” potential improvements in the relative performance ratio if $\mathbf{x}^n$ is more benign. The max-min universal portfolio and its performance bound is extended to a constrained set of price relative vectors in [4].

Extensions

Other universal portfolios for the target class of constant rebalanced portfolios that trade-off the above performance bounds for lower computational complexity are proposed in [1, 8, 13]. The uniform-weighted universal portfolio and the performance bound of [3] are extended to continuous time in [10]. In [16], a different continuous time universal portfolio is proposed that corresponds to the dynamic hedging strategy of a derivative security, termed the *hindsight-allocation option*, that pays the return of the best constant rebalanced portfolio computed in hindsight. Universal portfolios under transactions costs are pursued in [2, 9]. The former extends the performance bounds of the uniform-weighted universal portfolio to incorporate linear transactions costs and the latter considers an alternative target class (for $m = 2$ assets) of no-trade-region strategies that are known to be optimal under linear transactions costs in certain probabilistic settings.

Universal portfolios for alternative target classes are also proposed in [5] for side-information-dependent constant rebalanced portfolios, in [12, 17]

for piecewise constant rebalanced portfolios, and in [7] for a class of portfolio strategies that can depend on past asset prices. Finally, universal portfolios incorporating short sales and margin are considered in [6].

End Notes

^aThe max–min relative performance (5) continues to hold if the minimization over nonnegative sequences of price relatives is replaced by an infimum over strictly positive sequences. This also applies to (4).

ERIK ORDENTLICH

Risk-sensitive Asset Management

In risk-sensitive asset management, maximization of the criterion

$$J(v_0; T) = \frac{1}{\gamma} \log E[e^{\gamma \log V_T}] = \frac{1}{\gamma} \log E[V_T^\gamma] \quad (1)$$

for $\gamma < 1, \neq 0$ is considered, where V_T is the total wealth an investor possesses, defined by $V_T = \sum_i N_T^i S_T^i$ with N_T^i the number of shares invested into i th security S_T^i at time T and v_0 the initial wealth. It is equivalent to expected power utility maximization with the criterion $\frac{1}{\gamma} E[V_T^\gamma]$. Looking at asymptotics as $\gamma \rightarrow 0$,

$$\begin{aligned} \frac{1}{\gamma} \log E[e^{\gamma \log V_T}] &\sim E[\log V_T] \\ &+ \gamma \text{Var}[\log V_T] + O(\gamma^2) \end{aligned} \quad (2)$$

we see that maximizing the criterion amounts asymptotically to maximizing expected log utility while minimizing its variance if $\gamma < 0$. In that sense, $\gamma < 0$ means risk averse. On the other hand, $\gamma > 0$ means risk seeking since it comes to maximizing log utility as well as its variance.

The infinite time horizon problem of maximizing

$$\overline{\lim}_{T \rightarrow \infty} \frac{1}{T} J(v_0, x; T) = \overline{\lim}_{T \rightarrow \infty} \frac{1}{\gamma T} \log E[e^{\gamma \log V_T}] \quad (3)$$

is often considered in an incomplete market model, where security prices are defined by

$$dS^0(t) = r(X_t) S^0(t) dt \quad (4)$$

$$dS^i(t) = S^i(t) \left\{ \alpha^i(X_t) dt + \sum_{k=1}^{n+m} \sigma_k^i(X_t) dW_t^k \right\} \quad (5)$$

$i = 1, \dots, m$, with an $(n+m)$ -dimensional Brownian motion process $W_t = (W_t^1, W_t^2, \dots, W_t^{n+m})$ defined on a filtered probability space $(\Omega, \mathcal{F}, P; \mathcal{F}_t)$. Its volatilities σ , instantaneous mean returns α , and interest rate r , are affected by economic factors

$(X_t^1, \dots, X_t^n)$ defined as the solution of the stochastic differential equation

$$dX_t = \beta(X_t) dt + \lambda(X_t) dW_t, \quad X(0) = x \in R^n \quad (6)$$

Introducing portfolio proportion h_t^i invested into i th security defined by $h^i(t) = \frac{N^i(t) S^i(t)}{V(t)}$ for each $i = 0, \dots, m$ and setting $h(t) = (h^1(t), h^2(t), \dots, h^m(t))$, the total wealth V_t turns out to satisfy

$$\begin{aligned} \frac{dV(t)}{V(t)} &= \{r(X_t) + h(t)^* \hat{\alpha}(X_t)\} dt \\ &+ h(t)^* \sigma(X_t) W_t \end{aligned} \quad (7)$$

under the self-financing condition, where $\hat{\alpha}(x) = \alpha(x) - r(x)\mathbf{1}$. In these maximization problems, the portfolio proportion h_t is considered an investment strategy and assumed to be $\mathcal{G}_t^{S, X} := \sigma(S(u), X(u), u \leq t)$ progressively measurable in the case of full information. The problem is often considered under partial information where h_t is assumed to be $\mathcal{G}_t^S := \sigma(S(u), u \leq t)$ measurable. Here we discuss the case of full information and the set of admissible strategies $\mathcal{A}(T)$ (or $\mathcal{A}$) is determined as the totality of $\mathcal{G}_t^{S, X}$ progressively measurable investment strategies satisfying some suitably defined integrability conditions.

If $\gamma < 0$, introducing the value function

$$\hat{v}(t, x) = \inf_{h \in \mathcal{A}(T-t)} \log E[e^{\gamma \log V_{T-t}(h)}] \quad (8)$$

we see that

$$\sup_h J(v_0, x; T) = \frac{1}{\gamma} \hat{v}(0, x) \quad (9)$$

Under the change of measure,

$$P^h(A) = E \left[e^{\gamma \int_0^T h_s^* \sigma(X_s) dW_s - \frac{\gamma^2}{2} \int_0^T h_s^* \sigma \sigma^*(X_s) h_s ds} : A \right] \quad (10)$$

the value function is expressed as

$$\hat{v}(t, x) = \gamma \log v_0 + \inf_{h \in \mathcal{A}(T)} \log E^h \left[e^{\gamma \int_0^{T-t} \eta(X_s, h_s) ds} \right] \quad (11)$$

with the initial wealth v_0 , where

$$\eta(x, h) = h^* \hat{\alpha}(x) - \frac{1-\gamma}{2} h^* \sigma \sigma^*(x) h + r(x) \quad (12)$$

By using the Brownian motion $W_t^h := W_t - \gamma \int_0^t \sigma^*(X_s) h_s ds$ under the new probability measure P^h the dynamics of economic factor X_t is written as

$$dX_t = \{\beta(X_t) + \gamma \lambda \sigma^*(X_t) h_t\} dt + \lambda(X_t) dW_t^h \quad (13)$$

Thus the Hamilton–Jacobi–Bellman (H–J–B) equation for the value function is deduced as

$$\begin{cases} \frac{\partial v}{\partial t} + \frac{1}{2} \text{tr}[\lambda \lambda^* D^2 v] + \frac{1}{2} (Dv)^* \lambda \lambda^* Dv \\ \quad + \inf_h \{[\beta + \gamma \lambda \sigma^* h]^* Dv + \gamma \eta(x, h)\} = 0 \\ v(T, x) = \gamma \log v_0 \end{cases} \quad (14)$$

which can be rewritten as

$$\begin{cases} \frac{\partial v}{\partial t} + \frac{1}{2} \text{tr}[\lambda \lambda^* D^2 v] + \beta_\gamma^* Dv \\ \quad + \frac{1}{2} (Dv)^* \lambda N_\gamma^{-1} \lambda^* Dv - U_\gamma = 0 \\ v(t, x) = \gamma \log v_0 = 0 \end{cases} \quad (15)$$

where

$$\beta_\gamma = \beta + \frac{\gamma}{1-\gamma} \lambda \sigma^* (\sigma \sigma^*)^{-1} \hat{\alpha} \quad (16)$$

$$N_\gamma^{-1} = I + \frac{\gamma}{1-\gamma} \sigma^* (\sigma \sigma^*)^{-1} \sigma \quad (17)$$

$$U_\gamma = -\frac{\gamma}{2(1-\gamma)} \hat{\alpha}^* (\sigma \sigma^*)^{-1} \hat{\alpha} + r(x) \quad (18)$$

Under suitable conditions the H–J–B equation (15) has a solution with sufficient regularity [1, 13]. Moreover, if the condition

$$\hat{\alpha}^* (\sigma \sigma^*)^{-1} \hat{\alpha} \rightarrow \infty, |x| \rightarrow \infty \quad (19)$$

is assumed, then the solution such that $v(t, x) \rightarrow -\infty, \forall t < T, \text{ as } |x| \rightarrow \infty$ is unique and the identification

$$v(0, x; T) \equiv v(0, x) = \hat{v}(0, x) \equiv \inf_{h \in \mathcal{A}(T)} J^0(v, x; h; T) \quad (20)$$

can be verified.

The value for the problem on infinite time horizon is defined as

$$\hat{\chi}(\gamma) = \inf_{h \in \mathcal{A}} \chi(h; \gamma) \quad (21)$$

$$\chi(h; \gamma) = \lim_{T \rightarrow \infty} \frac{1}{T} \log E[V_T(h)^\gamma] \quad (22)$$

by suitably setting the set $\mathcal{A}$ of admissible strategies. The corresponding H–J–B equation of ergodic type for the problem is considered

$$\begin{aligned} \chi(\gamma) &= \frac{1}{2} \text{tr}[\lambda \lambda^* D^2 w] + \frac{1}{2} (Dw)^* \lambda \lambda^* Dw \\ &\quad + \inf_h \{[\beta + \gamma \lambda \sigma^* h]^* Dw + \gamma \eta(x, h)\}, \\ &= \frac{1}{2} \text{tr}[\lambda \lambda^* D^2 w] + \beta_\gamma^* Dw \\ &\quad + \frac{1}{2} (Dw)^* \lambda N_\gamma^{-1} \lambda^* Dw - U_\gamma \end{aligned} \quad (23)$$

However, even if we set as $\mathcal{A} = \{h_{\cdot|[0, T]} \in \mathcal{A}(T), \forall T\}$ identification of $\hat{\chi}(\gamma)$ with the solution $\chi(\gamma)$ to the H–J–B equation (23) cannot be shown in general. Indeed, even in the case of a linear Gaussian model (see below), such identification cannot be seen always to hold [5, 11, 13]. Instead, we introduce the asymptotic value

$$\tilde{\chi}(\gamma) = \lim_{T \rightarrow \infty} \frac{1}{T} v(0, x; T) \quad (24)$$

Then, a general discussion is possible for linear Gaussian models. Since the verification $v(0, x) = \hat{v}(0, x)$ holds in general for the problem on a finite time horizon, in the case of linear Gaussian models,

$$\lim_{T \rightarrow \infty} \frac{1}{T} \inf_{h \in \mathcal{A}} J^0(v, x; h; T) = \tilde{\chi}(\gamma) \quad (25)$$

is verified. Assume that $r(x) = r$, $\alpha(x) = Ax + a$, $\sigma(x) = \Sigma$, $\beta(x) = Bx + b$, $\lambda(x) = \Lambda$, where A, B, Σ, Λ are constant matrices, a, b are constant vectors and r is a constant. Then, the solution to equation (15) has an explicit expression as $v(t, x) = \frac{1}{2} x^* P(t) x + q(t)^* x + k(t)$, where $P(t)$ is a nonpositive definite solution to the Riccati equation

$$\begin{aligned} \dot{P}(t) + P(t) \Lambda N^{-1} \Lambda^* P(t) + K_1^* P(t) \\ + P(t) K_1 - C^* C = 0, \quad P(T) = 0 \end{aligned} \quad (26)$$

and $q(t)$, $K(t)$ are respectively solutions to

$$\begin{aligned} \dot{q}(t) + (K_1 + \Lambda N^{-1} \Lambda P(t))^* q(t) + P(t)b \\ + \frac{\gamma}{1-\gamma} (A^* + P(t) \Lambda \Sigma^*) \\ \times (\Sigma \Sigma^*)^{-1} \hat{a} = 0, \quad q(T) = 0 \end{aligned} \quad (27)$$

and

$$\begin{aligned} \dot{k}(t) + \frac{1}{2} \text{tr}[\Lambda \Lambda^* P(t)] + \frac{1}{2} q(t)^* \Lambda \Lambda^* q(t) \\ + \frac{\gamma}{2(1-\gamma)} (\hat{a} + \Sigma \Lambda^* q(t))^* (\Sigma \Sigma^*)^{-1} \\ \times (\hat{a} + \Sigma \Lambda^* q(t)) = 0 \end{aligned} \quad (28)$$

$$k(T) = \gamma \log v_0 \quad (29)$$

where

$$K_1 := B + \frac{\gamma}{1-\gamma} \Lambda \Sigma^* (\Sigma \Sigma^*)^{-1} A \quad (30)$$

$$C := \sqrt{-\frac{\gamma}{1-\gamma}} \Sigma^* (\Sigma \Sigma^*)^{-1} A \quad (31)$$

$$N^{-1} := I + \frac{\gamma}{1-\gamma} \Sigma^* (\Sigma \Sigma^*)^{-1} \Sigma \quad (32)$$

If $G := B - \Lambda \Sigma (\Sigma \Sigma^*)^{-1} A$ is stable, then $P(t) = P(t; T)$, $q(t) = q(t; T)$ converge as $T \rightarrow \infty$ respectively to $\bar{P}$, $\bar{q}$, which are respectively solutions to

$$K_1^* \bar{P} + \bar{P} K_1 + \bar{P} \Lambda N^{-1} \Lambda^* \bar{P} - C^* C = 0 \quad (33)$$

$$\begin{aligned} (K_1 + \Lambda N^{-1} \Lambda^* \bar{P})^* \bar{q} + \bar{P} b \\ + \frac{\gamma}{1-\gamma} (A^* + \bar{P} \Lambda \Sigma^*) (\Sigma \Sigma^*)^{-1} \hat{a} = 0 \end{aligned} \quad (34)$$

and $-\dot{k}(t) = -\dot{k}(t; T)$ converges to $\chi(\gamma)$ determined by

$$\begin{aligned} \chi(\gamma) = \frac{1}{2} \text{tr}[\Lambda \Lambda^* \bar{P}] + \frac{1}{2} \bar{q}^* \Lambda \Lambda^* \bar{q} \\ + \frac{\gamma}{2(1-\gamma)} (\hat{a} + \Sigma \Lambda^* \bar{q})^* (\Sigma \Sigma^*)^{-1} \\ \times (\hat{a} + \Sigma \Lambda^* \bar{q}) \end{aligned} \quad (35)$$

The nonpositive definite solutions to equations (33) and (34) are unique and $(K_1 + \Lambda N^{-1} \Lambda^* \bar{P})$ is stable under the present assumptions. Thus $\frac{1}{T} v(0; x; T)$

converges to $\tilde{\chi}(\gamma) = \chi(\gamma)$ and $(\chi(\gamma), w)$ defined by $w(x) = \frac{1}{2} x^* \bar{P} x + \bar{q}^* x$ turns out to be a solution to equation (23). If, furthermore,

$$\bar{P} \Lambda \Sigma^* (\Sigma \Sigma^*)^{-1} \Sigma \Lambda^* \bar{P} < A^* (\Sigma \Sigma^*)^{-1} A \quad (36)$$

holds, then one can show that $\chi(\gamma) = \hat{\chi}(\gamma)$ [11, 13]. The infimum in equation (23) is attained by $\hat{h}(x) = \frac{1}{1-\gamma} (\sigma \sigma^*)^{-1} (\hat{a} + \sigma \lambda^* D w)(x)$ and in the linear Gaussian model $\hat{h}(x) = \frac{1}{1-\gamma} (\Sigma \Sigma^*)^{-1} [\hat{a} + \Sigma \Lambda^* \bar{q} + (A + \Sigma \Lambda^* \bar{P})x]$. Thus, under condition (37) optimal strategy for $\hat{\chi}(\gamma)$ is defined as $\hat{h}_t = \hat{h}(X_t)$, $t < \infty$ [11]. Decomposing as $\hat{h}_t = \frac{1}{1-\gamma} \hat{h}_t^1 + \frac{1}{1-\gamma} \hat{h}_t^2 := \frac{1}{1-\gamma} (\Sigma \Sigma^*)^{-1} [\hat{a} + A X_t] + \frac{1}{1-\gamma} (\Sigma \Sigma^*)^{-1} [\Sigma \Lambda^* \bar{q} + \Sigma \Lambda^* \bar{P} X_t]$, Davis–Lleo [4] regard this decomposition as a generalization of Merton’s mutual funds theorem (see **Merton Problem**). Here $\hat{h}_t^1$ is a log utility portfolio (Kelly portfolio, see below and in **Kelly Problem**).

When $0 < \gamma < 1$ maximizing the criterion

$$\check{\chi}(h; \gamma) = \overline{\lim}_{T \rightarrow \infty} \frac{1}{T} \log E[V_T(h)]^\gamma \quad (37)$$

is considered. As a generic structure it can be seen that there exists γ^f such that $\check{\chi}(\gamma) = \sup_h \check{\chi}(h; \gamma)$ diverges for $\gamma^f < \gamma < 1$. However, it is only in one-dimensional linear Gaussian models that one can find the infimum of such γ^f explicitly [6].

The problems under bench-marked setting can be considered similarly (cf [2, 4]).

Noting that

$$\begin{aligned} \frac{1}{T} \log V_T(h) &= \frac{-1}{2T} \int_0^T \{h_t - \rho^{-1} \hat{a}(X_t)\}^* \\ &\quad \times \rho \{h_t - \rho^{-1} \hat{a}(X_t)\} dt \\ &\quad + \frac{1}{2T} \int_0^T \{r(X_t) + \hat{a}^* \rho^{-1} \hat{a}(X_t)\} dt \\ &\quad + \frac{1}{T} \int_0^T h_t^* \sigma(X_t) dW_t \end{aligned} \quad (38)$$

where $\rho = \sigma \sigma^*$, $h_t^K := (\sigma \sigma^*)^{-1} \hat{a}(X_t)$ turns out to maximize pathwise the growth rate of $V_T(h)$ on the long run and it is called *Kelly portfolio* (log-utility portfolio) [10] or *numéraire portfolio*. This is a control problem at the level of the law of large numbers.

The problem of maximizing the criterion

$$\overline{J}(\kappa, h) = \overline{\lim}_{T \rightarrow \infty} \frac{1}{T} \log P(\log V_T(h) \geq \kappa T) \quad (39)$$

is a kind of large deviation control problem and it is considered as the dual to risk-sensitive asset management in the risk-seeking case $0 < \gamma < 1$ [7, 9, 17, 18, 20]. On the other hand, the problem of minimizing the criterion

$$\underline{J}(\kappa, h) = \underline{\lim}_{T \rightarrow \infty} \frac{1}{T} \log P(\log V_T(h) \leq \kappa T) \quad (40)$$

is also a kind of large deviation control problem and it is considered as the dual to risk-sensitive asset management in the risk-averse case $\gamma < 0$ [3, 8, 15, 20]. Studies of these problems are still in progress.

Choosing as admissible strategies the set of all $\mathcal{G}_t^S := \sigma(S(u), u \leq t)$ progressively measurable processes satisfying some integrability conditions, the problems under partial information are considered as well [7, 12, 14–16, 19].

Robust Portfolio Optimization

Portfolio selection is the problem of allocating capital over a number of available assets in order to maximize the “return” on the investment while minimizing the “risk”. Although the benefits of diversification in reducing risk have been appreciated since the inception of financial markets, Markowitz [25, 26] formulated the first mathematical model for portfolio selection. In the Markowitz portfolio selection model, the “return” on a portfolio is measured by the expected value of the random portfolio return, and the associated “risk” is quantified by the variance of the portfolio return. Markowitz showed that, given either an upper bound on the risk that the investor is willing to take or a lower bound on the return the investor is willing to accept, the optimal portfolio can be obtained by solving a convex quadratic programming problem. This mean–variance model has had a profound impact on the economic modeling of financial markets and the pricing of assets—the capital asset pricing model (CAPM) developed primarily by Sharpe [30], Lintner [22], and Mossin [28] was an immediate logical consequence of the Markowitz theory. In 1990, Sharpe and Markowitz shared the Nobel Memorial Prize in Economic Sciences for their work on portfolio allocation and asset pricing.

In spite of the theoretical success of the mean–variance model, practitioners have shied away from this model. The following quote from Michaud [27] summarizes the problem: “Although Markowitz efficiency is a convenient and useful theoretical framework for portfolio optimality, in practice it is an error prone procedure that often results in *error-maximized* and *investment-irrelevant* portfolios.” This behavior is a reflection of the fact that solutions of optimization problems are often very sensitive to perturbations in the parameters of the problem; since the estimates of the market parameters are subject to statistical errors, the results of the subsequent optimization are not very reliable. Various aspects of this phenomenon have been extensively studied in the literature on portfolio selection. Chopra and Ziemba [8] study the cash-equivalent loss from the use of estimated parameters instead of the true parameters. Broadie [5] investigates the influence of errors on the efficient frontier

and Chopra [7] investigates the turnover in the composition of the optimal portfolio as a function of the estimation error (see also Part II of [31] for a summary of this research). Several studies have shown that imposing constraints on the portfolio weights in a mean–variance optimization problem leads to better out-of-sample performance [15, 16]. Practitioners have always imposed no short-sale constraints and/or bounds for each security to improve diversity. It is suggested that constraining portfolio weights may reduce volatility, increase realized efficiency, and decrease downside risk or shortfall probability. Jagannathan and Ma [19] provide theoretical justification for these observations. Michaud [27] suggests resampling the mean returns μ and the covariance matrix Σ of the assets from a confidence region around a nominal set of parameters, and then aggregating the portfolios obtained by solving a Markowitz problem for each sample. Recently, scenario-based stochastic programming models have also been proposed for handling the uncertainty in parameters (see Part V of [31] for a survey of this research). Neither of the above two scenario based approaches provide any hard guarantees on the portfolio performance, and both become very inefficient as the number of assets grows.

Robust optimization is a deterministic optimization framework in which one explicitly models the parameter uncertainty, and the optimization problems are solved assuming worst-case behavior of these perturbations. This robust optimization framework was introduced in [3] for linear programming and in [2] for general convex programming [4]. There is also a parallel literature on robust formulations of optimization problems originating from robust control [10, 12] and [11].

In order to clearly understand the main ideas underlying the robust portfolio selection approach, consider the following very simple model. Suppose the true (unknown) covariance matrix Σ and the true (unknown) mean return vector μ are known to lie in *uncertainty sets*

$$S_m = \{\mu : (\mu - \mu_0)^T \Sigma_0^{-1} (\mu - \mu_0) \leq \beta_1^2\} \quad (1)$$

and

$$S_v = \{\Sigma : \|\Sigma - \Sigma_0\|_F \leq \beta_2\} \quad (2)$$

where $\|\mathbf{A}\|_F = \sqrt{\text{Tr}(\mathbf{A}^T \mathbf{A})}$. The confidence regions associated with maximum likelihood estimates of

the parameters (μ, Σ) have precisely the ellipsoidal structure described above and these confidence regions may be used as the uncertainty sets. The robust portfolio selection problem corresponding to the uncertainty sets S_m and S_v is given by

$$\max_{\{\phi: \mathbf{1}^T \phi = 1\}} \min_{\{\mu \in S_m, \Sigma \in S_v\}} \{\mu^T \phi - \tau \phi^T \Sigma \phi\} \quad (3)$$

that is, the utility of holding a portfolio ϕ is the worst-case utility when the parameters are allowed to vary in their uncertainty sets. Thus, robust optimization implicitly assumes Knightian uncertainty, that is, the market parameters are assumed to be ambiguous.

For fixed ϕ , the solution of the inner minimization problem

$$\begin{aligned} \min_{\{\mu \in S_m, \Sigma \in S_v\}} \{\mu^T \phi - \tau \phi^T \Sigma \phi\} \\ = \mu_0^T \phi - \beta_1 \sqrt{\phi^T \Sigma_0 \phi} - \tau (\phi^T (\Sigma_0 + \beta_2 \mathbf{I}) \phi) \end{aligned} \quad (4)$$

Thus, the robust portfolio selection problem is equivalent to

$$\max_{\{\phi: \mathbf{1}^T \phi = 1\}} \left\{ \mu_0^T \phi - \beta_1 \sqrt{\phi^T \Sigma_0 \phi} - \tau (\phi^T (\Sigma_0 + \beta_2 \mathbf{I}) \phi) \right\} \quad (5)$$

The objective function of this optimization problem can be reinterpreted in the following manner. The optimal portfolio ϕ^* is the optimal solution of the classical mean–variance optimization problem with

1. a perturbed mean vector:

$$\mu = \hat{\mu} - \left(\frac{\beta_1}{\sqrt{(\phi^*)^T \Sigma_0 \phi^*}} \right) \Sigma_0 \phi^* \quad (6)$$

that is, each component of the mean vector is adjusted to reduce the return on the portfolio ϕ^* , and

2. a perturbed covariance matrix

$$\Sigma = \Sigma_0 + \beta_2 \mathbf{I} \quad (7)$$

that is, the volatility of each of the assets is increased by an amount β_2 .

Thus, the robust portfolio selection problem can be interpreted as a modification of the classical mean–variance optimization problem where the

parameter values are dynamically adjusted to account for the uncertainty.

The optimization problem (5) can be reformulated as a second-order cone program (SOCP) (see [23] or [29] for details). This fact has important theoretical and practical implications. Since the computational complexity of an SOCP is comparable to that of a convex quadratic program, it follows that robust active portfolio selection is able to provide protection against parameter fluctuations at very moderate computational cost. Moreover, a number of commercial solvers such as MOSEK, CPLEX, and Frontline System (supplier of EXCEL SOLVER) provide the capability for solving SOCPs in a numerically robust manner.

The simple model described in the preceding text does not scale as the number of assets grows. At the very minimum, the data required to calculate the maximum likelihood estimate Σ_0 grows as $\mathcal{O}(n^2)$, where n is the number of assets. Goldfarb and Iyengar [17] work with a robust factor model wherein the single period return $\mathbf{r}$ is assumed to be a random variable given by

$$\mathbf{r} = \mu + \mathbf{V}^T \mathbf{f} + \boldsymbol{\varepsilon} \quad (8)$$

where $\mu \in \mathbf{R}^n$ is the vector of mean returns, $\mathbf{f} \sim \mathcal{N}(\mathbf{0}, \mathbf{F}) \in \mathbf{R}^m$ is the vector of returns of the factors that drive the market, $\mathbf{V} \in \mathbf{R}^{m \times n}$ is the matrix of factor loadings of the n assets, and $\boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{D})$ is the vector of residual returns. For a detailed discussion of appropriate uncertainty sets for the parameters μ , $\mathbf{V}$, $\mathbf{F}$, and $\mathbf{D}$ and methods used to parameterize these sets from data, see Section 6 in [17].

Halldórsson and Tütüncü [18] show that if the uncertain mean return vector μ and the uncertain covariance matrix Σ of the asset returns $\mathbf{r}$ belong to the component-wise uncertainty sets $S_m = \{\mu : \mu^L \leq \mu \leq \mu^U\}$ and $S_v = \{\Sigma : \Sigma \succeq 0, \Sigma^L \leq \Sigma \leq \Sigma^U\}$, respectively, the robust problem reduces to a nonlinear saddle-point problem that involves semidefinite constraints. Here $\mathbf{A} \succeq 0$ (respectively > 0) denotes that the matrix $\mathbf{A}$ is symmetric and positive semidefinite (respectively definite). This approach has several shortcomings when applied to practical problems—the model is not a factor model (in applied work, factor models are popular because of the econometric relevance of the factors), no procedure is provided for specifying the extreme values (μ^L, μ^U) , and (Σ^L, Σ^U) defining the uncertainty structure and,

moreover, the solution algorithm, although polynomial, is not practicable when the number of assets is large. A multiperiod robust model, where the uncertainty sets are finite sets, was proposed in [1].

Recently, Delage and Ye [9] have proposed a distributionally robust model for portfolio selection. They assume that the distribution f of the random return ξ is uncertain and is assumed to belong to uncertainty sets of the form:

$$\mathcal{D}_1(\mathcal{S}, \mu_0, \Sigma_0, \gamma_1, \gamma_2) = \left\{ f : \begin{array}{l} \mathbb{P}_f(\xi \in \mathcal{S}) = 1 \\ (\mathbb{E}_f[\xi] - \mu_0)' \Sigma_0^{-1} (\mathbb{E}_f[\xi] - \mu_0) \leq \gamma_1 \\ \mathbb{E}_f[(\xi - \mu_0)(\xi - \mu_0)'] \leq \gamma_2 \Sigma_0 \end{array} \right\} \quad (9)$$

Notice that the uncertainty set for the covariance matrix $\mathbb{E}_f[(\xi - \mu_0)(\xi - \mu_0)']$ has an *upper* bound and the uncertainty set for the mean vector $\mathbb{E}_f[\xi]$ is centered around the nominal covariance matrix Σ_0 instead of the true covariance matrix. Delage and Ye consider robust portfolio selection problems of the form

$$\max_{\phi \in \Phi} \min_{f \in \mathcal{D}_1} \mathbb{E}_f[u(\phi, \xi)] \quad (10)$$

where $u(\phi, \xi)$ is a piece-wise linear concave utility function of the form $u(\phi, \xi) = \min_k \{a_k \xi' \phi + b_k\}$. Fix $\phi \in \Phi$. Then convex duality implies that the inner optimization problem $\min_{f \in \mathcal{D}_1} \mathbb{E}_f[u(\phi, \xi)]$ is equivalent to

$$\begin{aligned} \max \quad & r - t, \\ \text{s. t.} \quad & r \leq a_k \xi' \phi + b_k + \xi' Q \xi + \xi' q \quad \forall k, \forall \xi \in \mathcal{S} \\ & t \geq (\gamma_2 \Sigma_0 + \mu_0 \mu_0') \bullet Q + \mu_0' q \\ & \quad + \sqrt{\gamma_1} \|\Sigma_0^{\frac{1}{2}}(q + 2Q\mu_0)\| \\ & Q \succeq 0 \end{aligned} \quad (11)$$

where $A \bullet B = \text{Tr}(AB)$ denotes the Frobenius inner product of matrices. Note that equation (11) is a *semiinfinite* optimization problem since the first constraint has to hold for all $\xi \in \mathcal{S}$. Moreover, it is a semidefinite program, and is, therefore, a much harder problem compared to SOCPs or convex quadratic programs. Using results from convex optimization theory, Delage and Yu show that an ϵ -approximate

solution in $\mathcal{O}(n^{6.5} \log(\frac{1}{\epsilon}))$ iterations. This complexity is prohibitive for a portfolio selection problem of any reasonable size; however, it does provide a new perspective, namely, uncertainty sets for random returns. Lim *et al.* have studied a minimax regret formulation for portfolio selection in continuous time [21].

The robust optimization methodology has also been extended to *active* portfolio management problems where the goal is to beat a given benchmark by using information that is not broadly available in the market. Since errors in estimating the returns of assets are expected to have serious consequences for an active strategy, robust models are likely to result in portfolios with significantly superior performance. Erdoğan *et al.* [14] show how the basic robust portfolio selection model extends to robust active portfolio management. Since active portfolio strategies tend to execute many trades, properly modeling and managing trading costs are essential for the success of any practical active portfolio management model [20, 24]. Erdoğan *et al.* [14] show that a very large class of piecewise convex trading cost functions can be incorporated into an active portfolio selection problem in a tractable manner. Ceria and Stubbs [6] show how to impose a variety of side constraints on the exceptional return α and still recast the portfolio selection problem as an SOCP. Erdogan *et al.* [13] show how to incorporate analysts' views about α and nonparametric loss functions into robust active portfolio management.

GARUD IYENGAR

Diversification

Diversification involves spreading investments among various assets in order to improve portfolio performance in some manner. Mathematical analysis of portfolio diversification was introduced in 1952 by Markowitz [6] with his concept of mean/variance portfolio efficiency. A portfolio was called *efficient* if, among all portfolios of the same assets, the portfolio had minimum variance for a given expected rate of return. Hence, in the setting of expected portfolio return and variance, portfolio diversification served to control the risk of a portfolio. In 1982, Fernholz and Shay [3] showed that if the expected compound growth rate of a portfolio is considered rather than the expected rate of return, then portfolio diversification can increase the expected growth rate as well as control risk.

Mean/Variance Portfolio Diversification

Suppose that a portfolio $\mathbf{P}$ holds n assets $\mathbf{X}_1, \dots, \mathbf{X}_n$, and let $p_1, \dots, p_n$ be the weights, or proportions of each corresponding asset in the portfolio. In this case, the weights need not be all positive, but they must add up to 1, $p_1 + \dots + p_n = 1$. A negative value of p_i indicates a short sale of $\mathbf{X}_i$.

Suppose that α_i is the expected rate of return of $\mathbf{X}_i$ and that σ_{ij} is the covariance of return between $\mathbf{X}_i$ and $\mathbf{X}_j$, with the variance of return of $\mathbf{X}_i$ written as $\sigma_i^2 = \sigma_{ii}$. With this notation, the expected rate of return of $\mathbf{P}$ is given by

$$\alpha_P = \sum_{i=1}^n p_i \alpha_i \quad (1)$$

and the variance of $\mathbf{P}$ is

$$\sigma_P^2 = \sum_{i,j=1}^n p_i p_j \sigma_{ij} \quad (2)$$

In mean/variance theory [6, 7], a portfolio is optimally diversified if the portfolio variance σ_P^2 is minimal under the constraints

$$p_1 + \dots + p_n = 1 \quad \text{and} \quad \alpha_P \geq A \quad (3)$$

where A is a given constant. For a *long-only* portfolio, the additional constraints $p_1 \geq 0, \dots, p_n \geq 0$ are imposed.

In mean/variance theory, there is no specific measure of portfolio diversification, but it is understood that diversification can reduce the portfolio variance without lowering the expected return of the portfolio. Portfolios with minimum variance for a given value of portfolio return are called *efficient* portfolios, and we say that efficient portfolios lie on the *efficient frontier* in mean/variance space.

Diversification and Expected Growth Rate

The expected rate of return of a financial asset is more precisely called the expected *arithmetic* rate of return of the asset. Another measure of portfolio performance is the expected *logarithmic* rate of return of an asset, and this logarithmic rate is frequently called the expected (compound) *growth rate* of the asset. It was shown in [1, 3] that the expected growth rate of a financial asset is a better indicator of long-term performance than the expected return, and, for this reason, it is likely to be preferable for multiperiod performance analysis (see [4]). The relation between the expected rate of return α of an asset and its expected growth rate γ is

$$\alpha = \gamma + \frac{1}{2}\sigma^2 \quad (4)$$

where σ^2 is the variance of the asset. Equation (4) is an application of *Itô's rule* for stochastic integration [5]; the relation is exact for continuous-time analysis and approximate for multiperiod discrete-time analysis (see [1]).

For the portfolio $\mathbf{P}$, the portfolio variance σ_P^2 is the same whether it is measured with regard to the portfolio return or the portfolio growth rate. However, the relationship between the portfolio growth rate and the growth rates of the individual assets is more complicated than the corresponding relationship for arithmetic returns given by equation (1). If the assets $\mathbf{X}_1, \dots, \mathbf{X}_n$ have growth rates $\gamma_1, \dots, \gamma_n$, then the growth rate of $\mathbf{P}$ is given by

$$\gamma_P = \sum_{i=1}^n p_i \gamma_i + \gamma_P^* \quad (5)$$

where

$$\gamma_P^* = \frac{1}{2} \left(\sum_{i=1}^n p_i \sigma_i^2 - \sum_{i,j=1}^n p_i p_j \sigma_{ij} \right) \quad (6)$$

is called the *excess growth rate* of $\mathbf{P}$ (see [1–3]). From equation (2), we see that the excess growth rate is half the difference of the weighted average of the variances of the assets in the portfolio minus the variance of the portfolio itself. We see from equations (5) and (6) that diversification affects both the variance and the expected growth rate of the portfolio.

Excess Growth and the Efficacy of Diversification

The excess growth rate γ_P^* of the portfolio $\mathbf{P}$ can be used as a measure of the *efficacy of diversification* of the portfolio. The more effective the diversification, the greater the difference between the average variance of the assets and the portfolio variance, and the greater the contribution to the portfolio growth rate.

Equation (6) remains valid if the covariances σ_{ij} are replaced by covariances measured relative to some *numeraire* asset (see [1]), so in this sense the excess growth rate is *numeraire invariant*. Suppose $\mathbf{Z}$ is a financial asset; then the covariance of $\mathbf{X}_i$ and $\mathbf{X}_j$ relative to $\mathbf{Z}$ is given by

$$\sigma_{ij/Z} = \sigma_{ij} - \sigma_{iZ} - \sigma_{jZ} + \sigma_Z^2 \quad (7)$$

where σ_{iZ} is the covariance of $\mathbf{X}_i$ with $\mathbf{Z}$, σ_{jZ} is the covariance of $\mathbf{X}_j$ with $\mathbf{Z}$, and σ_Z^2 is the variance of $\mathbf{Z}$. With the notation $\sigma_{i/Z}^2 = \sigma_{ii/Z}$, equation (6) becomes

$$\gamma_P^* = \frac{1}{2} \left(\sum_{i=1}^n p_i \sigma_{i/Z}^2 - \sum_{i,j=1}^n p_i p_j \sigma_{ij/Z} \right) \quad (8)$$

In particular, if the asset $\mathbf{Z}$ is the portfolio $\mathbf{P}$ itself, then the variance of $\mathbf{P}$ relative to itself vanishes:

$$\sum_{i,j=1}^n p_i p_j \sigma_{ij/P} = \sigma_{P/P}^2 = 0 \quad (9)$$

so we have simply

$$\gamma_P^* = \frac{1}{2} \sum_{i=1}^n p_i \sigma_{i/P}^2 \quad (10)$$

If $\mathbf{P}$ is a long-only portfolio, then all the terms $p_i \sigma_{i/P}^2$ are nonnegative, and it follows from equation (10) that γ_P^* is also nonnegative. Hence, for such a portfolio, diversification will not decrease the portfolio growth rate, and is likely to increase it.

The Efficacy of Diversification in the US Stock Market

Here, we shall consider an example of the excess growth rate as a measure of efficacy of diversification. Figure 1 shows the smoothed, annualized excess growth rate for the US stock market over most of the twentieth century. The data used to construct Figure 1 come from the monthly stock database of the Center for Research in Securities Prices (CRSP) at the University of Chicago. The stocks included in this market are those traded on the New York Stock Exchange (NYSE), the American Stock Exchange (AMEX), and the NASDAQ Stock Market, with adjustments made for real estate investment trusts (REITs), closed-end funds, and American depository receipts (ADRs). Until 1962, the data included only NYSE stocks, after July 1962 AMEX stocks were included, and at the beginning of 1973 NASDAQ stocks were included. The number of stocks in this market varies from a few hundred in 1927 to about 7500 after 1999.

We see in Figure 1 that the excess growth rate of the market has varied considerably over time, from an estimated minimum excess growth rate

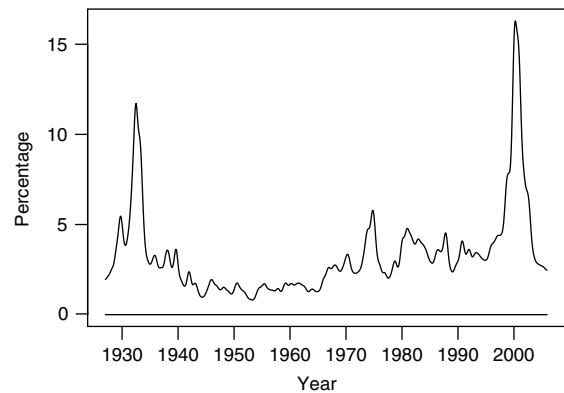

Figure 1 Efficacy of diversification of the US stock market, as measured by the market excess growth rate, 1927–2005

of about 1% a year in the 1950s to a maximum of about 16% a year near 2000. The volatility of the stocks has a significant effect on the efficacy of diversification, with higher excess growth rates appearing in the bubble years of the 1930s, the 1970s, and around 2000, even though during these periods there was concentration of capital into the larger stocks. In contrast, the excess growth rate increased only modestly with the increase in the number of stocks in the market from under 1000 in the early years to over 5000 in the later years. Hence, in the absence of higher volatility, the addition of new assets did not significantly increase the efficacy of diversification over the observed period.

ROBERT FERNHOLZ

Merton Problem

How does an individual decide on where to invest his wealth and how much of it to use during his lifetime? This is a basic question that needs to be answered in order to understand and predict individual economic behavior and also in order to derive the aggregate demands for securities that, together with their supply schedules, determine their prices in equilibrium.

In two path-breaking papers, Merton [21, 22] has formulated and derived the individual's optimal consumption–investment behavior in a continuous-time framework that allows the introduction of a useful structure that can be appropriately molded to model different interesting situations and to yield concrete results. This formulation has come to be known as the *Merton problem*.

Formulation of the Merton Problem

Let $P(t) = (P_0(t), \dots, P_n(t))$, $0 \leq t \leq T$, denote the prices at time t of $n + 1$ limited liability assets paying no dividends and traded continuously in a perfect market. The price dynamics of $P(t)$ is assumed to follow a correlated vector Ito process whose i th component obeys the general stochastic differential equation

$$\frac{dP_i}{P_i} = \alpha_i(P, t) dt + \sigma_i(P, t) dz_i \quad (1)$$

For $i, j = 0, \dots, n$, the dz_i s are correlated Wiener processes satisfying $dz_i dz_j = \rho_{ij}(P, t) dt$ for given real functions $\rho_{ij}(\cdot, \cdot)$; $dz_i dt = 0$; the expectations $E(dz_i)$ equal zero; and denote $\sigma_{ij}(\cdot, \cdot) := \sigma_i \sigma_j \rho_{ij}$.

At time 0, the individual is endowed with an initial number of units of wealth W_0 and he then selects a complete plan of consumption and investment spanning his lifetime $[0, T]$ so as to maximize his expected utility of consumption and the bequest he will leave at time T .

Formally, at any future time t in $(0, T]$, based on the history of the prices, his previous consumption, and previous investment choices, the individual plans to consume at a rate $c(t)$ and trade so as to hold his remaining wealth $W(t)$ in a portfolio that is invested in $N_i(t)$ shares of asset i . The consumption and investment choices are said to be the individual's controls.

The individual plans to control his consumption and investment so as to

$$\max E_0 \left[\int_0^T u(c(t), t) dt + B(W(T)) \right] \quad (2)$$

subject to his wealth constraint

$$W(0) = W_0, W(t) = \sum_{i=0}^n N_i(t) P_i(t), \quad 0 \leq t \leq T \quad (3)$$

where u is the individual's instantaneous utility, and $B(\cdot)$ is the bequest function.

Solution by Dynamic Programming

To solve the Merton problem by dynamic programming, the wealth constraint (3) is needed in differential form. Taking the total stochastic differential in equation (3), noting that both the number of shares and their prices are Ito processes, results in

$$\begin{aligned} dW(t) = & \sum_{i=0}^n N_i(t) dP_i(t) + \sum_{i=0}^n dN_i(t) dP_i(t) \\ & + \sum_{i=0}^n dN_i(t) P_i(t) \end{aligned} \quad (4)$$

Clearly, the first term on the right-hand side (RHS) of equation (4) is associated with the capital gains to the portfolio over the interval dt resulting from the change in the asset prices. Equally clearly, the third term on the RHS of that equation is associated with the inflow of wealth from external sources that is used to buy additional shares for the portfolio (negative inflow would mean outflow, as when shares are sold to finance consumption.). It is not clear, though, how to associate the middle term on the RHS—with the capital gain or with the cash inflow to the portfolio.

Taking care that choices made at any given time do not anticipate the future, Merton [22] shows that the middle term on the RHS of equation (4), along with the third term, comprise together the total inflow of funds to the portfolio. Therefore, in the absence of other income, the incremental inflow to the portfolio at time t in this problem is given by $-c(t) dt = \sum_{i=0}^n dN_i(t) dP_i(t)$

2 Merton Problem

+ $\sum_{i=0}^n dN_i(t)P_i(t)$, and equation (4) becomes the Merton self-financing condition

$$dW(t) = \sum_{i=0}^n N_i(t) dP_i(t) - c(t) dt \quad (5)$$

It is remarkable that a special case of Merton's self-financing condition in equation (5) is equivalent to the Black–Scholes partial differential equation (PDE), which is prominent in derivative pricing.^a

It is convenient to express the Merton self-financing condition, equation (4), in terms of portfolio weights, $w_i(t) := N_i(t)P_i(t)/W(t)$, which would serve as the portfolio controls from now on instead of the number of shares. Substituting the weights and the asset returns from equation (1) in equation (5) yields the differential wealth dynamics,

$$\begin{aligned} dW(t) = & \left(-c + W \sum_{i=0}^n w_i \alpha_i \right) dt \\ & + W \sum_{i=0}^n w_i \sigma_i dz_i, \text{ with } \sum_{i=0}^n w_i = 1 \end{aligned} \quad (6)$$

which the individual obeys when solving for the consumption and investment controls in the expected utility maximization problem (2).

Since the utility functional in equation (2) is time-additive, the Merton problem can be solved by dynamic programming. To that end, define the value function (also called the *indirect utility of wealth*) by

$$\begin{aligned} J(W(t), t) := & \max_{c(\tau), \{w_i(\tau)\}, t \leq \tau \leq T} \\ & E_t \left[\int_t^T u(c(\tau), \tau) d\tau + B(W(T)) \right] \end{aligned} \quad (7)$$

subject to the wealth dynamics in equation (6), and where E_t denotes the expectation operator given the information at time t , that is, the knowledge at time t of the prices, wealth, and consumption rate that determine the conditional probabilities of the future prices.

Then, $J(W(t), t) = \max_{c(\tau), \{w_i(\tau)\}, t \leq \tau \leq T}$

$$\begin{aligned} & E_t \left[\int_t^{t+\Delta t} u(c(\tau), \tau) d\tau \right. \\ & \left. + \int_{t+\Delta t}^T u(c(\tau), \tau) d\tau + B(W(T)) \right] \\ = & \max_{c(\tau), \{w_i(\tau)\}, t \leq \tau \leq t+\Delta t} E_t \left\{ \int_t^{t+\Delta t} u(c(\tau), \tau) d\tau \right. \\ & \left. + \max_{c(\tau), \{w_i(\tau)\}, t+\Delta t \leq \tau \leq T} E_{t+\Delta t} \left[\int_{t+\Delta t}^T u(c(\tau), \tau) d\tau \right. \right. \\ & \left. \left. + B(W(T)) \right] \right\} \end{aligned}$$

(the law of iterated expectations was used above: $E_t E_{t+\Delta t}[\cdot] = E_t[\cdot]$)

$$\begin{aligned} = & \max_{c(\tau), \{w_i(\tau)\}, t \leq \tau \leq t+\Delta t} E_t \left\{ \int_t^{t+\Delta t} u(c(\tau), \tau) d\tau \right. \\ & \left. + J(W(t+\Delta t), t+\Delta t) \right\} \\ = & \max_{c(t), \{w_i(t)\}} E_t [u(c(t), t) \Delta t + o(\Delta t) \\ & + J(W(t), t) + \Delta J] \\ = & J(W(t), t) + \max_{c(t), \{w_i(t)\}} \{u(c(t), t) \Delta t + o(\Delta t) \\ & + E_t[\Delta J]\} \end{aligned} \quad (8)$$

where $o(x)$ means a quantity that tends to zero faster than does x .

By Ito's lemma and by the wealth equation (5),

$$\begin{aligned} E_t[\Delta J] = & E_t \left[J_t \Delta t + J_W \Delta W + \frac{1}{2} J_{WW} (\Delta W)^2 \right. \\ & \left. + o(\Delta t) \right] = J_t \Delta t + J_W \left(-c + W \sum_{i=0}^n w_i \alpha_i \right) \Delta t \\ & + \frac{1}{2} J_{WW} W^2 \left(\sum_{i=0}^n \sum_{j=0}^n w_i w_j \sigma_{ij} \right) \Delta t + o(\Delta t) \end{aligned} \quad (9)$$

Substituting the last expression in equation (8), subtracting $J(W(t), t)$ from both sides, dividing by Δt , and taking the limit $\Delta t \rightarrow 0$, yields

$$0 = \max_{c(t), \{w_i(t)\}_0^n} \left\{ u(c(t), t) + J_t \right.$$

$$\begin{aligned}
& + J_W \left(-c + W \sum_{i=0}^n w_i \alpha_i \right) + \frac{1}{2} J_{WW} W^2 \\
& \times \left(\sum_{i=0}^n \sum_{j=0}^n w_i w_j \sigma_{ij} \right) \Big\} \\
& \text{subject to } \sum_{i=0}^n w_i = 1
\end{aligned} \tag{10}$$

Equation (10) is the Hamilton–Jacobi–Bellman (HJB) equation for the Merton problem.

A Solved Example

The HJB equation yields a nonlinear partial differential equation in the unknown function of two variables $J(W, t)$ with the end condition $J(W, T) = B(W(T))$, the utility from bequest. A solution example is illustrated next for the case with one riskless asset yielding a constant rate of return $\alpha_0 = r$ and with n risky assets following correlated geometric Brownian motions, that is, α_i, σ_i , and σ_{ij} are all constants, and $\sigma_{0j} = \sigma_{j0} = 0$, for $i, j = 0, \dots, n$.

Substituting $w_0 = 1 - \sum_{i=1}^n w_i$ and $\sum_{i=0}^n w_i \alpha_i = r + \sum_{i=1}^n w_i (\alpha_i - r)$ in the HJB equation (10) yields

$$0 = \max_{c(t), \{w_i(t)\}_1^n} G(c(t), w_1(t), \dots, w_n(t)), \tag{11}$$

where $G(c, w_1, \dots, w_n) := u(c, t) + J_t + J_W [-c + rW + W \sum_{i=1}^n w_i (\alpha_i - r)] + (1/2) J_{WW} W^2 (\sum_{i=1}^n \sum_{j=1}^n w_i w_j \sigma_{ij})$ is a real function of $n+1$ free real variables, and the maximization problem exhibits no constraints.

To locate the point $(c^*, w_1^*, \dots, w_n^*)$ that maximizes G , requires the $n+1$ first-order conditions,

$$\frac{\partial G}{\partial c} = 0 = \frac{\partial u}{\partial c}(c, t) - J_w \tag{12}$$

$$\begin{aligned}
\frac{\partial G}{\partial w_i} &= 0 = J_w (\alpha_i - r) + J_{WW} W \sum_{j=1}^n w_j \sigma_{ij}, \\
&(i = 1, \dots, n)
\end{aligned} \tag{13}$$

If for every time t , $u(c, t)$ is strictly concave and twice continuously differentiable in c , then equation (12) can be inverted to yield $c^* = f(J_w, t)$. The system of linear equations (13) can be solved for

the weights on the risky assets w_i^* as functions of J_w, J_{WW} , and W . Then these $(c^*, w_1^*, \dots, w_n^*)$ are substituted back in equation (11) to yield

$$0 = G(c^*, w_1^*, \dots, w_n^*) \tag{14}$$

which then becomes a nonlinear partial differential equation of the second order in the unknown function $J(W, t)$ with the end condition $J(W, T) = B(W(T))$.

Merton [21] demonstrates closed-form solutions to equation (14) for some special cases. For example, assume that the instantaneous utility of consumption is the isoelastic, $u(c, t) = \exp(-\rho t) c^\gamma / \gamma$; utility from bequest is 0; there are two available assets, one is risk-free returning at a rate r and the other risky, following a Geometric Brownian motion with a constant drift, α , and a constant variance per unit time, σ^2 . Then the optimal weight that the portfolio puts on the risky asset is the constant $w^*(t) = (\alpha - r) / [(1 - \gamma)\sigma^2]$, $0 \leq t \leq T$, and the optimal consumption rate is given by $c^*(t) = W(t)a / [1 - \exp(-a(T - t))]$, $0 \leq t \leq T$, where $W(t)$ is the value of the portfolio at time t , and where

$$a := \frac{\gamma}{1 - \gamma} \left[\frac{\rho}{\gamma} - r - \frac{1}{2} \left(\frac{\alpha - r}{\sigma} \right)^2 \frac{1}{1 - \gamma} \right] \tag{15}$$

Generally, however, equation (14) must be solved numerically.

The Merton Problem with State-dependent Price Process Parameters

Merton [23] extends his problem to include parameters of the price processes that depend on a state variable x which itself follows an Ito process, that is,

$$\begin{aligned}
\frac{dP_i}{P_i} &= \alpha_i(x, t) dt + \sigma_i(x, t) dz_i, \\
(0 \leq t \leq T, i = 0, \dots, n)
\end{aligned} \tag{16}$$

$$dx = a(x, t) dt + s(x, t) dz \tag{17}$$

where the dz_i and dz are correlated Wiener processes satisfying $dz_i dz_i = \rho_{ij}(x, t) dt$; $dz_i dz = \rho_{ix} dt$; $dz_i dt = dz dt = 0$, $E(dz_i) = 0$; $(i, j = 0, \dots, n)$. Denote $\alpha := (\alpha_1, \dots, \alpha_n)$, $r := (r, \dots, r)$, $\sigma_x := (\rho_{1x}\sigma_1, \dots, \rho_{nx}\sigma_n)$, and σ denote by the matrix with $\sigma_{ij} := \sigma_i \sigma_j \rho_{ij}$ in the ij place.

Defining the indirect utility $J(W, x, t)$ as before, but recognizing that it now depends also on the state variable, and following the same derivation as before with the obvious modifications, Merton [23] shows that in the presence of a riskless asset returning at the constant rate r , the optimal investment plan described by the control vector process of weights on the risky assets in the portfolio that maximizes lifetime utility of consumption is given by

$$\begin{aligned} \mathbf{w}_t^* &= \left(-\frac{J_W}{W J_{WW}} \right) \sigma^{-1} (\boldsymbol{\alpha} - \mathbf{r}) + \left(-\frac{J_{xW}}{W J_{WW}} \right) \sigma^{-1} \sigma_x \\ &=: D\mathbf{d} + H\mathbf{h}, \quad 0 \leq t \leq T \end{aligned} \quad (18)$$

The scalars D and H are agent specific, but the vectors $\mathbf{d}$ and $\mathbf{h}$ are not. It follows that every investor behaves as if the risky part of his portfolio is split between two mutual funds holding total portfolios with weights that are proportional to $\mathbf{d}$ and $\mathbf{h}$, respectively; then there is also the part that is invested in the risk-free asset. The result is a three-fund separation theorem. Merton [23] shows that while the first risky mutual fund is used to diversify, that is, to obtain the largest expected return for a given amount of risk borne, the second risky mutual fund is used to hedge unfavorable shifts in the state variable x , in the sense that if an increase in x diminishes planned consumption, then the investor compensates himself by shifting wealth to the asset with returns that increase with x .

The Merton problem was first formulated and solved using stochastic control in [21, 22]. It provides the basis for the intertemporal capital asset pricing model in [23]. Extensions of the problem include [19, 20, 26]. In references [3, 4, 12–15], the problem is treated in incomplete markets and under other market constraints. Transaction costs are introduced into the Merton problem in [1, 5, 11, 29]. The problem is extended to incomplete information settings in [6, 8, 27]; to settings with habit formation utilities in [7, 17, 28]; and to settings with recursive utilities in [2, 10]. Textbooks that provide a detailed treatment of the Merton problem include [9, 16, 25].

End Notes

^aSpecifically, suppose the portfolio comprises two assets, one risky and one riskless, and that there are no inflows to or outflows from the portfolio, that is, $c(t) = 0$ for all t . Then, if only Markov controls of the portfolio are considered,

namely, number of units of the two assets that depend only on time and the concurrent price, it follows that the value of the portfolio which then obviously depends only on time and the concurrent price of the risky asset, can be shown to necessarily satisfy the Black–Scholes PDE. Moreover, the number of shares of the risky asset in the portfolio is equal to the partial derivative of the said portfolio value function with respect to the price of the risky asset (see [18, 24]). The converse is also true.

YAACOV Z. BERGMAN

Mean–Variance Hedging

In a nutshell, *mean–variance hedging (MVH)* is the problem of approximating, with minimal mean-squared error, a given payoff by the final value of a self-financing trading strategy in a financial market. *Mean–variance portfolio selection (MVPS)*, on the other hand, consists of finding a self-financing strategy whose final value has maximal mean and minimal variance.

More precisely, let $S = (S_t)_{0 \leq t \leq T}$ be an $(\mathbb{R}^d$ -valued) stochastic process on a filtered probability space $(\Omega, \mathcal{F}, \mathbb{P}, P)$ and think of S_t as discounted time t prices of d underlying risky assets. Assume S is a semimartingale and denote by Θ a class of $(\mathbb{R}^d$ -valued) predictable S -integrable processes $\vartheta = (\vartheta_t)_{0 \leq t \leq T}$ satisfying suitable technical conditions. Together with an initial capital x , each ϑ describes, via its time t holdings ϑ_t in S , a self-financing strategy whose *value* at time t is given by the stochastic integral (see **Stochastic Integrals**)

$$V_t(x, \vartheta) = x + \int_0^t \vartheta_u dS_u =: x + G_t(\vartheta) \quad (1)$$

Mean–variance portfolio selection, for some risk aversion parameter $\gamma > 0$, then amounts to

$$\begin{aligned} & \text{maximize } E[V_T(x, \vartheta)] - \gamma \text{Var}[V_T(x, \vartheta)] \\ & \text{over all } \vartheta \in \Theta \end{aligned} \quad (2)$$

and MVH, for a final time T payoff given by a square-integrable $\mathcal{F}_T$ -measurable random variable H , amounts to (see **Hedging**)

$$\begin{aligned} & \text{minimize } E[|V_T(x, \vartheta) - H|^2] \\ & \text{over all } \vartheta \in \Theta \end{aligned} \quad (3)$$

By writing the objective of equation (2) as $m(\vartheta) - \gamma E[|V_T(x, \vartheta) - m(\vartheta)|^2]$ and adding the constraint $m(\vartheta) := E[V_T(x, \vartheta)] = m$, we can solve problem (2) by first solving problem (3) for a constant payoff $H \equiv m$ and then optimizing over m . So we first focus on mean–variance hedging.

Remark 1 A Google Scholar search quickly reveals that the literature on “mean–variance hedging” and “mean–variance portfolio selection” is vast; it cannot be properly surveyed here. Hence we have chosen

references partly for historical interest, partly for novelty, and partly for other subjective reasons. Any omissions may be blamed on this and lack of space.

In mathematical terms, MVH as in equation (3) is simply the problem of finding the best approximation in $L^2 = L^2(P)$ of H by an element of $\mathcal{G} := G_T(\Theta)$. Existence (for arbitrary H) is thus tantamount to closedness of $\mathcal{G}$ in L^2 , which depends on the precise choice of Θ ; results in that direction can be found in [15, 16, 18, 24, 44, 50]. Since the optimal approximand is given by the projection in L^2 of H onto $\mathcal{G}$, MVH (without constraints on strategies) has the pleasant feature that its solution is linear as a function of H . The main challenge, however, is to find more explicit descriptions of the optimal strategy $\hat{\vartheta}^H$, that is, the minimizer for problem (3). The key difficulty there stems from the fact that S is, in general, a P -semimartingale, but not a P -martingale.

Remark 2 If S is a P -martingale, MVH of H is solved by projecting the P -martingale V^H associated with H onto the stable subspace of all stochastic integrals of S , and the optimal strategy is the integrand in the Galtchouk–Kunita–Watanabe decomposition of V^H with respect to S under P . This is also the (first component of the) strategy which is *risk-minimizing* for H in the sense of [22]; see also [11]. However, in this mathematically classical case, MVH is of minor interest for finance since a martingale stock price process has zero excess return.

Historically, mean–variance portfolio selection is much older than mean–variance hedging. It is traditionally credited to Harry Markowitz (1952), although closely related work by Bruno de Finetti (1940) has been discovered recently; [2] provides an overview (see **Markowitz, Harry; Modern Portfolio Theory**). For the static one-period case where $G_T(\vartheta) = \vartheta^{\text{tr}}(S_T - S_0)$ and ϑ is a nonrandom vector, [40, 41] contain a general formulation and [43] an explicit solution (see also **Risk–Return Analysis**). A multi-period treatment, whether in discrete or in continuous time, is considerably more delicate; this was already noticed in [45] and is explained more carefully a bit later.

Mean–variance hedging in the general formulation (3) seems to have been introduced only around 1990. It first appeared in a specific framework in [49], which generalizes a particular example from

[21], and was subsequently extended to very general settings; see [47, 55] for surveys of the literature up to around 2000. Most of these papers use martingale techniques, and an important quantity in that context is the *variance-optimal martingale measure* $\tilde{P}$, obtained as the solution to the dual problem of minimizing over all (signed) local martingale measures Q for S the $L^2(P)$ -norm of the density dQ/dP (see **Equivalent Martingale Measures**). It turns out [53] that if one modifies problem (3) to

$$\begin{aligned} & \text{minimize } E[|V_T(x, \vartheta) - H|^2] \\ & \text{over all } x \in \mathbb{R} \text{ and } \vartheta \in \Theta \end{aligned} \quad (4)$$

the optimal initial capital is given by $\tilde{x} = E_{\tilde{P}}[H]$, and $\tilde{P}$ also plays a key role in finding the optimal strategy $\tilde{\vartheta}^H$. If S is continuous, then $\tilde{P}$ is equivalent to P (see **Equivalence of Probability Measures**) so that its density process $Z^{\tilde{P}}$ is strictly positive [19]. This can then be exploited to give a more explicit description of $\tilde{\vartheta}^H$, either *via* an elegant change of numeraire ([24], see also **Change of Numeraire**), or *via* a change of measure and a recursive formula [48]; see also [1] for an overview of partial extensions to discontinuous settings. For general discontinuous S , [15] have shown that the optimal strategy can be found in the same way as the locally risk-minimizing strategy [55] provided one first makes a change from P to a new (their so-called opportunity-neutral) probability measure P^* .

One common feature of all the above results is that they require for a more explicit description of $\tilde{\vartheta}^H$ the density process ($Z^{\tilde{P}}$ or Z^{P^*}) of some measure, and that this process is very difficult to find in general. Things become much simpler under the (frequently made but restrictive) assumption that S has a *deterministic mean–variance trade-off* (also called *nonstochastic opportunity set*), because $\tilde{P}$ then coincides with the *minimal martingale measure* $\hat{P}$ (see **Minimal Martingale Measure**), which can always be written down directly from the semimartingale decomposition of S ; see [52]. The process S typically has a deterministic mean–variance trade-off if it has independent returns or is a Lévy process (see **Lévy Processes**); this explains why MVH can be used so easily in such settings.

The original MVH problem (3) is a static problem in the sense that one tries at time 0 to find an optimal strategy for the entire interval $[0, T]$. For an

intertemporally dynamic formulation, one would at any time t

$$\begin{aligned} & \text{minimize } E[|V_T(x, \vartheta) - H|^2 | \mathcal{F}_t] \\ & \text{over all } \vartheta \in \Theta_t(\psi) \end{aligned} \quad (5)$$

where $\Theta_t(\psi)$ denotes all strategies $\vartheta \in \Theta$ that agree up to time t with a given $\psi \in \Theta$. In view of equation (1), one recognizes in equation (5) a *linear–quadratic stochastic control (LQSC)* problem, and this point of view allows to exploit additional theory (see **Stochastic Control**) and to obtain, in some situations, more explicit results about the optimal strategy as well. The idea to tackle MVH *via* LQ control techniques and backward stochastic differential equations (BSDEs; see **Backward Stochastic Differential Equations**) seems to originate with M. Kohlmann and X. Y. Zhou. Together with various coauthors, they developed this approach through several papers in an Itô diffusion setting for S ; references [29, 31, 37, 60, 61] provide an overview. A key contribution was made a little earlier in [36] in a discrete-time model by embedding the MVPS problem into a class of auxiliary LQSC problems. Extensions beyond the Brownian setting are given in [10, 38, 39] among others; approaches in discrete time can be found in [14, 25] or [51].

As already stated, MVH is very popular and has been used and studied in many examples and contexts. A few of these are mentioned below:

- stochastic volatility models ([5, 34]; see also **Stochastic Volatility Models**);
- insurance and ALM applications [17, 20, 57];
- weather derivatives or electricity loads ([12, 46]; see also **Weather Derivatives; Commodity Risk**);
- uncertain horizon models [42];
- insider trading [6, 13, 30];
- robustness and model uncertainty ([23, 58]; see also **Robust Portfolio Optimization**);
- default risk and credit derivatives ([4, 8, 28]; see also Section 10, “Credit Derivatives”, of this encyclopedia).

Perhaps the main difference between mean–variance hedging and mean–variance portfolio selection is that MVPS is not consistent over time, in the following sense. If, in analogy to equation (5), we

consider for each t the problem to

$$\begin{aligned} & \text{maximize } E[V_T(x, \vartheta)|\mathcal{F}_t] \\ & - \gamma \text{Var}[V_T(x, \vartheta)|\mathcal{F}_t] \text{ over } \vartheta \end{aligned} \quad (6)$$

this is no longer a standard stochastic control problem because of the variance term. In particular, the crucial *dynamic programming* property fails: if ϑ^* solves problem (2) on $[0, T]$ and we consider problem (6) where we optimize over all $\vartheta \in \Theta_t(\vartheta^*)$, that is, strategies ϑ that agree with ϑ^* up to time t , the solution of this conditional problem over $[t, T]$ will differ from ϑ^* , in general. This makes things surprisingly difficult and explains why MVPS in a general multiperiod setting has still not been solved in a satisfactorily explicit manner.

From the purely geometric structure of the problem, one can derive by elementary arguments the optimal final value

$$G_T(\vartheta^*) = \frac{1}{2\gamma} \left(\alpha - \frac{d\tilde{P}}{dP} \right) \quad (7)$$

with $\alpha = E \left[\left(d\tilde{P}/dP \right)^2 \right]$; this can be seen from [53, 54] or also found in [59]. However, (7) mainly shows that finding the optimal strategy ϑ^* is inextricably linked to a precise knowledge of the variance-optimal martingale measure $\tilde{P}$, which is very difficult to obtain in general. For the case of a *deterministic mean-variance trade-off* (nonstochastic opportunity set), we have already seen that $\tilde{P}$ equals the minimal martingale measure $\hat{P}$ so that equation (7) readily gives the solution to the MVPS problem (2) in explicit form. This includes for instance the results obtained by Li and Ng [36] in finite discrete time or by Zhou and Li [61] who used BSDE techniques in continuous time. Other work in various settings includes [7, 35, 56].

One major area of recent developments in MVPS is the inclusion of constraints (for instance, [9, 26, 27, 32, 33]). Another challenging open problem is to find a time-consistent formulation ([3] provides a first attempt).

Risk Exposures

Broadly speaking, risk can be defined as the volatility of returns leading to “unexpected losses” (see **Value-at-Risk**), with higher volatility indicating higher risk.^a The volatility of returns is directly or indirectly influenced by numerous variables, which we called *risk factors*, and by the interaction between these risk factors.

Risk factors can be broadly grouped together into the following categories: market risk, credit risk, liquidity risk, operational risk, legal and regulatory risk, business risk, strategic risk, and reputation risk [2]. These categories can then be further decomposed into more specific categories, as we show in Figure 1 for market risk and credit risk.

In this figure, we have subdivided market risk into equity risk, interest rate risk, currency risk, and commodity price risk in a manner that is in line with our detailed discussion below. Then we have divided interest rate risk into trading risk and the special case of gap risk: the latter relates to the risk that arises in the balance sheet of an institution from the different sensitivities of assets and liabilities to changes in interest rates.

In theory, the more all-encompassing the categorization and the more detailed the decomposition, the more closely the company’s risk will be captured. In practice, this process is limited by the level of model complexity that can be handled by the available technology and by the cost and availability of internal and market data.

Market Risk

Market risk is the risk that changes in financial market prices and rates will reduce the dollar value of a security or a portfolio. Price risk for fixed-income products can be decomposed into a “general market” risk component—the risk that the market as a whole will fall in value—and a “specific” risk component, unique to the particular financial transaction under consideration, that also reflects the credit risk hidden in the instrument. In trading activities, risk arises both from open (unhedged) positions and from imperfect correlations between market positions that are intended to offset one another.

Market risk is given many different names in different contexts. For example, in the case of a fund, the fund may be marketed as tracking the performance of a certain benchmark. In this case, market risk is important to the extent that it creates a “risk of tracking error”. *Basis risk* is a term used in the risk management industry to describe the chance of a breakdown in the relationship between the price of a product, on the one hand, and the price of the instrument used to hedge that price exposure, on the other hand. Again, it is really just a context-specific form of market risk.

There are four major types of market risk:

1. Interest rate risk

The simplest form of interest rate risk is the risk that the value of a fixed-income security will fall as a result of an increase in market interest rates. However, in complex portfolios of interest-rate-sensitive assets, many different kinds of exposure can arise from differences in the maturities, nominal values, and reset dates of instruments and cashflows that are asset like (i.e., “longs”) and those that are liability like (i.e., “shorts”).

In particular, “curve” risk can arise in portfolios in which long and short positions of different maturities are effectively hedged against a *parallel shift* in yields but not against a change in the *shape of the yield curve*. Meanwhile, even where offsetting positions have the same maturity, basis risk can arise if the rates of the positions are imperfectly correlated. For example, three-month Eurodollar instruments and three-month Treasury bills both naturally pay three-month interest rates. However, these rates are not perfectly correlated with each other, and spreads between their yields may vary over time. As a result, a three-month Treasury bill funded by three-month Eurodollar deposits represents an imperfect offset or hedged position.

2. Equity price risk

This is the risk associated with volatility in stock prices. The general market risk of equity refers to the sensitivity of an instrument or portfolio value to a change in the level of broad stock market indices. The “specific” or “idiosyncratic” risk of equity refers to that portion of a stock’s price volatility determined by characteristics specific to the firm, such as its line of business, the quality of its management, or a breakdown in its production process. According

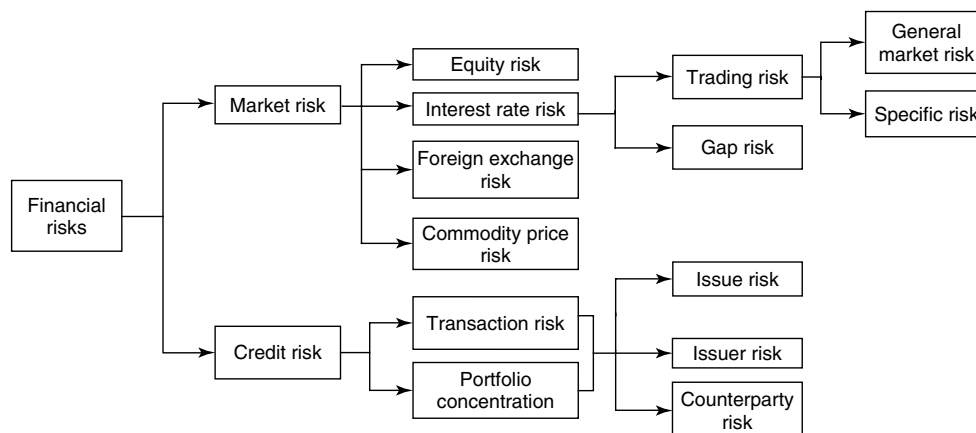

Figure 1 Schematic presentation, by categories, of financial risks

to portfolio theory, general market risk cannot be eliminated through portfolio diversification, whereas specific risk can be diversified away.

3. Foreign exchange risk

Foreign exchange risk arises from open or imperfectly hedged positions in a particular currency. These positions may arise as a natural consequence of business operations, rather than from any conscious desire to take a trading position in a currency. Foreign exchange volatility can sweep away the return from expensive cross-border investments, and at the same time place a firm at a competitive disadvantage in relation to its foreign competitors. It may also generate huge operating losses and, through the uncertainty it causes, inhibit investment. The major drivers of foreign exchange risk are imperfect correlations in the movement of currency prices and fluctuations in international interest rates. Although it is important to acknowledge exchange rates as a distinct market risk factor, the valuation of foreign exchange transactions requires knowledge of the behavior of domestic and foreign interest rates, as well as of spot exchange rates.

4. Commodity price risk

The price risk of commodities differs considerably from interest rate and foreign exchange risk, since most commodities are traded in markets in which the concentration of supply in the hands of a few suppliers can magnify price volatility. Fluctuations in the depth of trading in the market (i.e., market

liquidity) often accompany and exacerbate high levels of price volatility. Other fundamentals affecting a commodity price include the ease and cost of storage, which varies considerably across the commodity markets (e.g., from gold, to electricity, to wheat). As a result of these factors, commodity prices generally have higher volatilities and larger price discontinuities—that is, moments when prices leap from one level to another—than most traded financial securities. Commodities can be classified according to their characteristics as follows: hard commodities are non-perishable commodities, the markets for which are further divided into precious metals (e.g., gold, silver, and platinum), which have a high price/weight value and base metals (e.g., copper, zinc, and tin); soft commodities or commodities with a short shelf life and that are hard to store, mainly agricultural products (e.g., grains, coffee, and sugar); and energy commodities that consist of oil, gas, electricity, and other energy products.

Credit Risk

Credit risk is the risk that a change in the credit quality of a counterparty will affect the value of a security or a portfolio. Default, whereby a counterparty is unwilling or unable to fulfill its contractual obligations, is the extreme case; however, institutions are also exposed to the risk that a counterparty might be downgraded by a rating agency.

Credit risk is only an issue when the position is an asset, that is, when it exhibits a positive replacement

value. In that situation, if the counterparty defaults, the firm loses either all of the market value of the position or, more commonly, the part of the value that it cannot recover following the credit event. (The value it is likely to recover is called the *recovery value* or *recovery rate* when expressed as a percentage; the amount it is expected to lose is called the *loss given default*.)

Unlike the potential loss given default on coupon bonds or loans, the one on derivative positions is usually much lower than the nominal amount of the deal, and in many cases is only a fraction of this amount. This is because the economic value of a derivative instrument is related to its replacement or market value rather than its nominal or face value. However, the credit exposures induced by the replacement values of derivative instruments are dynamic: they can be negative at one point in time, and yet become positive at a later point in time after market conditions have changed. Therefore, firms must examine not only the current exposure measured by the current replacement value but also the profile of potential future exposures up to the termination of the deal.

Liquidity Risk

Liquidity risk comprises both “funding liquidity risk” and “asset liquidity risk”, though these two dimensions of liquidity risk are closely related. Funding liquidity risk relates to a firm’s ability to raise the necessary cash to roll over its debt, to meet the cash, margin and collateral requirements of counterparties, and (in the case of funds) to satisfy capital withdrawals. Funding liquidity risk can be managed through holding cash and cash equivalents, setting credit lines in place, and through monitoring “buying power”. (Buying powers refers to the amount a trading counterparty can borrow against assets under stressed market conditions.)

Asset liquidity risk, often simply called *liquidity risk*, is the risk that an institution will not be able to execute a transaction at the prevailing market price because there is, temporarily, no appetite for the deal on the “other side” of the market. If the transaction cannot be postponed, its execution may lead to substantial loss on the position. This risk is generally very hard to quantify.

Operational Risk

Operational risk (*see* **Operational Risk**) refers to *potential losses* resulting from inadequate systems, management failure, faulty controls, fraud, and human error.^b Many of the large losses from derivative trading over the last decade are the direct consequence of operational failures. Derivative trading is more prone to operational risk than cash transactions because derivatives are, by their nature, leveraged transactions. The valuation of complex derivatives also creates considerable operational risk. Very tight controls are an absolute necessity if a firm is to avoid large losses.

Operational risk includes “fraud”, for example, when a trader or other employee intentionally falsifies and misrepresents the risks incurred in a transaction. Technology risk, and principally computer systems risk, also falls into the operational risk category.

Human factor risk is a special form of operational risk. It relates to the losses that may result from human errors such as pushing the wrong button on a computer, inadvertently destroying a file, or entering the wrong value for the parameter input of a model.

Legal and Regulatory Risk

Legal and regulatory risk arises for a whole variety of reasons and is closely related to reputation risk (see below). For example, a counterparty might lack the legal or regulatory authority to engage in a risky transaction. In the derivative markets, legal risks often only become apparent when a counterparty, or an investor, loses money on a transaction and decides to sue the provider firm to avoid meeting its obligations. Another aspect of regulatory risk is the potential impact of a change in tax law on the market value of a position. For example, when the British government changed the tax code to remove a particular tax benefit during the summer of 1997, one major investment bank suffered huge losses.

Business Risk

Business risk refers to the classic risks of the world of business such as uncertainty about the demand for products, or the price that can be charged for those products, or the cost of producing and delivering products.

In the world of manufacturing, business risk is largely managed through core tasks of management, for example, choices about channel, products, suppliers, how products are marketed, and so on.

However, there remains the question of how business risk should be addressed within formal risk management frameworks and that have become prevalent in the financial industries.

Although business risks should surely be assessed and monitored, it is not obvious how to do this in a way that complements the banking industry's treatment of classic credit and market risks. There is also room for debate over whether business risks need to be supported by capital in the same explicit way (*see* **Economic Capital**). In the new Basel Capital Accord (*see* **Regulatory Capital**), "business risk" is excluded from the regulators' definition of operational risk, even though some researchers believe it to be a greater source of volatility in bank revenue than the operational event/failure risk that the regulators *have* included within bank minimum capital requirements.

Business risk is affected by such factors as the quality of the strategy and/ or the reputation of the firm as well as other factors. Therefore, it is common practice to view strategic and reputation risks as components of business risk and the risk literature sometimes refers to a complex of business/strategic/reputation risk. In this typology, we differentiate these three components.

Strategic Risk

Strategic risk refers to the risk of significant investments for which there is a high uncertainty about success and profitability. If the venture is not successful, then the firm will usually suffer a major write-off and its reputation among investors will be damaged.

Reputation Risk

Reputation risk is taking on a new dimension after the accounting scandals that defrauded the shareholders, bondholders, and employees of many major corporations during the boom in the equity markets in the late 1990s. Investigations into the mutual funds and insurance industry by New York Attorney General Eliot Spitzer have also made clear just how important a reputation for fair dealing is with both customers and

regulators. In a survey released in August 2004 by PricewaterhouseCoopers (PwC) and the Economist Intelligence Unit (EIU), 34% of the 134 international bank respondents believed that reputation risk is the biggest risk to market and shareholder value faced by banks, while market and credit risk scored only 25% each.

No doubt this was partly because corporate scandals like Enron, Worldcom, and others were still fresh in bankers' minds. Some experts, however, believe that reputation is a genuine emerging issue, and that the new Basel Capital Accord will help to shift the attention of regulators and investors from quantifiable risks like market and credit risk toward strategic and business risk.

Reputation risk poses a special threat to financial institutions because the nature of their business requires the confidence of customers, creditors, regulators, and the general market place. The development of a wide array of structured finance products, including financial derivatives for market and credit risk, asset-backed securities with customized cash flows, and specialized financial conduits that manage pools of purchased assets, has placed pressure on the interpretation of accounting and tax rules, and, in turn, has given rise to significant concerns about the legality and appropriateness of certain transactions. Involvement in such transactions may damage an institution's reputation and franchise value.

Financial institutions are also under increasing pressure to demonstrate their ethical, social, and environmental responsibility. As a defensive mechanism, 10 international banks from seven countries announced in June 2003 the adoption of the "Equator Principles", a voluntary set of guidelines developed by the banks for managing social and environmental issues related to the financing of projects in emerging countries. The Equator Principles are based on the policy and guidelines of the World Bank and International Finance Corporation (IFC) and require the borrower to conduct an environmental assessment for high-risk projects to address issues such as sustainable development and use of renewable natural resources, protection of human health, pollution prevention and waste minimization, socioeconomic impact, and so on.

Banks should clearly monitor and manage risks to their reputation. However, as for business risk, there is no clear industrial view on whether these risks can be meaningfully *measured* or whether they should

be supported by risk capital. In the case of reputation risk, the problem is compounded: a bank that reserves money against the danger of reputation damage may be tacitly admitting in advance that its conduct is reprehensible.

End Notes

^aFor a more detailed discussion of financial and nonfinancial risks, see Crouhy *et al.* [3]

^bThe Basel Committee on Banking Supervision [1] has identified the following event types as having the potential to result in substantial operational risk losses: internal fraud, for example, intentional misreporting of positions, employee theft, and insider trading on an employee's own account; external fraud, for example, robbery, forgery, check kiting and damage from computer hacking; employment practices, and workplace safety, for example, workers compensation claims, violation of employee health and safety rules, organized labor activities, discrimination claims and general liabilities; clients, products and business practices, for example, fiduciary breaches, misuse of confidential customer information, improper trading activities on the bank's account, money laundering, and sales of unauthorized products; damage to physical assets, for example, terrorism, vandalism, earthquakes, fires, and floods; business disruption and system failures, for example, hardware

and software failures, telecommunication problems, and utility outages; and execution, delivery and process management, for example, data entry errors, collateral management failures, incomplete legal documentation, unapproved access given to client accounts, nonclient counterparty misperformance, and vendor disputes (*see Regulatory Capital*).

Risk Management: Historical Perspectives

Financial risk management refers to the design and implementation of procedures for identifying, measuring, and managing financial risks. At the heart of any activity in financial markets lies a trade-off between expected profit and risk. Naturally, deciding on a course of action should be based on the best possible evaluation of risk. After all, ignoring risk is a sure recipe for financial disaster.

Financial risk management evolved as a distinct discipline in the early 1990s. This was made possible by advances in risk methodologies that, coupled with vast increases in computer processing capabilities, could be applied at the top level of financial institutions. This led to a new type of function, the financial risk manager, which is distinct from the usual business lines. By now, most financial institutions have a “Chief Risk Officer” reporting directly to the top management.

The 1970s and Earlier: Foundations of Risk Management

Modern risk management builds on a century of advances in analytical risk-management tools, as described in Table 1. To simplify, start with a position in a single financial instrument. Conceptually, risk measurement can be separated into two drivers. The first is exposure or change in the value of the position in response to changes in the risk factor(s). The second is the range of possible movements in the risk factors, which can be described by a probability distribution function. Risk measurement brings together these two drivers by describing the range of possible losses on the position.

As an example, consider the most basic financial instrument: a bond, which represents a promise of future cash flows. The value of the bond depends on the yield to maturity, which is the main risk factor. The linear part of this exposure is called *duration*. Duration is a measure of the sensitivity of bond prices to small movements in yields (*see Bond*). This concept was first developed by Macaulay [7] in 1938 and has become the cornerstone of fixed-income portfolio management. Similar concepts were

developed later for other instruments. For example, “delta” measures the linear exposure of an option relative to the underlying risk factor. For a long time, risk was evaluated by instrument or for separate business lines.

In 1952, Markowitz [8] developed the mean–variance framework (*see Risk–Return Analysis*), which emphasizes the importance of measuring risk in a total portfolio context. This view was the foundation for modern risk management and led to the award of the 1990 Nobel Prize in Economics.

By its nature, centralized risk measurement is a large-scale aggregation problem, which involves a large number of parameters. Consider, for example, the problem of allocating assets among the thousands of stocks available for investment. Generally, the joint movements in the stock prices can be described by a covariance matrix that lists all pairwise correlations. The problem, however, is that the number of coefficients in this matrix rises with the square of the number of stocks. Too many coefficients create several problems, ranging from numerical instability in the covariance matrix to loss of intuitive understanding of the economic drivers of risk. As a result, simplifications are useful.

In 1963, Sharpe [10] simplified the covariance structure of stocks with a one-factor model (*see Capital Asset Pricing Model*). This reduced the dimensionality of the covariance matrix to a number of coefficients that increased linearly with the number of stocks. Such simplification is at the heart of mapping methods in modern risk measurement. In addition, this decomposition leads to a neat decomposition of risk into a systematic factor and an idiosyncratic effect. The first component is common to all the stocks and cannot be diversified away. In contrast, idiosyncratic effects become less important in a large portfolio because they tend to cancel out each other. Sharpe then showed that the only risk that should be priced in equilibrium is systematic risk. This theory of asset pricing, known as the *capital asset pricing model (CAPM)*, led to the award of the 1990 Nobel Prize in Economics. In 1966, following Sharpe’s single-factor model, multiple-factor models were developed. These provide a more realistic description of common movements among risk factors that it still parsimonious.

In parallel, the financial industry was creating new financial instruments to manage, hedge, or take, financial risks. Derivatives are private contracts

whose value derives from some underlying price. Early instruments such as forwards or futures had linear exposures to risk factors. For instance, a farmer could hedge the price risk of a wheat harvest by shorting wheat futures. Because a forward or futures contract implies an obligation to buy or sell, the payoff is a linear function of movements in the underlying risk factor, which is the price of wheat in this case. A drop in this price would cause a loss in the value of the harvest, but this should be largely hedged by a gain on the futures position. Commodity contracts exist since 1874; foreign currency futures were introduced in 1972 and interest rate futures in 1975. Over time, the industry started to offer more flexible contracts such as options, which involve the right, as opposed to the obligation, to buy or sell. This right creates a payoff function that is nonlinear in the underlying asset. Such instruments are more complicated to price and hedge.

In 1973, Black and Scholes [3] developed a breakthrough option pricing model (*see* **Black–Scholes Formula**), which led to the award of the 1997 Nobel Prize in Economics, along with Merton. The model provides a particularly elegant formula for the pricing of options, based on a remarkably small set of inputs. It also generates measures of exposure, or sensitivity, which are called the *Greeks*. The timing of this discovery was fortuitous, as equity options started trading in 1973.

The 1980s: Start of Expansion of Derivatives Markets

The need for efficient risk-management tools led to rapid growth in the market for derivatives. These markets can be described in terms of their notional

Table 2 Global markets for derivatives: outstanding contracts (\$ billion)

Instruments, by location and type	1986	2007
Exchange-traded instruments	583	80 624
Interest rate	516	71 095
Currency	18	9237
Stock index	49	292
OTC instruments	500	596 004
Interest rate swaps	400	393 138
Currency swaps	100	56 238
Credit default swaps	0	57 894
Equity, commodity	0	17 509
Total	1083	676 628

outstanding amounts, because the face value represents the amount of exposure exchanged. The year 1986 was the first one for which we started having reliable market statistics. Before that, markets were smaller or even nonexistent. Table 2 shows that the derivatives markets have grown from \$1 trillion to \$677 trillion in 21 years from 1986 to 2007.

The 1980s witnessed the introduction of major new instruments: currency swaps (1981), interest rate swaps (1982), Eurodollar futures (1981), equity index futures (1982), and swaptions (1985), just to name a few.

As a result of the expansion of these markets, risk-management methods started to take hold in the financial industry. As exposures grew, financial institutions started to impose position limits for fixed-income exposures by duration buckets. Later, positions were imposed on options using the “Greeks”. Banks also began to evaluate performance in terms of risk-adjusted profits. Economic capital, which is essentially a Value at Risk (VAR) measure, was assigned to business lines (*see* **Economic Capital**). This led to risk-adjusted return on capital (RAROC) measures, which deflate expected profits by economic capital, thus providing a consistent view of risk-adjusted profitability across businesses (*see* **Risk-adjusted Return on Capital (RAROC)**).

The expansion of these markets was followed by a number of spectacular losses in the early 1990s, however. Headline cases such as Orange County (1994), Metallgesellschaft (1994), and Barings (1995) threatened to create a backlash against derivatives whose risks were apparently not fully appreciated by

their users. In response, the industry devised more comprehensive measures of risk.

The 1990s: Modern Risk Management

Prodded by regulators, the Group of Thirty [5] endorsed VAR in 1993 as part of “best practices” for dealing with derivatives. VAR had been developed at Morgan, in response to the request of its chairman, “At the close of each business day, tell me what the market risks are across all businesses and locations.” VAR summarizes the worst loss over a target horizon that will not be exceeded with a given level of confidence. For instance, at that time, Morgan’s daily VAR was approximately \$15 million at the 95% level of confidence. In other words, the bank should not expect to lose more than \$15 million in 95 days out of 100. This single number describes the risk of the entire trading portfolio of the bank and therefore involves a large-scale aggregation of positions (*see* Jorion [6] and Figure 1 in **Market Risk**).

Morgan [9] then unveiled its “RiskMetrics” system in October 1994. RiskMetrics, available free on the Internet, provided a datafeed for computing VAR, as well as a detailed technical manual. The widespread availability of data immediately engaged the industry and spurred academic and practitioner research into risk management. The methodology was partly based on new models of time-variation in risk, such as the autoregressive conditional heteroskedasticity (ARCH) model, developed by Engle [4] in 1982 and for which he received the 2003 Nobel Prize in Economics.

The basic idea behind VAR is not new, however. It can be traced back to the mean–variance framework developed by Markowitz in 1952. What is new is the integration of all market risks into a centralized common “metric”, combined with the use of current positions. Consider again the two conceptual drivers of risk, exposure, and range of possible movements in the risk factors. This information should be combined into a distribution of dollar gains and losses, which can be summarized by one number, the quantile at some confidence level, or VAR. An alternative measure of risk is the conditional VAR (CVAR), which is the average of losses beyond VAR (*see Expected Shortfall*). The same analysis can be performed for a portfolio of financial instruments exposed to multiple sources of risk.

The new aspect of modern risk management is that risk measures are now position based. Traditionally, risk was measured from historical return information. Nowadays, however, proprietary trading portfolios turn over very quickly. As a result, returns-based risk measures give incomplete information. This is because today’s risk profile may be very different from the average risk profile over a recent history.

Position-based risk measures, however, are rather complex to build. They involve large-scale structural bottom-up models that aggregate risks from individual position data. The choice of the model reflects a trade-off between speed and accuracy. A portfolio may contain millions of positions, which cannot be modeled individually. Instead, the manager has to choose a set of risk factors that spans the risk space effectively. The risk measurement system then has to “map” all the positions on these risk factors, replacing the value of all positions by exposures. Next, these exposures are aggregated across the entire portfolio. The last step then combines the exposures with the statistical distribution of risk factors, which gives a distribution of profits and losses at the top level.

This modern risk architecture has many more uses than for reporting a single VAR number, however. Once this system is in place, the risk manager can easily examine the effect of extreme or unusual situations. In fact, stress testing is an important complement to VAR because VAR only provides an estimate of losses under normal market conditions, that is, at a prespecified confidence level. Once a risk-management system is in place, however, stress scenarios are just hypothetical realizations of the risk factors (*see Stress Testing*). More generally, risk manager should be keenly aware of weaknesses in their risk models.

By now, VAR is the most widely used measure of market risk. Its use has been widely sanctioned by regulators. In 1996, for example, the Basel Committee on Banking Supervision [1] passed a new rule allowing commercial banks to compute their capital charge for market risk based on their own internal VAR measures. This methodology has spread to most financial institutions. Risk systems are also increasingly used to control risk. Position limits are now routinely based on VAR numbers and stress-test results.

The 2000s: Extensions to Other Risks

VAR methods were initially applied to market risk, which is the risk of losses due to movements in the level or volatility of market prices. Later, modern risk-management techniques were extended to credit risk and operational risk. This led to another round of fundamental developments.

Credit risk is the risk of losses due to the fact that counterparties may be unwilling or unable to fulfill their contractual obligations. This is a major source of risk for the economy and has proved much more damaging than episodic losses due to market risk. Time and again, countries have experienced crises in their banking sector due to credit losses that required expensive recapitalizations.

Toward the end of the 1990s, several portfolio credit risk models were developed. Examples are KMV and CreditMetrics. These models integrate the various components of credit risk, which include probability of default, exposures, and loss given default, as well as all their correlations, in large-scale models.

The banking industry dutifully started to measure their credit risk and soon realized that they needed new financial instruments to manage their credit exposures. This led to the rapid expansion of credit default swaps (*see Credit Default Swaps*), which were created in 1994. These instruments created a new market for the exchange of pure credit risk. The market expanded quickly because of its low transaction costs and also because it allowed short positions in credit, which was not feasible before. Buying a credit default swap creates a profit if the credit event happens. This is akin to shorting a corporate bond but much more practical. By 2007, the outstanding notional amount for credit default swaps was close to \$60 trillion, several times the size of the corporate bond markets.

Credit risk models led to fundamental changes in the banking industry. The industry soon realized that holding loans on their books immobilized large amounts of capital and was not very profitable. In response, banks moved to a model where they could reap fees from the origination of loans, which were then repackaged and distributed to other investors. This led to the creation of the structured credit industry, where pools of debt are put together and sold as securities with various levels of priority on the collateral.

Structured credit had its roots in the collateralized mortgage obligation (CMO) market developed in the early 1980s. Mortgage loans were placed in pools and sold to investors in the form of tranches with different priority claims. The same principle applies to collateralized debt obligations (CDOs, *see Collateralized Debt Obligations (CDO)*). By 2001, the methodology of credit risk portfolio measurement was applied to CDOs, allowing rapid pricing of the various tranches. This spurred an exponential growth of this market, until 2007.

This growth revealed flaws, however. On the one hand, these new instruments dispersed risk to investors and financial institutions across the globe, which is a positive development. In the case of the subprime crisis of 2007, the subprime losses were considerable, amounting to several hundred billion dollars. In the past, such losses could have bankrupted the US financial system. This has not happened, fortunately. On the other hand, this securitization process led to laxer credit standards that aggravated the scale of losses. Lenders were more interested in generating fee income than about the ultimate creditworthiness of borrowers because losses would be borne by somebody else, after all.

In addition to credit risk, risk measurement techniques are now being applied to operational risk, which is the risk of losses resulting from inadequate or failed internal processes, people, and systems or from external events (*see Operational Risk*). Operational risk has caused large losses to financial institutions. In 1995, a single rogue trader caused a loss of \$1.3 billion at Barings, which led to the failure of the bank. As a result, the Basel Committee on Banking Supervision [2] mandated a new capital charge against operational risk, which can be based on a VAR measure. Admittedly, however, operational risk measures are much less precise than those covering market and credit risk. Data on operational risk losses are scarcer than for other types of risk. In addition, losses may not be applicable to banks with different control environments.

In the 2000s, many institutions started to develop an integrated approach to enterprisewide risk management (ERM). This is an extension of the VAR concept, whose essence is centralization, to firmwide risks. ERM consists of identification, assessment, and measurement of all relevant risks, including market, credit, operational, and business risk. In the past, risks were considered separately from each other and

hedged one at a time. In contrast, an integrated view accounts for diversification effects and allows more efficient use of capital. It can also help the firm manage the trade-off between risk and expected profit across and within business lines.

Conclusions

It is fair to conclude by stating that modern risk-management techniques have truly revolutionized the financial industry. Institutions are now busily trying to measure and manage their aggregate risks.

The elegance of these risk models should not create a sense of false security, however. VAR risk measures are not designed to provide worst-loss estimates. We should expect losses to exceed VAR numbers with some regularity. In addition, these risk models can be sensitive to the underlying assumptions. This is why stress tests should be used on a regular basis, including scenario analyses and model tests. A good risk manager should understand the weak spots of the models, combined with an economic intuition of the fundamental driver of the risk factors. The subprime crisis that started in 2007, for example, illustrated severe shortcomings in risk models, as institutions suffered losses that were much worse than anticipated, both in terms of frequency and size. A widespread reaction was for these institutions to strengthen their risk-management structures.

More fundamentally, quantitative risk measurement tools do not apply well to some important sources of risk, such as liquidity risk. This is the risk of loss due to the inability to meet payments obligations, which may force early liquidation of assets at fire-sale prices. Creditors may refuse to roll over their funding, creating “bank runs” such as those that befell Northern Rock and Bear Stearns. At an even broader level, no model can fully account for systemic risk, which arises when by default one institution has a cascading effect on other firms, thus posing a threat to

the viability of the entire financial system. Systemic risk should be handled by the central bank, which is effectively becoming the risk manager of last resort.

Convex Risk Measures

Quantifying the risk of the uncertainty in the future value of a portfolio is one of the key tasks of risk management. This quantification is usually achieved by modeling the uncertain payoff as a random variable, to which then a certain functional is applied. Such functionals are usually called *risk measures*. The corresponding industry standard, Value at Risk, is often criticized for encouraging the accumulation of shortfall risk in particular scenarios. This deficiency has led to a search for more appropriate alternatives. The first step of this search consists in specifying certain desirable axioms for risk measures. In the second step, one then tries to characterize those risk measures that satisfy these axioms and to identify suitable examples. In the section Monetary, Convex, and Coherent Risk Measures, we first provide the various axiom sets for *monetary*, *convex*, and *coherent* risk measures. In the section Acceptance Sets, the representation of monetary risk measures in terms of their *acceptance sets* is briefly discussed. The general *dual representation* for convex and coherent risk measures is given in the section Dual Representation. Various examples are provided in the section Examples and Applications. In many situations, it is reasonable to assume that a risk measure depends on the randomness of the portfolio value only through its probability law. Such risk measures are usually called *law invariant*. They are discussed in the section Law-invariant Risk Measures. Finally, section Conditional Convex Risk Measures and Time Consistency analyzes various notions of *dynamic consistency* that naturally arise in a multiperiod setting.

Monetary, Convex, and Coherent Risk Measures

The uncertainty in the future value of a portfolio is usually described by a function $X : \Omega \rightarrow \mathbb{R}$, where Ω is a fixed set of scenarios. For instance, X can be the (discounted) value of the portfolio or the sum of its P&L and some economic capital. The goal is to determine a number $\rho(X)$ that quantifies the risk and can serve as a capital requirement, that is, as the minimal amount of capital that, if added to the position and invested in a risk-free manner, makes the position acceptable. The following axiomatic approach

to such risk measures was initiated in the coherent case by [1] and later extended to the class of convex risk measures in [26, 30, 33]. In the sequel, $\mathcal{X}$ denotes a given linear space of functions $X : \Omega \rightarrow \mathbb{R}$ containing the constants.

Definition 1 A mapping $\rho : \mathcal{X} \rightarrow \mathbb{R} \cup \{+\infty\}$ is called a *monetary risk measure* if $\rho(0)$ is finite and if ρ satisfies the following conditions for all $X, Y \in \mathcal{X}$.

- *Monotonicity*: if $X \leq Y$, then $\rho(X) \geq \rho(Y)$.
- *Cash invariance*: if $m \in \mathbb{R}$, then $\rho(X + m) = \rho(X) - m$.

The financial meaning of monotonicity is clear: the downside risk of a position is reduced if the payoff profile is increased. Cash invariance is also called *translation property*; in the normalized case $\rho(0) = 0$ and $\rho(1) = -1$, it is equivalent to *cash additivity*, that is, $\rho(X + m) = \rho(X) + \rho(m)$. This is motivated by the interpretation of $\rho(X)$ as a capital requirement, that is, $\rho(X)$ is the amount that should be raised in order to make X acceptable from the point of view of a supervising agency. Thus, if the risk-free amount m is appropriately added to the position or to the economic capital, then the capital requirement is reduced by the same amount. Note that we work with discounted quantities (cf. [22] for a discussion of forward risk measures and interest rate ambiguity).

Definition 2 A monetary risk measure ρ is called a *convex risk measure* if it satisfies the following:

- *Convexity*: $\rho(\lambda X + (1 - \lambda)Y) \leq \lambda \rho(X) + (1 - \lambda)\rho(Y)$, for $0 \leq \lambda \leq 1$.

Consider the collection of possible future outcomes that can be generated with the resources available to an investor: one investment strategy leads to X , while a second strategy leads to Y . If one *diversifies*, spending only the fraction λ of the resources on the first possibility and using the remaining part for the second alternative, one obtains $\lambda X + (1 - \lambda)Y$. Thus, the axiom of convexity gives a precise meaning to the idea that diversification should not increase the risk. This idea becomes even clearer when we note that, for a monetary risk measure, convexity is in fact equivalent to the weaker requirement of

- *Quasi convexity*: $\rho(\lambda X + (1 - \lambda)Y) \leq \max(\rho(X), \rho(Y))$, for $0 \leq \lambda \leq 1$.

Definition 3 A convex measure of risk ρ is called a *coherent risk measure* if it satisfies the following:

- *Positive homogeneity*: if $\lambda \geq 0$, then $\rho(\lambda X) = \lambda \rho(X)$.

Under the assumption of positive homogeneity, the convexity of a monetary risk measure is equivalent to the following:

- *Subadditivity*: $\rho(X + Y) \leq \rho(X) + \rho(Y)$.

This property allows to decentralize the task of managing the risk arising from a collection of different positions: if separate risk limits are given to different “desks”, then the risk of the aggregate position is bounded by the sum of the individual risk limits.

Value at Risk at level $\alpha \in]0, 1]$, defined for random variables X on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ by

$$V @ R_\alpha(X) = \inf\{m \in \mathbb{R} \mid \mathbb{P}[X + m < 0] \leq \alpha\} \quad (1)$$

is a monetary risk measure that is positively homogeneous but not subadditive and hence not convex (see **Value-at-Risk**). *Average Value at Risk* at level $\lambda \in]0, 1]$,

$$AV @ R_\lambda = \frac{1}{\lambda} \int_0^\lambda V @ R_\alpha(X) \, d\alpha \quad (2)$$

also called *Conditional Value at Risk*, *expected shortfall*, or *Tail Value at Risk* (see **Expected Shortfall**), is a coherent risk measure. Other examples are discussed in Section “Examples and Applications”.

It is sometimes convenient to reverse signs and to emphasize on the *utility* of a position rather than on its risk. Thus, if ρ is a convex risk measure, then $\phi(X) := -\rho(X)$ is called a *concave monetary utility functional*. If ρ is coherent, then ϕ is called a *coherent monetary utility functional*.

Acceptance Sets

A monetary measure of risk ρ induces the set

$$\mathcal{A}_\rho := \{X \in \mathcal{X} \mid \rho(X) \leq 0\} \quad (3)$$

of positions that are acceptable in the sense that they do not require additional capital. The set $\mathcal{A}_\rho$ is called

the *acceptance set* of ρ . One can show that ρ is a convex risk measure if and only if $\mathcal{A}_\rho$ is a convex set and that ρ is positively homogeneous if and only if $\mathcal{A}_\rho$ is a cone. In particular, ρ is coherent if and only if $\mathcal{A}_\rho$ is a convex cone. The acceptance set completely determines ρ , because

$$\rho(X) = \inf\{m \in \mathbb{R} \mid m + X \in \mathcal{A}_\rho\} \quad (4)$$

Moreover, $\mathcal{A} := \mathcal{A}_\rho$ satisfies the following properties.

$$\mathcal{A} \cap \mathbb{R} \neq \emptyset \quad (5)$$

$$\inf\{m \in \mathbb{R} \mid X + m \in \mathcal{A}\} > -\infty \text{ for all } X \in \mathcal{X} \quad (6)$$

$$X \in \mathcal{A}, Y \in \mathcal{X}, Y \geq X \implies Y \in \mathcal{A} \quad (7)$$

Conversely, one can take a given class $\mathcal{A} \subset \mathcal{X}$ of acceptable positions as the primary object. For a position $X \in \mathcal{X}$, we can then define

$$\rho_{\mathcal{A}}(X) := \inf\{m \in \mathbb{R} \mid m + X \in \mathcal{A}\} \quad (8)$$

If $\mathcal{A}$ satisfies the properties (5)–(7), then $\rho_{\mathcal{A}}$ is a monetary risk measure. If $\mathcal{A}$ is convex, then so is $\rho_{\mathcal{A}}$. If $\mathcal{A}$ is a cone, then $\rho_{\mathcal{A}}$ is positively homogeneous. Note that, with this notation, equation (4) takes the form $\rho_{\mathcal{A}_\rho} = \rho$. The validity of the analogous identity $\mathcal{A}_{\rho_{\mathcal{A}}} = \mathcal{A}$ requires that $\mathcal{A}$ satisfies a certain closure property.

Dual Representation

Suppose now that $\mathcal{X}$ consists of measurable functions on $(\Omega, \mathcal{F})$. A *dual representation* of a convex risk measure ρ has the form

$$\rho(X) = \sup_{Q \in \mathcal{M}} (E_Q[-X] - \alpha(Q)) \quad (9)$$

Here, $\mathcal{M}$ is a set of probability measures on $(\Omega, \mathcal{F})$ such that $E_Q[X]$ is well defined for all $Q \in \mathcal{M}$ and $X \in \mathcal{X}$. The functional $\alpha : \mathcal{M} \rightarrow \mathbb{R} \cup \{+\infty\}$ is called *penalty function*.

The elements of $\mathcal{M}$ can be interpreted as possible probabilistic models, which are taken more or less seriously according to the size of the penalty $\alpha(Q)$. Thus, the value $\rho(X)$ is computed as the worst-case expectation taken over all models $Q \in \mathcal{M}$ and penalized by $\alpha(Q)$ (see [8, 28, 42]).

In the dual representation theory of convex risk measures, one aims at deriving a representation (9)

in a systematic manner. The general idea is to apply convex duality. For every $Q \in \mathcal{M}$, we define the *minimal penalty function* of ρ by

$$\alpha_\rho(Q) := \sup_{X \in \mathcal{X}} (E_Q[-X] - \rho(X)) = \sup_{X \in \mathcal{A}_\rho} E_Q[-X] \quad (10)$$

With additional assumptions on the structure of $\mathcal{X}$ and on continuity properties of ρ , it is often possible to derive the representation

$$\rho(X) = \sup_{Q \in \mathcal{M}} (E_Q[-X] - \alpha_\rho(Q)) \quad (11)$$

via Fenchel–Legendre duality. In this case, ρ is coherent if and only if α_ρ takes only the values 0 and $+\infty$, and so

$$\rho(X) = \sup_{Q \in \mathcal{Q}_\rho} E_Q[-X] \quad (12)$$

where $\mathcal{Q}_\rho$ consists of all $Q \in \mathcal{M}$ with $\alpha_\rho(Q) = 0$. We now discuss some situations in which representation (11) can be obtained. In general, however, it may be necessary to consider extended sets $\mathcal{M}$ that also contain, for example, finitely additive set functions. Dual representation theory goes back to [1, 18, 26, 30, 32–34].

First, let $\mathcal{X}$ be the space of all bounded measurable functions on $(\Omega, \mathcal{F})$. Then, every convex risk measure ρ takes only finite values and is Lipschitz continuous with respect to the supremum norm. For $\mathcal{M}$, we can take the set of all probability measures on $(\Omega, \mathcal{F})$. The validity of the dual representation (9) implies that ρ is *continuous from above* in the sense that

$$X_n \searrow X \implies \rho(X_n) \nearrow \rho(X) \quad (13)$$

On the other hand, the condition of *continuity from below*,

$$X_n \nearrow X \implies \rho(X_n) \searrow \rho(X) \quad (14)$$

is equivalent to the validity of the *strong representation*

$$\rho(X) = \max_{Q \in \mathcal{M}} (E_Q[-X] - \alpha_\rho(Q)) \quad (15)$$

in which for every $X \in \mathcal{X}$ the maximum is attained by some $Q \in \mathcal{M}$. In particular, continuity from below is stronger than the continuity from above. Continuity

from above is equivalent to the so-called *Fatou property*,

$$\liminf_{n \uparrow \infty} \rho(X_n) \geq \rho(X) \text{ for any bounded sequence } (X_n) \text{ converging pointwise to } X \quad (16)$$

Continuity from below is equivalent to the stronger *Lebesgue property*,

$$\lim_{n \uparrow \infty} \rho(X_n) = \rho(X) \text{ for any bounded sequence } (X_n) \text{ converging pointwise to } X \quad (17)$$

Next, we fix a reference probability measure $\mathbb{P}$ on $(\Omega, \mathcal{F})$ and consider the case in which $\mathcal{X} = L^p := L^p(\Omega, \mathcal{F}, \mathbb{P})$ for some $p \in [1, \infty]$. This choice implicitly requires that $\rho(X) = \rho(\tilde{X})$ whenever $X = \tilde{X}$ $\mathbb{P}$ -almost surely. For $\mathcal{M}$, we take the set of all probability measures that are absolutely continuous with respect to $\mathbb{P}$ and whose density belongs to L^q , where $q = p/(p-1)$ is the dual exponent.

The space $\mathcal{X} = L^\infty$ can be regarded as a subset of the space of all bounded measurable functions, and so all corresponding results carry over. In addition, continuity from above (or, equivalently, the Fatou property) of ρ is now even equivalent to a dual representation (11) in terms of probability measures.

For a convex risk measure ρ on $\mathcal{X} = L^p$ with $1 \leq p < \infty$, the existence of a dual representation (11) is equivalent to the lower semicontinuity of ρ with respect to the standard L^p -norm. If ρ takes only finite values, then it is even Lipschitz continuous and admits a strong representation (15). Here, we assume for simplicity that $(\Omega, \mathcal{F}, \mathbb{P})$ is atomless and L^2 is separable.

For the discussion of the dual representation of convex risk measures on spaces of bounded measurable functions, we refer to [28, 37, 38]. For L^p spaces, see [23, 36] and the references therein. Representation theory on Orlicz spaces is considered in [9].

Examples and Applications

In this section, we take $\mathcal{X} = L^\infty(\Omega, \mathcal{F}, \mathbb{P})$. The class of convex risk measures comprises many of the common valuation methods in finance and economics. The risk-neutral expectation in a nice arbitrage-free

market model, for instance, clearly corresponds to a coherent risk measure. If the market model is incomplete, then the cost of superhedging a position $X \in \mathcal{X}$ is given by the coherent risk measure

$$\sup_{Q \in \mathcal{P}} E_Q[-X] \quad (18)$$

where $\mathcal{P}$ is the set of equivalent local martingale measures (see **Superhedging**). If one imposes additional convex trading constraints, the cost of superhedging is a convex risk measure whose representation (9) is explicitly known (see [24, 26, 28]).

Let us now consider the case in which valuation of positions $X \in \mathcal{X}$ is based on the expected utility $\mathbb{E}[u(X)]$ for a concave and strictly increasing function $u : \mathbb{R} \rightarrow \mathbb{R}$. Then, a position can be called *acceptable* if $E_Q[u(X)]$ is bounded from below by $u(c)$ for a given threshold c . The set

$$\mathcal{A} := \{X \in \mathcal{X} \mid E_Q[u(X)] \geq u(c)\} \quad (19)$$

is a valid and convex acceptance set. Hence, $\rho_{\mathcal{A}}$, defined by equation (8), is a convex risk measure called *utility-based shortfall risk measure*. It is continuous from below and admits the strong representation (15) with minimal penalty function

$$\alpha_{\rho}(Q) = \inf_{\lambda > 0} \frac{1}{\lambda} \left(\mathbb{E} \left[\tilde{u} \left(\lambda \frac{dQ}{d\mathbb{P}} \right) \right] - u(c) \right) \quad (20)$$

where $\tilde{u}(y) = \sup_x (u(x) - xy)$ denotes the convex conjugate function of u (see [26] or [28]). In the exponential utility case with $u(x) = -e^{-\theta x}$ for some $\theta > 0$, we obtain for $c = 0$ the *entropic risk measure*,

$$\rho^{\text{ent}}(X) = \frac{1}{\theta} \log \mathbb{E} [e^{-\theta X}] \quad (21)$$

Its minimal penalty function is given by $\alpha_{\rho}(Q) = \theta^{-1} H(Q|\mathbb{P})$, where

$$H(Q|\mathbb{P}) = \mathbb{E} \left[\frac{dQ}{d\mathbb{P}} \log \frac{dQ}{d\mathbb{P}} \right] \quad (22)$$

is the relative entropy of $Q \ll \mathbb{P}$ (see [28]). For the role of entropic risk measures in problems of risk transfer, (see [3]).

To introduce another closely related class of concave monetary utility functionals, let $g : [0, \infty[\rightarrow \mathbb{R} \cup \{+\infty\}$ be a lower semicontinuous convex function satisfying $g(1) < \infty$ and the superlinear growth

condition $g(x)/x \rightarrow +\infty$ as $x \uparrow \infty$. Associated to it is the *g-divergence*

$$I_g(Q|\mathbb{P}) := \mathbb{E} \left[g \left(\frac{dQ}{d\mathbb{P}} \right) \right], \quad Q \ll \mathbb{P} \quad (23)$$

as introduced in [14, 15]. The *g-divergence* $I_g(Q|\mathbb{P})$ can be interpreted as a statistical distance between the hypothetical model Q and the reference measure $\mathbb{P}$, so that $\gamma_g(Q) := I_g(Q|\mathbb{P})$ is a natural choice for a penalty function. The risk measure

$$\rho_g(X) := \sup_{Q \ll \mathbb{P}} (E_Q[-X] - I_g(Q|\mathbb{P})) \quad (24)$$

corresponding to such a divergence penalty, is continuous from below, and $I_g(\cdot|\mathbb{P})$ is its minimal penalty function. The corresponding concave utility functional, $\phi_g = -\rho_g$, was called *optimized certainty equivalent* in [5]. This name stems from the variational identity

$$\phi_g(X) = \sup_{z \in \mathbb{R}} (\mathbb{E}[u(X - z)] + z), \quad X \in L^{\infty} \quad (25)$$

where $u(x) = \inf_{z > 0} (xz + g(z))$ is the concave conjugate function of g (see [4, 47]). In [13], the name *divergence utility* is used. Note that the particular choice $g(x) = x \log x$ corresponds to the relative entropy, $I_g(Q|\mathbb{P}) = H(Q|\mathbb{P})$, and so ρ_g coincides with the entropic risk measure. Another important example is provided by taking $g(x) = 0$ for $x \leq \lambda^{-1}$ and $g(x) = \infty$ otherwise, so that the corresponding coherent risk measure is given by Average Value at Risk at level λ :

$$\begin{aligned} AV @ R_{\lambda}(X) &= \inf_{Q \in \mathcal{Q}_{\lambda}} E_Q[X] \quad \text{for} \\ \mathcal{Q}_{\lambda} &:= \left\{ Q \ll \mathbb{P} \mid \frac{dQ}{d\mathbb{P}} \leq \frac{1}{\lambda} \right\} \end{aligned} \quad (26)$$

see Definition (1) and **Expected Shortfall**. In this case, we have $u(x) = 0 \wedge x/\lambda$ and hence get the classical duality formula

$$AV @ R_{\lambda}(X) = \frac{1}{\lambda} \inf_{z \in \mathbb{R}} (\mathbb{E}[(z - X)^+] - \lambda z) \quad (27)$$

as a special case of equation (25). The mixtures of Average Value at Risk at various levels λ are called *spectral risk measures*. They are again coherent risk measures and discussed in more detail in **Spectral Measures of Risk**.

Many of these risk measures can be extended in a straightforward manner to spaces of unbounded random variables (see [23] for a systematic study of such extensions). For Gaussian random variables X , Value at Risk, Average Value at Risk, and the spectral risk measures all take the form

$$\rho(X) = \mathbb{E}[-X] + c \cdot \sigma(X) \quad (28)$$

with different constants c ; for the entropic risk measure, the standard deviation $\sigma(X)$ is replaced by the variance $\sigma^2(X)$.

Model uncertainty is another situation in which it is natural to consider risk measures, due to the interpretation of the measures Q in the dual representation (9) as suitably penalized probabilistic models. This idea already appears in robust statistics [34]. More recently, coherent and convex risk measures were applied in obtaining numerical representations of investors who are averse against both risk and model uncertainty [27, 29, 32, 43] or to define *measures of model uncertainty* [16].

In a financial market model, it makes sense to combine risk measurement with dynamic or static hedges. For instance, measuring the residual risk of a position after hedging by a convex risk measure ρ is equivalent to using the convex risk measure that arises as the *inf-convolution* of ρ and the superhedging risk measure, defined at the beginning of this section (cf. [3, 26, 28, 46] and the references therein).

Law-invariant Risk Measures

Here, we discuss those convex risk measures ρ on $\mathcal{X} = L^\infty(\Omega, \mathcal{F}, \mathbb{P})$ that satisfy $\rho(X) = \rho(\tilde{X})$ for random variables $X, \tilde{X} \in \mathcal{X}$ that have the same law under $\mathbb{P}$. These risk measures are usually called *law invariant*. Examples from the preceding section are Average Value at Risk, the spectral risk measures, the utility-based shortfall risk measures, and the optimized certainty equivalents. Under mild conditions on the underlying probability space, every

law-invariant convex risk measure ρ can be represented in the form

$$\rho(X) = \sup_{\mu} \left(\int_{(0,1]} AV @ R_{\lambda}(X) \mu(d\lambda) - \beta(\mu) \right) \quad (29)$$

where the supremum is taken over all Borel probability measures μ on $]0,1]$ and $\beta(\mu)$ is a penalty for μ . Under the additional assumption of continuity from above, this representation was obtained in the coherent case by [41] and later extended by [17, 28, 31, 39]. More recently, it was shown in [35] that the condition of continuity from above can actually be dropped.

Conditional Convex Risk Measures and Time Consistency

A risk measure should take into account the available information, and it should do so in a consistent manner as new information comes in. Here, we limit the discussion to discrete time and fix a filtration $(\mathcal{F}_t)_{t=0,1,\dots}$ on $(\Omega, \mathcal{F}, \mathbb{P})$; for continuous time and the connection to backward stochastic differential equations (BSDEs), (see [10, 20]) and the references therein. A *conditional convex risk measure* at time t is now defined as a map

$$\rho_t : L^\infty \rightarrow L_t^\infty := L^\infty(\Omega, \mathcal{F}_t, \mathbb{P}) \quad (30)$$

which satisfies the obvious conditional versions of monotonicity, cash invariance, and convexity where the constants m and λ are replaced by functions in L_t^∞ . The associated *acceptance set*

$$\mathcal{A}_t := \{X \in L^\infty \mid \rho_t(X) \leq 0\} \quad (31)$$

is conditionally convex (i.e., $\alpha X + (1 - \alpha)Y \in \mathcal{A}_t$ for $X, Y \in \mathcal{A}_t$ and $\mathcal{F}_{t-1}$ -measurable α with $0 \leq \alpha \leq 1$) and it determines ρ_t via

$$\rho_t(X) = \text{ess inf} \{Y \in L_t^\infty \mid X + Y \in \mathcal{A}_t\} \quad (32)$$

The *Fatou property* is now equivalent to a *dual representation* of the form

$$\rho_t(X) = \text{ess sup}_{Q \in \mathcal{M}} (E_Q[-X \mid \mathcal{F}_t] - \alpha_t(Q)) \quad (33)$$

where the conditional penalty function α_t is given by

$$\alpha_t(Q) = \operatorname{ess\,sup}_{X \in \mathcal{A}_t} E_Q[-X | \mathcal{F}_t] \quad (34)$$

The inequality $\geq$ immediately follows from the definition of α_t , and the converse inequality is obtained by using the dual representation of the unconditional convex risk measure $\rho(X) := \mathbb{E}[\rho_t(X)]$ (cf. [6, 11, 21, 25, 45]).

For the conditional entropic risk measure,

$$\rho_t^{\text{ent}}(X) = \frac{1}{\theta} \log \mathbb{E}[e^{-\theta X} | \mathcal{F}_t] \quad (35)$$

the dual representation holds with

$$\alpha_t(Q) = \frac{1}{\theta} \widehat{H}_t(Q|P) \quad (36)$$

where

$$\widehat{H}_t(Q|P) := \mathbb{E} \left[\frac{Z}{Z_t} \log \frac{Z}{Z_t} \middle| \mathcal{F}_t \right] I_{\{Z_t > 0\}} \quad (37)$$

denotes the *conditional entropy* of $Q \in \mathcal{M}$ with respect to P , defined in terms of the densities $Z = dQ/dP$ and $Z_t = dQ/dP|_{\mathcal{F}_t}$.

In our dynamic setting, the key question is how the conditional risk assessments of a financial position at different times are connected to each other.

Definition A dynamic risk measure given by a sequence of conditional convex risk measures $(\rho_t)_{t=0,1,\dots}$ is called *time-consistent* if

$$\rho_{t+1}(X) \leq \rho_{t+1}(Y) \implies \rho_t(X) \leq \rho_t(Y) \quad (38)$$

and this is equivalent to recursiveness:

$$\rho_t = \rho_t(-\rho_{t+1}) \quad \text{for } t = 0, 1, \dots \quad (39)$$

To characterize time consistency in terms of acceptance sets and penalty functions, we define the “myopic” acceptance sets

$$\mathcal{A}_{t,t+1} := \{X \in L_{t+1}^\infty \mid \rho_t(X) \leq 0\} \quad (40)$$

and the corresponding “myopic” penalty functions

$$\alpha_{t,t+1}(Q) := \operatorname{ess\,sup}_{X \in \mathcal{A}_{t,t+1}} E_Q[-X | \mathcal{F}_t] \quad (41)$$

We also assume that the class $\mathcal{Q}^*$ of all equivalent probability measures Q with $\alpha_0(Q) < \infty$ is not

empty. Then time consistency is equivalent to each of the following conditions:

- $\mathcal{A}_t = \mathcal{A}_{t,t+1} + \mathcal{A}_{t+1}$ for $t = 0, 1, \dots$
- For any $Q \in \mathcal{M}$,

$$\alpha_t(Q) = \alpha_{t,t+1}(Q) + E_Q[\alpha_{t+1} | \mathcal{F}_t] \quad \text{for } t = 0, 1, \dots \quad (42)$$

- For any $Q \in \mathcal{Q}^*$ and any $X \in L^\infty$, the process $\rho_t(X) + \alpha_t(Q)$, $t = 0, 1, \dots$ (43)

is a Q -supermartingale

(cf. [2, 7, 11, 12, 19, 25]). Moreover, each condition implies that the dynamic risk measure admits a robust representation in terms of the set $\mathcal{Q}^*$, that is,

$$\rho_t(X) = \operatorname{ess\,sup}_{Q \in \mathcal{Q}^*} (E_Q[-X | \mathcal{F}_t] - \alpha_t(Q)) \quad (44)$$

for all $X \in L^\infty$ and all $t \geq 0$ (cf. [25]).

The entropic dynamic risk measure is time consistent as long as the parameter θ remains constant. On the other hand, time consistency fails for the dynamic risk measure defined by conditional Average Value at Risk. Under the assumption of *law invariance*, the entropic case is in fact the only time-consistent example, if we include the limiting cases $\theta = 0$ and $\theta = \infty$ corresponding to the conditional expected loss under $\mathbb{P}$ and the *conditional worst-case risk measure*,

$$\rho_t(X) = \operatorname{ess\,inf} \{Y \in L_t^\infty \mid Y \geq -X\} \quad (45)$$

respectively (cf. [40]). This suggests to consider weaker versions of time consistency. For example, the supermartingale property above implies that for each $Q \in \mathcal{Q}^*$ the process $\alpha_t(Q)$, $t = 0, 1, \dots$, is a Q -supermartingale, and this is equivalent to the weaker requirement

$$\rho_{t+1}(X) \leq 0 \implies \rho_t(X) \leq 0 \quad (46)$$

that is, $\mathcal{A}_t \subseteq \mathcal{A}_{t+1}$ for all $t = 0, 1, \dots$. In the law invariant case, such weaker notions of consistency may be used for a characterization of utility-based shortfall risk (cf. [48]). The notion of *prudence* introduced in [44] requires

$$X \in \mathcal{A}_t \implies -\rho_{t+s}(X) \in \mathcal{A}_t \quad \text{for all } s \geq 0 \quad (47)$$

and this is characterized by the fact that

$$\rho_t(X) - \sum_{k=0}^{t-1} \alpha_k(Q), \quad t = 0, 1, \dots \quad (48)$$

is a Q -supermartingale for any $Q \in \mathcal{Q}^*$ and any $X \in L^\infty$.

For an infinite time horizon, the supermartingale criteria for time consistency and for prudence both yield almost sure convergence of the capital requirements $\rho_t(X)$ to an asymptotic capital requirement $\rho_\infty(X)$. We may now ask whether the sequence is *asymptotically safe* in the sense that $\rho_\infty(X) \geq -X$, or even *asymptotically precise* in the sense of $\rho_\infty(X) = -X$; note that asymptotic precision can be viewed as a nonlinear analog of martingale convergence. Criteria in terms of acceptance sets and penalty functions are derived in [25] for the time-consistent case and in [44] for the case of prudence.

Value-at-Risk

The Value at Risk (VaR) is the maximum likely loss that a portfolio experiences over a specified horizon period, where the key term is “likely” to be interpreted in terms of a specified probability, known as a *confidence level*. For example, if the daily VaR at the 95% confidence level is \$1m, then we would expect a maximum loss of \$1m on the best prospective 95 days out of 100. More formally, the VaR at the confidence level p can be defined as the $100 \times p\%$ quantile of the loss distribution [8, 9, 16]. Note, therefore, that the VaR is measured in units of loss: a positive VaR means that the likely worst outcome is a monetary loss, whereas a negative VaR implies that the likely worst outcome is a profit. Also note that although we have defined the VaR here in terms of a quantile of the loss distribution, the VaR can equivalently be defined in terms of a quantile of the profit/loss (P/L) distribution (i.e., the negative of our loss distribution) or in terms of a quantile of the distribution of financial returns (*see Market Risk*).

The values of the parameters on which the VaR is defined, the horizon period and the confidence level, would be chosen by the user and depend on the context and the use to which the VaR is put. The horizon might be anything from a fraction of a day to decades ahead, but is typically somewhere between 1 day and a month. Confidence levels are typically in the 95%+ range and can be well above 99%.

Virtually unknown in 1990, the VaR risk measure rose rapidly to prominence in the early 1990s, as leading financial institutions competed with one another to build risk models that would forecast daily VaRs on traded market portfolios. The best known was Morgan’s RiskMetrics model, which was published on the web in October 1994. The resulting debate on the merits and demerits of the RiskMetrics model did much to stimulate interest in and awareness of the issues involved in risk modeling [13, 14]. Since then, risk models have become much more sophisticated, and VaR methodologies have been used to forecast other types of risks such as credit, operational, liquidity, and cash flow risks.

Uses of VaR

VaR models have been used for many different risk management purposes. They can be used by senior

management to determine an institution’s overall risk target and can be used to determine risk targets and position limits down the line. They can be used to determine internal capital requirements, both at the level of the firm and at the level of individual business units. They can also be used to identify risk-expected return trade-offs and to assess investment, trading, and hedging decisions. They can be used to determine the remuneration of managers and traders in ways that take into account not just the profits made but also the risks taken to achieve those profits. And, finally, they can be used for risk reporting and risk disclosure purposes.

Attractions of VaR as a Risk Measure

The VaR has a number of attractive properties as a risk measure: (i) It is expressed in the simplest and most easily understood unit of measurement, namely, “lost money”. (ii) The VaR provides a common consistent risk measure across different positions and risk factors and can be applied to any type of portfolio. It enables us to compare the risk of an equity position, say, against that of a fixed-income position, and do so in a consistent way. The VaR can be applied to a broader range of risks than the traditional measures such as beta (which is restricted to equity and commodity risks), duration and convexity (which are restricted to fixed-income risks), and the Greeks (which are restricted to derivatives risks). (iii) The VaR enables us to aggregate the risks of individual positions in a way that takes into account how the risk factors in those positions interact, that is, the VaR can take account of correlations between different risk factors. For their part, most traditional risk measures do not easily allow for the “sensible” aggregation of component risks. (iv) The VaR is holistic in the sense that it takes into account all risk factors, whereas traditional risk measures look at one risk factor at a time (e.g., the Greeks) or collapse multiple risk factors into one (e.g., duration, beta). The VaR is also holistic in the sense that it can readily be applied to forecast a firm’s corporate-wide risk exposure, as well as the exposures of individual desks or business units. (v) The VaR is probabilistic and gives a risk manager a sense of the probabilities associated with possible loss outcomes. Traditional risk measures do not give any such information and only give the answers to questions about “what if?” scenarios.

Limitations of the VaR as a Risk Measure

The VaR also has major limitations as a risk measure. The underlying problem with the VaR is that it takes no account of the sizes of possible losses bigger than itself. It tells us the worst we can expect on the, say, 95 “good” days out of a possible 100, but tells us nothing about we can expect on the “bad” 5 remaining days. It is therefore “blind” to the sizes of tail losses and does not tell us how bad “bad” might be. This is a serious drawback for risk managers concerned with the managing of their firm’s exposure to “lower tail” loss outcomes.

A consequence of this “tail blindness” is that the VaR risk measure fails to satisfy the important property of subadditivity [3, 4]. A risk measure $\rho(\cdot)$ is said to be subadditive if, for *any* two position A and B , the risk measure always satisfies the condition $\rho(A + B) \leq \rho(A) + \rho(B)$, that is, the risk of the sum is always less than or equal to the sum of the risks. This subadditivity condition reflects the intuitive expectation that a “reasonable” risk measure should exhibit some or, at worst, no diversification when two positions are aggregated. We would certainly *not* expect the overall risk exposure as measured by a “respectable” risk measure to increase when individual risks are put together (*see Convex Risk Measures*).

Yet the VaR does not satisfy this basic property. For example, consider the case where we have 100 bonds and 100 possible equally likely states of nature, in each one of which one of the bonds defaults and inflicts a loss of \$10 on the holder. The probability of loss on any given bond is therefore 1%, but the probability of loss on a fully diversified portfolio is 100%. Thus, if an investor holds any one of these bonds, the VaR at the 95% confidence level will be 0, but if the investor holds a fully diversified bond portfolio, the VaR at the 95% confidence level will be equal to $\$10/100 = \0.1 . This example suffices to prove that the VaR is not subadditive.

VaRs “tail blindness” can lead to other problems. For example, if a prospective investment involves the possibility of low-probability high loss, a VaR-based decision calculus might suggest that the investor should go ahead with the investment regardless of the size of the possible loss, provided only that the probability of loss is small enough. In effect, the risk involved can fall under the VaRs radar screen. Such a categorical acceptance of a risk—regardless

of the size of the possible loss, provided that only the probability involved is sufficiently low—undermines sensible risk-return analysis and can leave an investor very exposed without realizing it.

A further problem that can occur in the context of decentralized decision making—that is, when traders or asset managers are managing other people’s funds—is the danger of traders or asset managers “gaming” VaR systems that are used to control or remunerate their risk-taking. A standard example is where traders facing a VaR-based risk target have an incentive to sell out-of-the-money options that lead to greater income in most states of the world and the occasional large hit when the firm is unlucky. If the options are suitably chosen, the probabilities of them expiring in the money will be sufficiently low that they will have no impact on the VaR. The trader then benefits from the higher income and hence higher bonuses earned in “normal” times when the options expire worthless. The fact that the VaR does not take into account the possible large losses involved can distort incentives and encourage traders to “game” the VaR system and promote their own interests at the expense of the institutions that employ them.

Alternative Risk Measures

These problems have encouraged research into alternative risk measures—most particularly, other quantile-based risk measures that share the attractions of the VaR but avoid its main drawbacks. The seminal work in this area is the theory of coherent risk measures proposed by Artzner *et al.* [3, 4]. The best-known coherent risk measure is the expected shortfall (ES) also referred to as *conditional VaR* (*CVaR*), which is the loss we can expect if a tail loss should occur (*see Convex Risk Measures; Expected Shortfall; Market Risk*). Hence, although the VaR gives us the maximum loss we can expect if a tail loss does not occur, the ES tells us what to expect in the tail itself. The ES is therefore not “blind” to the tail in the way that the VaR is. At the same time, the ES shares the attractive properties of the VaR—it is measured in units of lost money, provides a common consistent measure of risk across different positions, is probabilistic, and so forth. Another type of coherent risk measure is a spectral risk measure that takes into account a user’s risk aversion ([1, 2]; *see Spectral Measures of Risk*). It is also interesting to note

that the outcomes of scenario analyses are coherent risk measures as well (*see Stress Testing*). Thus, the ES, spectral risk measures and scenario analyses each give us financial risk measures that are “respectable” in a sense that the VaR is not.

When to Choose the VaR?

This raises a natural question: when would a rational user choose the VaR as a preferred risk measure? The answer is that although the VaR is not generally a suitable risk measure for the reasons already mentioned, it *can* be suitable in special case circumstances where we restrict either the return distribution or the user’s utility function (or, if you prefer, the user’s risk preferences). An example of the former would be where a user believes that he/she faces normally (or, more generally, elliptically) distributed risks. In such circumstances, the VaR obeys the sub-additivity property and might be used both to measure risks in a portfolio analysis framework and to determine capital requirements. Examples of the latter would be where a user has a quadratic utility function (which implies that the user does not care about the skewness or kurtosis of the return distribution), a lexicographic utility function (in which the risk-expected return trade-off becomes degenerate) or, in the context of the theory of lower partial moments, where the user has a lower partial moment of zero (which reflects a rather extreme form of negative risk aversion [12]). However, each of these special cases is implausible: most empirical return distributions are not elliptical, and experts would regard quadratic and lexicographic utility functions and lower partial moments of zero as inconsistent with any notions of “well-behaved” risk preferences. The implausibility of these special cases reinforces the point that the VaR is not, in general, an advisable risk measure to choose.

This said, the special case circumstances where VaR is appropriate include probability-of-ruin problems, where the VaR is the quantile associated with the probability of ruin [11]. An important example of this type of problem is where the VaR might be used to determine the capital requirements necessary to achieve some target probability of insolvency. Typically, the target insolvency probability would be set to some very small value p and the capital requirement would be equal to the VaR at the confidence level $1 - p$. Since p is very small, the VaR itself

should then be estimated by using extreme value (EV) methods rather than some arbitrary approach picked off the shelf, as it were (*see Operational Risk*).

Methods to estimate VaR are discussed in **Market Risk**.

VaR in Practice

There is considerable evidence that real-world VaR estimates are often highly inaccurate. This evidence is both direct, in studies such as [6, 7, 15], and indirect. Indirect evidence comes from the many instances since the early 1990s where firms suffered large losses, such as alleged “25 sigma” losses, that are much greater than their VaR models anticipated [10]. The causes of this inaccuracy include model risk (i.e., that we do not in practice know what the “true” distributions actually are; *see Models*), parameter risk (i.e., that, for given any distribution, we do not know the “true” values of its parameters but have to work with estimates of those parameters instead), and implementation risk (i.e., that different institutions will implement any given VaR system in different ways, so leading to different VaR estimates).

In practice, VaR systems often perform fairly well under “normal” stable market conditions, but perform badly during crises. A common problem is where VaR models predicated on “everyday” confidence levels (such as 95 or even 99%) perform very poorly when “tail events” when very large losses occur. Other common problems are the radicalization of correlations and the disappearance of market liquidity during crises. VaR models can also perform badly in circumstances where they are used to control or remunerate traders, who respond by “gaming” the models and exploiting their weaknesses. There is also the problem of systemic risk, where a bank’s risk models perform poorly because they failed to allow for other institutions following similar risk management strategies—a problem analogous to the mistake a cinema-goer makes when he fails to anticipate that everyone else will also run for the exit in the event of a fire [5].

All these problems can contribute to institutions experiencing much larger losses than their risk models anticipated. They also highlight the importance of backtesting risk models and complementing risk forecasts with stress tests and scenario analyses that seek to determine an institution’s vulnerability to “what

if?” events that might not be present in the data used to calibrate those models ([9]; see **Stress Testing; Backtesting**).

Expected Shortfall

The synonymous terms conditional Value at Risk (CV@R) and expected shortfall (ES) refer to a particular statistics of a random variable, which is widely adopted as a measure of portfolio risk. It is also known as tail Value at Risk (TV@R) or average Value at Risk (AV@R) among other names. Here we adopt the name ES.

The “ES of a random variable X ”, denoted by $ES_\alpha(X)$, is most easily defined in plain English as *minus the average of the α lowest outcomes of X* , where $\alpha \in [0, 1]$ is a chosen confidence level (e.g., $\alpha = 5\%$). There are several equivalent mathematical expressions of this definition. We discuss the most useful ones in the section “Mathematical Expressions for ES”.

In financial risk management, the “ES of a portfolio π ” is usually meant as the expected shortfall $ES_\alpha(r_T^{(\pi)})$ of the return $r_T^{(\pi)} = \pi_T - (1 + R)\pi_0$ between the current date $t = 0$ and a chosen future date $t = T$, in perfect analogy with the practice introduced by V@R (see **Value-at-Risk**). Here, R is the risk-free interest on $[0, T]$. It is then clear that $ES_\alpha(r_T^{(\pi)})$ represents the *average portfolio loss at time T in the α worst cases*.

Measures of risk similar to ES (in particular TCE, equation (2), and “average shortfall” [10]) appeared in the practice of risk management already in the early 1990s, along with the diffusion of V@R methods. The main motivation for their introduction was to remedy the fact that V@R is totally blind to the severity of the losses contained in the tail beyond the specified confidence level. The idea of averaging the outcomes contained in the tail instead of detecting only its threshold quantile is so natural that it came simultaneously from several academicians and practitioners, and this is probably the reason why no consensus was ever achieved on the name of this risk measure.

The interest around ES increased considerably after the appearance of [5] with the advent of coherent measures of risk (CMRs) (see **Convex Risk Measures**) and the consequent criticism that was addressed to V@R when it was recognized to be not subadditive, that is, not compatible with the risk diversification principle. ES, in fact, in the modern version introduced in [1, 12], turned out to be a subadditive measure of risk and, in fact, it provides

the best-known example of a coherent measure of risk.

A lively debate has arisen in the past years on whether ES should replace V@R in the regulatory framework of the Basel Committee on Banking Supervision. A number of arguments [3, 5, 6] have been given to display the superiority of a coherent measure of risk for capital adequacy purposes, like absence of regulatory arbitrage opportunities, huge computational advantages related to subadditivity and convexity, and absence of risk paradoxes. No sound arguments have ever been given to display why V@R should be more appropriate than ES, instead. Yet, to date, ES still plays no role in the Basel II Accord (see **Regulatory Capital**).

Mathematical Expressions for ES

We denote with $F_X(x) = \mathbb{P}\{X \leq x\}$ the probability distribution function of X in a chosen probability space and we define for any $p \in (0, 1)$ the lower p -quantile $q_p(X) = \inf\{x \in \mathbb{R} | F_X(x) \geq p\}$ and the upper p -quantile $q^p(X) = \inf\{x \in \mathbb{R} | F_X(x) > p\}$. A (generic) p -quantile X_p is defined as any value in the interval $[q_p(X), q^p(X)]$.

For any $\alpha \in (0, 1]$, ES_α can then be expressed as

$$ES_\alpha(X) = -\frac{1}{\alpha} \int_0^\alpha X_p \, dp \quad (1)$$

where X_p is a p -quantile whose choice is irrelevant, showing that there exists a unique definition for ES. For V@R, on the contrary, which is defined as $V@R_\alpha(X) = -X_\alpha$, this choice does indeed affect the result, leading to possible alternative different notions (upper and lower V@R, for instance) when the quantiles $p \mapsto X_p$ turn out not to be single valued.

For the extreme case $\alpha = 0$, the definition is naturally extended by placing $ES_0(X) = -\text{ess inf } X = -\inf\{x \in [-\infty, +\infty] | F_X(x) > 0\}$, while for $\alpha = 1$ one easily recognizes that $ES_1(X) = -\mathbb{E}[X]$.

Note how equation (1) clearly expresses the fact that ES is indeed *minus the average of the α lowest outcomes of X* .

It is important to distinguish ES from the so-called tail conditional expectation (TCE) defined as [5]

$$TCE_\alpha(X) = -\mathbb{E}[X | X \leq q_\alpha(X)] \quad (2)$$

This expression can be shown to coincide with $ES_\alpha(X)$ only under special conditions on the distribution function, for instance, when $F_X(x)$ is a continuous function. However, for general distribution functions, ES and TCE differ and it is only the former, which can be shown to be subadditive [1, 12]. Equation (2) is, in any case, a useful expression for ES when one works with parametric distributions whose continuity is assumed to hold *a priori*.

The correction to expression (2) needed to express ES on general (noncontinuous) probability distributions is contained in the following formula [1]:

$$ES_\alpha(X) = -\frac{1}{\alpha} \{ \mathbb{E} [X \mathbf{1}_{\{X \leq X_\alpha\}}] - X_\alpha(F_X(X_\alpha) - \alpha) \} \quad (3)$$

where the choice of the α -quantile X_α is again irrelevant. This formula shows that $ES_\alpha(X) = TCE_\alpha(X)$ if and only if $F_X(X_\alpha) = \alpha$.

ES can also be defined as the solution of a convex minimization problem [9, 11, 12]:

$$ES_\alpha(X) = \min_s \left\{ -s + \frac{1}{\alpha} \mathbb{E} [s - X]^+ \right\} \quad (4)$$

attaining the minimum in any $s \in [q_\alpha(X), q^\alpha(X)]$. This formulation of ES is very important because it allows to obtain fast algorithms for portfolio ES-optimization [11, 12].

Properties of ES

ES satisfies the following important properties for any $\alpha \in [0, 1]$ and random variables X, Y [1, 7, 9]:

(i) *monotonicity*

$$ES_\alpha(X) \geq ES_\alpha(Y) \quad \text{if } X \leq Y \text{ a.s.} \quad (5)$$

(ii) *translational invariance*

$$ES_\alpha(X + c) = ES_\alpha(X) - c \quad \text{if } c \in \mathbb{R} \quad (6)$$

(iii) *positive homogeneity*

$$ES_\alpha(\lambda X) = \lambda ES_\alpha(X) \quad \text{if } \lambda \geq 0 \quad (7)$$

(iv) *subadditivity*

$$ES_\alpha(X + Y) \leq ES_\alpha(X) + ES_\alpha(Y) \quad (8)$$

Formally, these properties coincide with the axioms of coherence [5]. However, it has to be kept in mind that the concept of coherence is not just a property of a statistics of a generic random variable but a property of a portfolio statistics with a precise economic interpretation. To speak of coherence of a portfolio measure of risk, it is also necessary that the random variables X and Y in these conditions represent future “portfolio values” (as opposed to “portfolio returns”). This fact is crucial for the correct economic interpretation of condition (6) in the spirit of capital adequacy. A CMR is, in fact, supposed to decrease by the amount c when a risk-free capital of future deterministic value c (and not a portfolio yielding a deterministic return c) is added to any portfolio X .

Hence, strictly speaking, the *expected shortfall of a portfolio* $ES_\alpha(r_T^{(\pi)})$, widely adopted by practitioners as an alternative to $V@R$, although monotonic, translational invariant, positive homogeneous, and subadditive with respect to its return argument, is, nevertheless, *not* a CMR in the sense of [5]. It is the *expected shortfall of a portfolio value* $ES_\alpha(\pi_T)$, which represents a truly CMR. The connection between the two notions is however just a constant offset, thanks to property (2).

$$ES_\alpha(\pi_T) = ES_\alpha(r_T^{(\pi)}) - (1 + R)\pi_0 \quad (9)$$

Properties (5)–(8) are, in any case, extremely important also for return-based measures, in particular for the convexity properties they induce on portfolio optimization problems. That is why some authors (e.g., [3, 6]) (somehow improperly) call them *axioms of coherence* also when referred to statistics acting on portfolio returns.

Particularly important is the subadditivity property, which $V@R$ fails to satisfy. Inequality (8) formalizes the fact that the risk (expressed by ES) of the sum of two portfolios X and Y never exceeds the sum of their individual risks. The difference between right- and left-hand side of the inequality expresses the hedging benefit of merging the two portfolios. In a CMR this benefit is positive, and just in exceptional cases vanishing, but never negative, a situation that would give rise to paradoxes and

regulatory arbitrages (see, for instance, [3–5] for a discussion).

An important immediate consequence of properties (7) and (8) is convexity.

(v) *convexity*

$$\begin{aligned} ES_\alpha(\mu X + (1 - \mu)Y) \\ \leq \mu ES_\alpha(X) + (1 - \mu)ES_\alpha(Y) \quad \text{if } \mu \in [0, 1] \end{aligned} \quad (10)$$

which states that the risk of a blend of two portfolios is less than the blend of the individual risks. This expresses the clearest formalization of the risk diversification principle and is of utmost importance for portfolio optimization problems [3, 11, 12], because they generally turn out to be convex.

Other important properties of ES are related to the concepts of portfolio preference under first or second stochastic dominance. We recall that a random variable X is said to dominate Y according to first-order stochastic dominance (notation: $X \succ^{1st} Y$) if $F_X(z) \leq F_Y(z)$ for all $z \in \mathbb{R}$, while X is said to dominate Y according to second-order stochastic dominance (notation: $X \succ^{2nd} Y$) if $\int_{-\infty}^z [F_Y(t) - F_X(t)] dt \geq 0$ for all $z \in \mathbb{R}$. First order implies second-order stochastic dominance. It can be shown [7–9] that ES is compatible with both these preferences.

(vi) *monotonicity with respect to first- and second-order stochastic dominance*

$$ES_\alpha(X) \leq ES_\alpha(Y) \quad \text{if } X \succ^{1st, 2nd} Y \quad (11)$$

which tells us that if a portfolio X is preferable to Y under either first- or second-order stochastic dominance, its ES will be smaller.

Furthermore, one can show comonotonic additivity [7, 8].

(vii) *comonotonic additivity*

$$\begin{aligned} ES_\alpha(X + Y) &= ES_\alpha(X) + ES_\alpha(Y) \quad \text{if} \\ &X, Y \text{ comonotonic} \end{aligned} \quad (12)$$

Comonotonic additivity represents the limiting case of subadditivity, achieved when two random variables

happen to be comonotonic and therefore ineffective to hedge each other. It is in this case that the hedging benefit of subadditivity is expected to vanish. Comonotonic additivity is not implied by the axioms of coherence and this is sometimes argued to be a weakness of the axioms, because noncomonotonic additive CMRs can give rise to capital regulatory arbitrages [4].

Furthermore, ES belongs to the class of law-invariant, comonotonic additive CMRs [8], also known as spectral measures of risk (SMRs) [2] (see **Spectral Measures of Risk**). Actually, the set $\{ES_\alpha | \alpha \in [0, 1]\}$ of all possible ES is the smallest set whose convex hull corresponds to the class of SMRs. In other words, any SMR can be uniquely expressed as a convex combination of ESs [8].

Law-invariance plays a special role as the distinguishing property of the CMRs, which may be estimated from data sets.

Estimation of ES

A number of cases are known where exact expressions of ES can be computed directly from equation (1) by direct calculation (analytical or numerical) knowing the distribution of X . However, in general cases, and in particular when parametric distributions are not assumed *a priori* like in many risk management platforms, ES is obtained by estimation.

Given a sample of N independent and identically distributed outcomes x_i , of a random variable X , a consistent estimator of $ES_\alpha(X)$ can be obtained by [1, 3]

$$\begin{aligned} \widehat{ES}_\alpha(X) &= -\frac{1}{N\alpha} \left(\sum_{i=1}^{\lfloor N\alpha \rfloor} x_{i:N} \right. \\ &\quad \left. + (N\alpha - \lfloor N\alpha \rfloor)x_{\lfloor N\alpha \rfloor+1:N} \right) \\ &= \frac{1}{\lfloor N\alpha \rfloor} \sum_{i=1}^{\lfloor N\alpha \rfloor} x_{i:N} + o(1/N) \end{aligned} \quad (13)$$

where $\lfloor n \rfloor$ denotes the integer part of n and $x_{i:N}$ denotes the ordered statistics, that is, the vector $\{x_{i:N}\}_{i=1, \dots, N}$ of values $x_{1:N} \leq \dots \leq x_{N:N}$ obtained sorting the vector $\{x_i\}_{i=1, \dots, N}$. This expression converges to $ES_\alpha(X)$ for $N \rightarrow \infty$. It can be shown to

be nothing but the ES of the empirical distribution of the sample, and as such, it is clearly coherent for any finite N .

In equation (13) the $o(1/N)$ term can be neglected for simplicity in those applications where N is large like some Monte Carlo simulations, but it is not at all negligible, for instance, in a historical simulation of $N = 252$ data, with a confidence level of say, 5%. In general, it is always safer, and not computationally penalizing, to adopt the complete estimator.

An equivalent expression [11, 12] can be obtained by exploiting equation (4):

$$\widehat{ES}_\alpha(X) = \min_s \left\{ -s + \frac{1}{N\alpha} \sum_{i=1}^N [s - x_i]^+ \right\} \quad (14)$$

which has the solution $s \in [x_{\lfloor N\alpha \rfloor}, x_{\lfloor N\alpha \rfloor + 1}]$. From a computational point of view, there may be cases where the cost of minimization of equation (14) is smaller than the cost of the sorting procedure needed for equation (13). These formulas are essential tools for any risk management application based on exact Monte Carlo or historical simulation.

Economic Capital Allocation

In a bank, risk is usually quantified in terms of risk capital (or economic capital). The reason for the close connection between risk and capital is the fact that the main purpose of the bank's capital is to provide protection against extreme losses, that is, capital invested in safe and liquid assets should ensure solvency of the bank even in adverse economic scenarios. Hence, the capital requirements of a bank are determined by its risk profile. The actual calculation is based on risk measures like Value-at-Risk (VaR) or expected shortfall; see [12] or **Convex Risk Measures** for an exposition of the theory of risk measures.

Techniques for measuring risk are not only required for capital management but are also prerequisites for profitability analysis and portfolio optimization. The development of the theoretical relationship between risk and expected return is built on two economic theories: portfolio theory and capital market theory [18, 19, 25]. Portfolio theory deals with the selection of portfolios that maximize the expected returns consistent with individually acceptable levels of risk, whereas capital market theory focuses on the relationship between security returns and risk. These theories also provide a natural framework for measuring profitability. The profitability analysis is commonly carried out by expressing the risk–return relationship as simple rational functions of risk and return components. The two basic variants of these so-called risk adjusted ratios are known as *RORAC* or *RAROC*, respectively; see [20] for details.

Portfolio optimization and the profitability analysis of individual business units, portfolios, and transactions require the quantification of risk at the respective levels of the bank's hierarchy. In line with portfolio theory, the main objective of this analysis is to measure the contribution of each unit to the total risk of the bank and to allocate risk capital accordingly. For a mathematical formalization of the allocation problem, we assume that a risk measure ρ has been fixed and that X is a portfolio that consists of subportfolios $X_1, \dots, X_m$. The objective is to distribute the risk capital $k := \rho(X)$ of the portfolio $X = X_1 + \dots + X_m$ to its subportfolios, that is, to

compute risk contributions $k_1, \dots, k_m$ of $X_1, \dots, X_m$ with $k = k_1 + \dots + k_m$.

In recent years, theoretical and practical aspects of different allocation schemes have been analyzed in several articles; see for instance [5–8, 11, 14, 22, 23, 26–28]. An allocation scheme proposed by several authors is the allocation by the gradient or Euler principle: the capital allocated to the subportfolio X_i of X is the derivative of the associated risk measure ρ at X in the direction of X_i (see formula (9) for a precise formalization). In the following, we review a simple axiomatization of capital allocation proposed in [15]. The main axioms are the property that the entire risk capital of a portfolio is allocated to its subportfolios and a diversification property that is closely linked to the subadditivity of the underlying risk measure. It turns out that in this framework the Euler principle is an immediate consequence of the proposed axioms.

Axioms for Capital Allocation

Let $(\Omega, \mathcal{A}, \mathbb{P})$ be a probability space, L^0 the space of all equivalence classes of real-valued random variables on Ω and V a subspace of the vector space L^0 , which represents portfolios. More precisely, we will identify each portfolio X with its loss function, that is, X is an element of V and $X(\omega)$ specifies the loss of X at a future date in state $\omega \in \Omega$. We assume that a function $\rho : V \rightarrow \mathbb{R}$ has been defined. For each $X \in V$, $\rho(X)$ specifies the risk capital associated with portfolio X . At this point, we do not require that the risk measure ρ has specific properties.

The axiomatization in [15] is based on the assumption that the capital allocated to subportfolio X_i only depends on X_i and X but not on the decomposition of the remainder $X - X_i = \sum_{j \neq i} X_j$ of the portfolio. Hence, a capital allocation can be considered as a function Λ from $V \times V$ to $\mathbb{R}$. Its interpretation is that $\Lambda(X, Y)$ represents the capital allocated to the portfolio X considered as a subportfolio of portfolio Y .

Definition 1 (Axiomatization of Capital Allocation). *A function $\Lambda : V \times V \rightarrow \mathbb{R}$ is called a capital allocation with associated risk measure ρ if it satisfies the condition $\Lambda(X, X) = \rho(X)$ for all $X \in V$, that is, if the capital allocated to X (considered as stand-alone portfolio) is the risk capital $\rho(X)$ of X . The following requirements for Λ are proposed. The capital allocation Λ is called*

$$\begin{array}{ll} \text{linear :} & \forall a, b \in \mathbb{R}, X, Y, Z \in V \end{array} \quad (1)$$

$$\begin{array}{ll} \Lambda(aX + bY, Z) = a\Lambda(X, Z) + b\Lambda(Y, Z) & \\ \text{diversifying :} & \forall X, Y \in V \end{array} \quad (2)$$

$$\begin{array}{ll} \Lambda(X, Y) \leq \Lambda(X, X) & \\ \text{continuous at } Y \in V : & \forall X \in V \end{array} \quad (3)$$

$$\lim_{\epsilon \rightarrow 0} \Lambda(X, Y + \epsilon X) = \Lambda(X, Y)$$

The first two axioms ensure that the risk capital of the portfolio equals the sum of the (contributory) risk capital of its subportfolios and that the capital allocated to a subportfolio X never exceeds the risk capital of X considered as a stand-alone portfolio. If Λ is continuous at $Y \in V$, then small changes to the portfolio Y only have a limited effect on the risk capital of its subportfolios. We refer to [7, 8] for alternative axiomatizations based on game-theoretic concepts.

The above axiom system provides a close link between risk measures and capital allocation rules. First, given a capital allocation Λ the corresponding risk measure ρ is obviously given by the values of Λ on the diagonal, that is, $\rho(X) = \Lambda(X, X)$. Conversely, assume that a risk measure ρ is

a capital allocation Λ_ρ by

$$\Lambda_\rho(X, Y) := h_Y^\rho(X) \quad (8)$$

The set H_ρ can be interpreted as a collection of (generalized) scenarios: the capital allocated to a subportfolio X of portfolio Y is simply the loss of X under scenario h_Y^ρ .

The following theorem (Theorem 4.2 in [15]) states the equivalence between positively homogeneous, subadditive (but not necessarily coherent) risk measures and linear, diversifying capital allocations.

Theorem 1 (Existence of Capital Allocations). *Let $\rho: V \rightarrow \mathbb{R}$.*

$$\begin{array}{ll} \text{positively homogeneous :} & \forall a \geq 0, X \in V \end{array} \quad (4)$$

$$\begin{array}{ll} \rho(aX) = a\rho(X) & \\ \text{subadditive :} & \forall X, Y \in V \end{array} \quad (5)$$

$$\rho(X + Y) \leq \rho(X) + \rho(Y)$$

Then, the corresponding capital allocation Λ_ρ can be constructed as follows: let V^* be the set of real linear functionals on V and for a given risk measure ρ consider the subset

$$H_\rho := \{h \in V^* \mid h(X) \leq \rho(X) \text{ for all } X \in V\} \quad (6)$$

It is an easy consequence of the Hahn–Banach theorem (see, for instance, Theorem II.3.10 in [10]) that for a positively homogeneous and subadditive risk measure ρ

$$\rho(X) = \max\{h(X) \mid h \in H_\rho\} \quad (7)$$

for all $X \in V$. Hence, for every $Y \in V$ there exists an $h_Y^\rho \in H_\rho$ with $h_Y^\rho(Y) = \rho(Y)$. This allows to define

1. *If there exists a linear, diversifying capital allocation Λ with associated risk measure ρ , then ρ is positively homogeneous and subadditive.*
2. *If ρ is positively homogeneous and subadditive, then Λ_ρ is a linear, diversifying capital allocation with associated risk measure ρ .*

If a linear, diversifying capital allocation Λ is moreover continuous at a portfolio $Y \in V$, then it is uniquely determined by the directional derivative of its associated risk measure, as the next theorem (Theorem 4.3 in [15]) shows.

Theorem 2 (Uniqueness of Capital Allocations). *Let ρ be a positively homogeneous and subadditive risk measure and $Y \in V$. Then the following three conditions are equivalent:*

1. Λ_ρ is continuous at Y , that is, for all $X \in V$ $\lim_{\epsilon \rightarrow 0} \Lambda_\rho(X, Y + \epsilon X) = \Lambda_\rho(X, Y)$.
2. The directional derivative

$$\lim_{\epsilon \rightarrow 0} \frac{\rho(Y + \epsilon X) - \rho(Y)}{\epsilon} \quad (9)$$

exists for every $X \in V$.

3. There exists a unique $h \in H_\rho$ with $h(Y) = \rho(Y)$.

If these conditions are satisfied then $\Lambda_\rho(X, Y)$ equals the directional derivative (9) for all $X \in V$, that is, Λ_ρ is given by the Euler principle.

If the equivalent conditions in Theorem 2 are not satisfied for $Y \in V$, then the two-sided directional derivative (9) does not exist for all X and the capital allocation $\Lambda_\rho(\cdot, Y)$ is not uniquely defined. In a recent article, Cherny and Orlov [6] propose two different solutions to this problem: either the replacement of the two-sided directional derivative by a one-sided directional derivative or a modification of the axiomatization in Definition 1 obtained by adjusting the continuity axiom and adding law invariance. They show that for a spectral risk measure [1, 27], (see also **Spectral Measures of Risk**), there exists a unique capital allocation satisfying the proposed axiom system. Capital allocations for spectral risk measures are also investigated in [23]. An axiomatic characterization of capital allocations of coherent risk measures [3] is given in [16].

The Euler principle is an allocation scheme that has been proposed by several authors; see [28] for an overview. Tasche [26] argues that allocation based on the Euler principle provides the right signals for performance measurement. Another justification for the Euler principle is given by Denault [8] using the framework of cooperative game theory. He shows that the Euler principle is the only fair allocation principle for a differentiable coherent risk measure. The existence of the directional derivative (9) is analyzed in several articles, for example, in [4, 11, 13, 27]. Alternative allocation techniques have been explored in the actuarial sciences; see, for example, [9, 21]. A comparison of different combinations of risk measures and allocation methods can be found in [29].

Capital Allocation for Specific Risk Measures

In classical portfolio theory, risk is measured by standard deviations [19]. More precisely, let c be a nonnegative real number and define the risk measure ρ_c^{Std} and the capital allocation Λ_c^{Std} by

$$\rho_c^{\text{Std}}(X) := c \cdot \text{Std}(X) + E(X) \quad (10)$$

$$\Lambda_c^{\text{Std}}(X, Y) := \begin{cases} c \cdot \text{Cov}(X, Y) / \text{Std}(Y) + E(X) & \text{if } \text{Std}(Y) > 0, \\ E(X) & \text{if } \text{Std}(Y) = 0 \end{cases} \quad (11)$$

The risk measure ρ_c^{Std} is positively homogeneous and subadditive but not coherent for $c > 0$. The covariance allocation Λ_c^{Std} is linear and diversifying. It is derived from the risk measure ρ_c^{Std} using the construction principle (8). If $\text{Std}(Y) > 0$ then Λ_c^{Std} is continuous at Y and equals the directional derivative (9) by Theorem 2.

The current standard in the finance industry is to define the risk capital in terms of a quantile of the loss distribution (see **Value-at-Risk**): the Value-at-Risk $\text{VaR}_\alpha(X)$ of the portfolio X at a specified confidence level $\alpha \in (0, 1)$ is defined by

$$\text{VaR}_\alpha(X) := \inf\{l \in \mathbb{R} \mid \mathbb{P}(X \leq l) \geq \alpha\} \quad (12)$$

VaR has an intuitive economic interpretation, that is, it specifies the capital needed to absorb losses with probability α , and has even achieved the high status of being written in industry regulations. However, VaR also has an obvious limitation as a risk measure: in general, it is not subadditive if applied to portfolios with nonelliptic distributions. Theorem 1 implies that in the general case there do not exist linear, diversifying capital allocations for VaR. However, under regularity conditions (see, for example, [26]), the directional derivative (9) exists for VaR_α and equals

$$E(X|Y = \text{VaR}_\alpha(Y)) \quad (13)$$

The most prominent coherent risk measure is expected shortfall (see, for instance, [2, 24], **Expected Shortfall**) given by

$$\text{ES}_\alpha(X) = \frac{1}{1 - \alpha} \int_\alpha^1 \text{VaR}_u(X) \, du \quad (14)$$

Instead of fixing a quantile at a particular confidence level α , expected shortfall averages VaR across the entire tail specified by α . Coherence implies that expected shortfall is positively homogeneous and subadditive. Hence, application of equation (8) yields

$$\begin{aligned} \Lambda_{\alpha}^{\text{ES}}(X, Y) &:= \left(\int X \cdot \mathbf{1}_{\{Y > \text{VaR}_{\alpha}(Y)\}} d\mathbb{P} \right. \\ &\quad \left. + \beta_Y \int X \cdot \mathbf{1}_{\{Y = \text{VaR}_{\alpha}(Y)\}} d\mathbb{P} \right) / (1 - \alpha), \quad \text{with} \\ \beta_Y &:= \frac{\mathbb{P}(Y \leq \text{VaR}_{\alpha}(Y)) - \alpha}{\mathbb{P}(Y = \text{VaR}_{\alpha}(Y))} \\ &\quad \text{if } \mathbb{P}(Y = \text{VaR}_{\alpha}(Y)) > 0 \end{aligned} \quad (15)$$

which is a linear, diversifying capital allocation with respect to ES_{α} . If

$$\begin{aligned} \mathbb{P}(Y > \text{VaR}_{\alpha}(Y)) &= 1 - \alpha \\ \text{or } \mathbb{P}(Y \geq \text{VaR}_{\alpha}(Y)) &= 1 - \alpha \end{aligned} \quad (16)$$

then $\Lambda_{\alpha}^{\text{ES}}$ is continuous at Y and equals the directional derivative (9). In particular, equation (16) holds if $\mathbb{P}(Y = \text{VaR}_{\alpha}(Y)) = 0$; in that case, $\Lambda_{\alpha}^{\text{ES}}(X, Y)$ takes the particularly intuitive form

$$\Lambda_{\alpha}^{\text{ES}}(X, Y) = E(X \mid Y > \text{VaR}_{\alpha}(Y)) \quad (17)$$

The impact of capital allocation techniques on portfolio management has been analyzed in a case study in [17], which compares expected shortfall allocation and covariance allocation in large credit portfolios.

Spectral Measures of Risk

The term *spectral measures of risk* (SMRs) [1] denotes a subclass of coherent measures of risk (CMRs) [4] (see **Convex Risk Measures**) characterized by the additional properties of law invariance and comonotonic additivity, which make them particularly appropriate for financial risk management applications. In financial mathematics, this class was first defined in [1] and [7], which studied it from different perspectives. It was however soon realized that this class is in close correspondence with so-called distortion measures already introduced in 1996 in actuarial mathematics [9] in a different axiomatic framework from that of CMRs.

The most popular example of SMR is given by conditional Value at Risk/expected shortfall (*ES*) (see **Expected Shortfall**), which is, in fact, the building block of all the class of SMRs as will be seen.

An SMR of a random variable (r.v.) X denoted by $\rho_\phi(X)$ can be defined as *minus the ϕ -weighted average of all possible outcomes of X sorted from the lowest to the highest*, where ϕ is a weight function, called the *risk spectrum* of the SMR, which needs to be positive, normalized, and decreasing.

In financial risk management, the SMR of a portfolio π usually means the SMR $\rho_\phi(r_T^{(\pi)})$ of the return $r_T^{(\pi)} = \pi_T - (1 + R)\pi_0$ between the current date $t = 0$ and a chosen future date $t = T$, R being the risk-free interest. Clearly, $\rho_\phi(r_T^{(\pi)})$ expresses the *ϕ -weighted average of all possible losses of π sorted in decreasing order*.

Strictly speaking, it is only the SMR $\rho_\phi(\pi_T)$ of the “value” (and not of the “return”) of a portfolio that is a true CMR for the same reasons as explained for *ES* in **Expected Shortfall**. In this article, we discuss the mathematical properties of an SMR as a statistic of a generic r.v. X and loosely use the term *coherent* to mean monotonic, translational invariant, positive homogeneous, and subadditive.

Formal Definition of SMR

For the sake of simplicity, we overlook some technical details such as integrability of r.v.’s and continuity of risk measures. For a more detailed exposition, we refer to [6].

SMRs can be defined as the most general convex combinations of all possible *ES*s. Let us consider a probability space with probability measure P and let X be an r.v. A generic SMR $\rho^\mu(X)$ can therefore be uniquely written as

$$\rho^\mu(X) = \int_0^1 ES_\alpha(X) d\mu(\alpha) \quad (1)$$

where $d\mu$ is a measure on the interval $[0, 1]$ and, *vice versa*, any such $d\mu$ defines an SMR.

For the sake of financial intuition, this expression can be recast into a mixture of quantiles of the variable X . Let $F_X^{-1} : (0, 1) \rightarrow \mathbb{R}$ denote an inverse function of the probability distribution function $F_X(x)$ of X . Choose, for instance, the lower p -quantile function $F_X^{-1}(p) := q_p(X) = \inf\{x \in \mathbb{R} | F_X(x) \geq p\}$. One can show that $\rho^\mu = \rho_\phi$ with

$$\rho_\phi(X) = - \int_0^1 \phi(p) F_X^{-1}(p) dp \quad (2)$$

with ϕ defined by

$$\begin{aligned} \phi(p) &= \mu(\{0\}) \delta_0(p) & p = 0 \\ \phi(p) &= \int_{[p,1]} d\mu(\alpha) \alpha^{-1} & p \in (0, 1] \end{aligned} \quad (3)$$

Alternatively, one can adopt equation (2) as a definition of SMR. The *risk spectrum* ϕ must be of the form $\phi = c\delta_0(p) + \tilde{\phi}$ with $c \in [0, 1]$ and $\tilde{\phi} : [0, 1] \rightarrow \mathbb{R}$ and satisfy the conditions

$$\begin{aligned} \phi(p) &\geq 0 & 0 < p \leq 1 \\ \int_{[0,1]} \phi(p) dp &= 1 \\ \phi(p_1) &\geq \phi(p_2) & 0 < p_1 < p_2 \leq 1 \end{aligned} \quad (4)$$

which can be shown to be necessary and sufficient for ρ_ϕ in equation (2) to be a coherent measure of risk [1]. We see therefore that equation (2) can indeed be read as *minus the ϕ -weighted average of all the outcomes of X sorted in decreasing order*, where ϕ is a positive, normalized, and decreasing function. In general, ϕ also admits a Dirac delta term $c\delta_0$ in the origin, but the singular case $c \neq 0$ is of no practical interest.

Expression (2) together with conditions (4) tells us that a mixture of quantiles is coherent only when they are weighted in such a way that worse events

are given higher weights. This is an important lesson we learn when dealing with quantile-based measures of risk. We immediately also learn that for such a measure to be coherent it needs to weight all the left tail without neglecting any portion of its extreme values.

If we consider α -Value at Risk ($V@R_\alpha$) (see **Value-at-Risk**), which is not a CMR (and hence not an SMR), we see that it can also be expressed through formula (2), but its risk spectrum turns out to be a Dirac delta $\phi^{V@R_\alpha}(p) = \delta_\alpha(p)$, which is clearly not decreasing on $[0, 1]$. Here, we see that the reason why $V@R$ is not a CMR lies exactly in the fact that it completely neglects the worst cases at quantiles smaller than α .

Taking ES_α (see **Expected Shortfall**) as an example of SMR, it is easy to show that its risk spectrum is given by $\phi^{ES_\alpha}(p) = \alpha^{-1} \mathbf{1}_{p \leq \alpha}$, namely, it is flat on $[0, \alpha]$ and vanishing elsewhere. This is a perfectly coherent choice corresponding to an equally weighted average of all the cases beyond the α quantile only.

The function ϕ is also termed a *risk-aversion function* of the SMR [1] because it expresses different aversions encoded in ρ_ϕ to different quantiles of the profit–loss distribution.

The relationship with the class of “distortion measures” defined in [9] is established by writing

$$\rho_\phi(X) = D_g(-X) \quad (5)$$

where the distortion measure D_g is defined as the *Choquet integral* (see, for instance, [6])

$$\begin{aligned} D_g(Y) &:= \int Y \, d(g \circ P) = \int_0^\infty g(1 - F_Y(y)) \, dy \\ &\quad + \int_{-\infty}^0 [g(1 - F_Y(y)) - 1] \, dy \end{aligned} \quad (6)$$

and the function $g : [0, 1] \rightarrow \mathbb{R}$ is a “concave distortion” of the probability measure P . The function g is related to ϕ by

$$\begin{aligned} g(p) &= 0 & p &= 0 \\ g(p) &= c + \int_{(0,p]} \phi(q) \, dq & p &\in (0, 1] \end{aligned} \quad (7)$$

The expression $D_g(-X)$ is another possible definition of SMR, provided that $g : [0, 1] \rightarrow \mathbb{R}$ is increasing and concave and satisfies $g(0) = 0$ and $g(1) = 1$.

In [9], the definition of “distortion measures” is slightly less general, as it is given on positive-valued loss variables Y only, which reflects the actuarial context. Notice also the different convention between the actuarial literature (where losses are modeled as positive variables) and the financial literature (where profits are modeled as positive variables). Apart from these technical details, Wang’s work [9] can be considered a precursor of the development of SMRs in all respects.

As an example of SMR, consider the one-parameter family class of exponential risk spectra given by

$$\phi_\gamma(p) = \frac{e^{-p/\gamma}}{\gamma(1 - e^{-1/\gamma})} \quad (8)$$

It is easy to show that this expression satisfies equation (4) and therefore defines an SMR for any $\gamma > 0$. This risk spectrum is nonvanishing on all the quantiles range $p \in [0, 1]$. Smaller values of γ provide SMRs that are more focused on the extreme left tail of the distribution.

The corresponding concave distortion is easily obtained from equation (7):

$$g(p) = \frac{1 - e^{-p/\gamma}}{1 - e^{-1/\gamma}} \quad (9)$$

Properties of SMRs and Their Characterization

Any SMR ρ_ϕ can be shown to be coherent [1, 7] (see **Convex Risk Measures**). In other words, it satisfies the following properties [4]:

(i) *monotonicity*

$$\rho_\phi(X) \geq \rho_\phi(Y) \quad \text{if } X \leq Y \text{ almost surely.} \quad (10)$$

(ii) *translational invariance*

$$\rho_\phi(X + c) = \rho_\phi(X) - c \quad \text{if } c \in \mathbb{R} \quad (11)$$

(iii) *positive homogeneity*

$$\rho_\phi(\lambda X) = \lambda \rho_\phi(X) \quad \text{if } \lambda \geq 0 \quad (12)$$

(iv) *subadditivity*

$$\rho_\phi(X + Y) \leq \rho_\phi(X) + \rho_\phi(Y) \quad (13)$$

These conditions represent the cornerstone of axiomatic financial risk theory and strong arguments have been given to show that any measure of risk violating them turns out to be inappropriate for capital allocation purposes. In particular, subadditivity embodies the risk diversification principle and prevents the occurrence of paradoxical regulatory arbitrages. Adopting a nonsubadditive measure of risk to compute the regulatory capital of a portfolio, in fact, one can, in principle, obtain a lower value by just splitting the portfolio into two parts and computing the regulatory capital on each part [3].

Conditions (iii) and (iv) imply, in particular, convexity

(v) *convexity*

$$\begin{aligned} \rho_\phi(\mu X + (1 - \mu) Y) \\ \leq \mu \rho_\phi(X) + (1 - \mu) \rho_\phi(Y) \quad \text{if } \mu \in [0, 1] \end{aligned} \quad (14)$$

which plays a fundamental role in asset allocation as it entails the convexity of portfolio optimization problems (see, for instance, [2, 8]).

It is particularly important to identify the additional properties that characterize SMRs as a subclass of CMRs. It can be shown that SMRs are, in fact, all CMRs that are also *law invariant* and *comonotonic additive* [6, 7].

A measure of risk is said to be *law invariant* if it only depends on the probability distribution function of its argument, or, in other words, if it takes the same value on any two r.v.'s that are identically distributed.

(vi) *law invariance*

$$\rho_\phi(X) = \rho_\phi(Y) \quad \text{if } X \sim Y \quad (15)$$

This property may appear puzzling at first sight because every statistic obviously satisfies it. It has, however, to be kept in mind that not all CMRs are “statistics” because they are defined without necessarily specifying a probability space, but by specifying only a set of events [4] (see **Convex Risk Measures**). Hence, law invariance is a stringent condition on CMRs, and, in fact, it is the condition characterizing all CMRs that are also statistics and can therefore *be estimated from data* [2]. This condition is therefore often considered as inevitable for practical risk

management applications, where portfolios are confronted with a model of the “real-world” probability distribution.

The further characterizing property of SMRs within CMRs is comonotonic additivity

(vii) *comonotonic additivity*

$$\begin{aligned} \rho_\phi(X + Y) &= \rho_\phi(X) + \rho_\phi(Y) \quad \text{if} \\ X, Y &\text{ comonotonic} \end{aligned} \quad (16)$$

This means that for SMRs the subadditivity diversification benefit of adding two portfolios X and Y vanishes in the limiting case when they happen to be comonotonic, which means they are perfectly dependent on each other (for a definition of comonotonicity, see, for instance, [5]). This property is also crucial, particularly in the context of capital adequacy in association with subadditivity, because, if it does not hold, another kind of regulatory arbitrage opportunity appears. By exploiting subadditivity, one could lower the capital requirement of two distinct portfolios by just putting them together, even in the comonotonic case when they provide no mutual hedge at all. It seems, in other words, that the diversification principle is correctly represented by conditions (iv) and (vii) together and not by subadditivity alone.

Law invariance and comonotonic additivity, therefore, enrich the set of coherency axioms (i)–(iv). Owing to these additional properties, SMRs are considered to be a particularly interesting subset of CMRs for concrete risk management applications (see, for instance, [3] for a discussion).

Further properties of SMRs are monotonicity with respect to both first- and second-order stochastic dominance [6], which are important preference criteria among portfolios in utility theory. We recall that an r.v. X is said to dominate Y according to first-order stochastic dominance (notation: $X \succ^{1st} Y$) if $F_X(z) \leq F_Y(z)$ for all $z \in \mathbb{R}$, while X is said to dominate Y according to second-order stochastic dominance (notation: $X \succ^{2nd} Y$) if $\int_{-\infty}^z [F_Y(t) - F_X(t)] dt \geq 0$ for all $z \in \mathbb{R}$. First-order implies second-order stochastic dominance. SMRs turn out to be compatible with the notions of preference among portfolios induced by stochastic dominance.

(viii) *monotonicity with respect to first- and second-order stochastic dominance*

$$\rho_\phi(X) \leq \rho_\phi(Y) \quad \text{if} \quad X \stackrel{1^{st}, 2^{nd}}{\succ} Y \quad (17)$$

This means that an SMR always detects higher risk on dominated portfolios.

It is important to stress that conditions (vi)–(viii) do not hold, in general, for CMRs.

Estimation of SMRs

Thanks to law invariance, SMRs can be estimated from data. This is fundamental both when an empirical distribution for the variable X is given and when a closed-form solution for $\rho_\phi(X)$ is not known, but one can sample from the distribution of X to perform a Monte Carlo simulation.

Consider an SMR ρ_ϕ with a given risk spectrum ϕ . Given a sample of N i.i.d. outcomes x_i , of an r.v. X , a consistent estimator of $\rho_\phi(X)$ can be obtained by [1, 2]

$$\hat{\rho}_\phi(X) = - \sum_{i=0}^N \phi_i x_{i:N} \quad (18)$$

where $x_{i:N}$ denotes the ordered statistics, that is, the vector $\{x_{i:N}\}_{i=1,\dots,N}$ of values $x_{1:N} \leq \dots \leq x_{N:N}$ obtained sorting the vector $\{x_i\}_{i=1,\dots,N}$ and the weights ϕ_i are given by

$$\phi_i = \int_{(i-1)/N}^{i/N} \tilde{\phi}(p) dp + \delta_{i,1} c \quad (19)$$

It can be shown that $\hat{\rho}_\phi(X)$ converges to $\rho_\phi(X)$ for $N \rightarrow \infty$. $\hat{\rho}_\phi(X)$ is, in fact, nothing but the SMR ρ_ϕ of the empirical distribution of the sample and as such it is coherent by construction for any finite N .

As an example, consider the family of SMRs defined by equation (8). It can be seen immediately that the spectrum is nonsingular ($c = 0$) and that the weights of the estimator (18) are given by

$$\phi_i = \frac{e^{1/N\gamma} - 1}{1 - e^{-1/\gamma}} e^{-i/N\gamma} \quad (20)$$

Market Risk

Market risk models were developed in the 1990s following the growth in proprietary trading in banking institutions. As an example, the chairman of Morgan asked his staff: “At the close of each business day, tell me what the market risks are across all businesses and locations.” This led to quantitative risk measurements systems, such as Value at Risk (VAR), which aggregate risk at the top level of the institution, based on the most current positions.

The impetus for using VAR models came not only from the industry but also from financial regulators. Notably, the Basel Committee on Banking Supervision [2] allowed commercial banks to use their internal VAR models as the basis for their market risk charge, starting in 1998.

VAR summarizes the worst loss over a target horizon that will not be exceeded with a given level of confidence. For instance, in 1994, Morgan’s daily VAR was approximately \$15 million at the 95% level of confidence over a horizon of one day. In other words, the bank should not expect to lose more than \$15 million in 95 days out of 100. Conversely, it should expect to lose \$15 million or more in the remaining 5 days out of 100. This single number describes the risk of the entire trading portfolio of the bank. Until then, risk was measured and managed at the level of a desk or business unit.

Portfolio Distributions

VAR took hold as a universally accepted measure of risk because of its simplicity. It summarizes the downside risk in one measure, easy to understand, which is expressed in terms of a loss in the relevant currency. Because it is associated with a confidence level, it is sometimes called a *statistical measure of risk*.

The most useful aspect of VAR system, however, is the process that led to this number. To compute VAR, the institution has to set up systems to collect position and market data for the entire firm. From this information, its risk manager can build the entire probability density function of profits and losses over the risk horizon. As shown in Figure 1, VAR is just a quantile of the distribution. Specifying a confidence

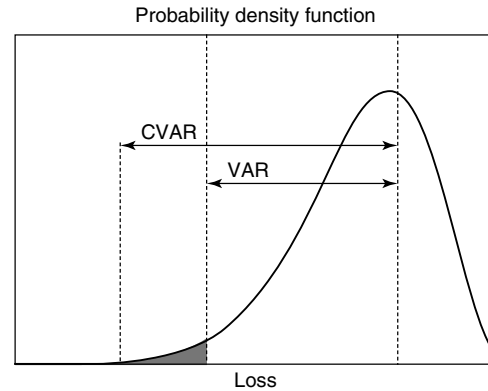

Figure 1 Summarizing the distribution of losses

level c , this is the cutoff point such that the area to its left is precisely $1 - c$.

If the distribution is normal, or more generally elliptical, the quantile can be derived from the standard deviation σ and a multiplier that is distribution-specific. For a normal distribution, for instance, the standard normal deviate that corresponds to the 99% confidence level is $\alpha = 2.33$. Therefore, the 99% VAR can be obtained by multiplying σ by 2.33.

The entire distribution, however, is of interest. We should examine whether the distribution is symmetric or skewed. Skewness to the left implies a greater probability of large losses than gains. Another question is, what is the expected loss when VAR is exceeded? This is known as the *conditional VAR* (CVAR). This must be greater than VAR by construction. In most cases, CVAR is only slightly greater than VAR. In other cases, however, it can be much larger. In such situations, VAR limits may not be effective, as rare losses could bankrupt the institution.

As a risk measure, CVAR has other useful properties. Ideally, risk measures should obey several properties to be “coherent”, as suggested by Artzner *et al.* [1]. If a portfolio has lower returns for all states of the world, its risk must be greater (monotonicity); adding cash to the portfolio should reduce its risk by this amount (translation invariance); scaling a portfolio should simply scale its risk (homogeneity); and merging portfolios cannot increase risk (subadditivity). VAR does not obey the last property, unlike CVAR. Hence, merging two portfolios could sometime produce a higher VAR than the sum of the two separate VAR measures. When distributions are

elliptical, however, VAR measures are coherent (*see Convex Risk Measures*).

The VAR framework can also be used to uncover progressively larger but rarer losses, by increasing the confidence level. However, the empirical distribution becomes more irregular in the extreme tails due to the scarcity of data. To some extent, this problem can be alleviated by extreme value theory (EVT), which provides a theoretically sound analytical density function for the smoothing of the tails. Even so, historical data have severe limitations in some cases.

For instance, a trader may have a position on a foreign currency that is fixed against the dollar and for which there is no history of devaluations. Because the recent history shows no volatility, a VAR measure based on this would mistakenly indicate that the position is riskless, which may not be the case. In the case of corporate credits, there is usually no history of defaults by the creditors in the portfolio. A typical solution consists of assessing default probability from a history of similar creditors, perhaps within the same credit rating group. Even so, credit ratings may be flawed, as we have seen in the case of structured products that received very high credit ratings based on a recent history of home price appreciation, but led to massive defaults as soon as home prices turned lower in 2007.

This is why VAR systems must be supplemented by stress-tests scenarios. The risk manager needs to devise scenarios derived from history, perhaps from

a very long time ago, and from prospective events. Stress tests can be used to estimate the effects of these scenarios on the portfolio. Such measures of risk are nonstatistical, yet are essential to evaluate the risk profile of the portfolio.

Structure of Risk Measurement Systems

The potential for losses can be attributed to two sources. On the one hand are the exposures, derived from active positions taken by the trader or portfolio manager. On the other hand are the movements in the risk factors, which are outside their control. This dichotomy is reflected in the structure of risk management systems, which is described in Figure 2.

The left-hand side describes the portfolio positions, which takes as input trades from the front office. The right-hand side describes the risk factors, which has as input datafeeds with current market prices. Positions and risk factor distributions are brought together in the risk engine, which generates a distribution of portfolio values that can be summarized, for instance, by its VAR.

Different VAR methods make different assumptions for the modeling of positions and risk factors. Because modern risk measurement involves large-scale aggregation, positions are routinely simplified or mapped to the risk factors. Positions can be replaced by their linear exposures to the risk factors,

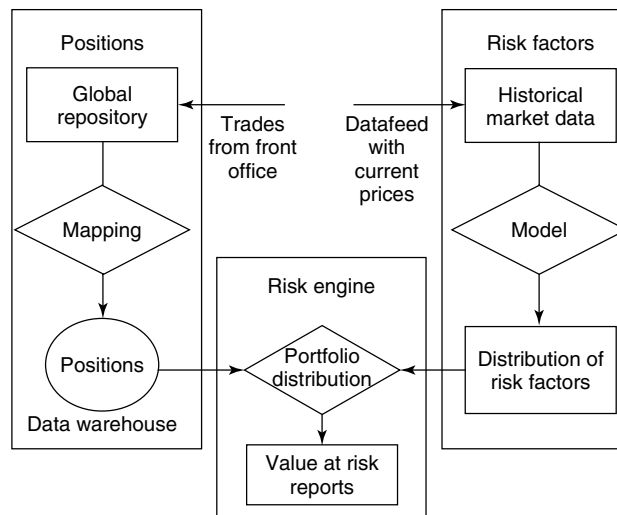

Figure 2 Structure of risk measurement systems

by the quadratic exposures, or using full repricing. The distributions of risk factors can be modeled using a normal distribution, or the historical data, or using Monte Carlo simulations (MCSs). For more details on implementation, see [6, 7].

Local Versus Full Valuation

Conceptually, risk measurement methods can be separated into local valuation and full valuation methods, as shown in Figure 3. The left branch describes local valuation methods, also known as *analytical methods*, which provide closed-form solutions to risk measures. These include linear models and nonlinear models. Linear models are based on the covariance matrix approach. This matrix can be simplified using factor models, or even a diagonal model, which is a one-factor model. Nonlinear models take into account the first and second partial derivatives. The latter are called *gamma* or *convexity* (see **Bond**). Next, the right branch describes full valuation methods, which include historical or MCSs.

To illustrate different approaches, consider a simple instrument, a bond whose value depends on its yield to maturity, which can be taken as the single driving risk factor. The potential for loss depends on the exposure of the bond value to the yield and on potential movements in this yield dy . The linear exposure involves modified duration D^* and dollar duration D^*P . We can write

$$(dP) = (-D^*P) \times (dy) \quad (1)$$

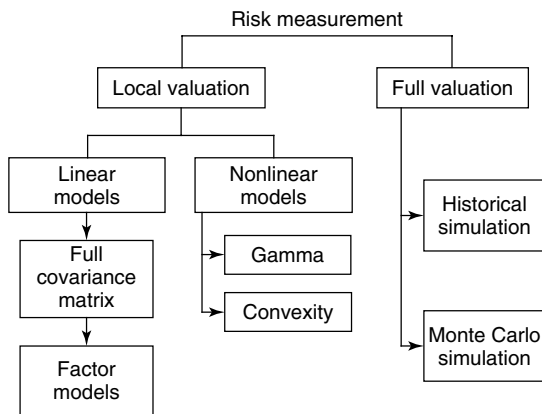

Figure 3 Comparison of risk measurement methods

Hence, the worst loss in the value of the bond at a specified confidence level can be derived from the worst movements in the yield at the same confidence level:

$$(\text{Worst } dP) = (-D^*P) \times (\text{Worst } dy) \quad (2)$$

More generally, the linear model implies a direct link between the bond's VAR and that of the risk factor. Because VAR is reported as a positive number, we take absolute values and have

$$\text{VAR}(dP) = |D^*P| \times \text{VAR}(dy) \quad (3)$$

As an example, take a position in a bond worth \$100 million. We wish to assess VAR over a horizon of one month at the 99% confidence level. Modified duration D^* is four years. From the distribution of yield changes, we observe that the worst increase in yields at the same confidence level and over the same horizon is 0.9%. Putting all of this together, the bond's VAR is $(4 \times \$100) \times 0.9\% = \3.6 million. Note that we priced the bond only once, at the initial yield, which is why this is called a *local valuation method*.

This VAR measure is an approximation only because the bond price is not a simple linear function of the yield. For more precision, we could revalue the bond at the worst yield. Defining y_0 as the initial yield, this gives

$$(\text{Worst } dP) = P[y_0 + (\text{Worst } dy)] - P[y_0] \quad (4)$$

We call this approach full valuation because it requires repricing the asset at the new yield. This is more precise but, unfortunately, is more complex than a simple, linear valuation method, especially if the instrument requires valuation through lengthy simulations. More generally, this method requires full revaluation over the entire risk space, which involves a very large number of data points.

Ideally, we would like to keep the simplicity of the local valuation method while accounting for nonlinearities in the payoffs patterns. We can expand the price-yield function using a Taylor approximation:

$$\begin{aligned} dP &\approx \frac{\partial P}{\partial y} dy + \left(\frac{1}{2}\right) \frac{\partial^2 P}{\partial y^2} (dy)^2 \\ &= (-D^*P) dy + \left(\frac{1}{2}\right) CP(dy)^2 \end{aligned} \quad (5)$$

where the second-order term involves a coefficient called *convexity* C . Here, the valuation is still local because we only value the bond once, at the original point. The first and second derivatives are also evaluated at the local point.

Because the price is a monotonic function of the underlying yield, we can use the Taylor expansion to find the worst down move in the bond price from the worst move in the yield. This leads to a simple adjustment for VAR:

$$\text{VAR}(dP) = |D^*P| \times \text{VAR}(dy) - \left(\frac{1}{2}\right) (CP) \text{VAR}(dy)^2 \quad (6)$$

More generally, this method can be applied to derivatives, whose value depends on the underlying asset as a function $f(S)$. The Taylor approximation is

$$df \approx \frac{\partial f}{\partial S} dS + \left(\frac{1}{2}\right) \frac{\partial^2 f}{\partial S^2} dS^2 = \Delta dS + \left(\frac{1}{2}\right) \Gamma dS^2 \quad (7)$$

where delta, Δ , is the first derivative and gamma, Γ , is now the second derivative, like convexity.

For a long call option position, for example, the worst value is achieved when the underlying price moves down by $\text{VAR}(dS)$. With $\Delta > 0$ and $\Gamma > 0$, the VAR for the derivative is now

$$\text{VAR}(df) = |\Delta| \times \text{VAR}(dS) - \left(\frac{1}{2}\right) \Gamma \times \text{VAR}(dS)^2 \quad (8)$$

This method is called *delta-gamma* because it provides an analytical, second-order correction to the delta-normal VAR. This explains why long positions in options, with positive gamma, have lower risk than with a linear model. This type of analysis can be used to understand how the option characteristics affect its VAR. Unfortunately, this analysis is most useful when there is one only risk factor. With multiple risk factors, the second-order corrections become unwieldy. As a result, this analysis is not applicable to large portfolios.

Mapping

Whichever VAR method is used, the first step consists of mapping. Mapping is the process by which the current values of the portfolio positions are replaced by

global exposures on the risk factors. Mapping arises because of the fundamental nature of VAR, which is portfolio measurement at the highest level. As a result, this is usually a very large-scale aggregation problem. It would be too complex and time consuming to model all positions individually as risk factors. Furthermore, this is unnecessary because many positions are driven by the same set of risk factors. Once a portfolio has been mapped on the risk factors, any of the three VAR methods can be used to build the distribution of profits and losses.

Typical portfolios consist of a large number of instruments, say M . The risk manager must then decide on a small number of risk factors that effectively spans the risk space for the portfolio strategy. Define the number of risk factors as N . In the first step, each position is decomposed into a list of N exposures. In the second step, the exposures are aggregated across instruments. This yields global exposures x_i on each of the risk factors. The final step then consists of combining the exposures with the distribution of the risk factors using one of the three VAR methods.

Consider, for example, a portfolio consisting of many government bonds. The value of each bond represents the sum of the present values of cash flows at different point in times. So, in theory, we could have a number of risk factors that represent the number of days until the longest maturity, typically 30 years. This would involve too many factors. Instead, we could reduce the number of risk factors to three maturities only, for example. Figure 4 illustrates the mapping process with six bonds, which are replaced by three sets of exposures. These are summed across the portfolio, which is then prepared for the next step.

The choice of the number of risk factors must be done taking into account the trading strategies. For example, most fixed-income mutual funds follow a simple, long-only strategy, in which case one factor may be sufficient. The exposure to this factor is then the dollar duration. The portfolio can then be described by its total duration. This choice, however, still leaves out exposures to changes in the shape of the yield curve and would be totally inappropriate for a leveraged trading portfolio that can take long and short positions. If this portfolio is duration-neutral, the risk model would erroneously indicate that there is no risk. More factors are needed for this second type of portfolio. A third type of portfolio could also

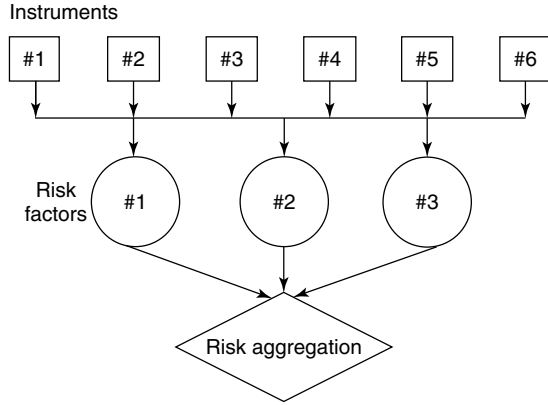

Figure 4 Mapping process

contain options, in that case additional factors such as implied volatilities are needed. In general, more complex strategies require more risk factors. Next, we turn to the different VAR methods.

Delta-normal Method

The delta-normal method is the simplest VAR approach. This method, which is sometimes called *variance-covariance method*, assumes that the portfolio exposures are linear in the risk factors and that the risk factors are jointly normally distributed. As such, it is a local valuation method. The joint normal assumption is very useful, because a linear combination of normal variables is itself normally distributed. As a result, VAR can be expressed in analytical form, directly from the portfolio variance:

$$\sigma^2(R_{p,t+1}) = x_t' \Sigma_{t+1} x_t \quad (9)$$

where Σ_{t+1} is the forecast of the covariance matrix over the horizon, x_t represents the dollar exposures on the risk factors, obtained via mapping and current as of t , and σ^2 is the forecast variance of the portfolio dollar return $R_{p,t+1}$. If needed, the covariance matrix can be simplified to factor models. VAR is directly obtained from the dollar volatility and the standard normal deviate α that corresponds to the confidence level c :

$$\text{VAR}^{\text{DN}} = \alpha \sigma(R_{p,t+1}) \quad (10)$$

More generally, this method can be adapted to portfolio distributions that differ from the normal, by

changing α . VAR can change over time as a result of changes in the positions x_t or in the forecast of the covariance matrix Σ_{t+1} . In the RiskMetrics approach developed by Morgan [8], variances and covariances are forecast using an exponentially weighted moving average (EWMA) model. This is a particular case of the class of generalized autoregressive conditional heteroskedasticity (GARCH) model developed by Engle [3]. Such models are widely employed for predicting time variation in risk because they are parsimonious and fit the data rather well.

Figure 5 shows an application to daily volatility forecasts of the S&P 500 stock index. The graph shows wide swings in the volatility over the short term. In addition, we observe longer term cycles, with elevated volatility from 1999 to 2002, followed by a much quieter period until 2007.

The EWMA model generates forecasts of the covariance between two risk factors i and j as follows. As of today, we observe the previous forecast $\sigma_{ij,t}$ and innovations in the two risk factors R_i and R_j , taken as deviation from their respective means. The forecast for tomorrow is then constructed as

$$\sigma_{ij,t+1} = \lambda \sigma_{ij,t} + (1 - \lambda)(R_{i,t} \times R_{j,t}) \quad (11)$$

This also applies to forecasts of the variance, in that case the two risk factors are the same. This model builds the covariance forecast in recursive form, which not only ensures some persistence in the forecast but also accounts for recent shocks. The relative weight is given by the decay factor λ , which is between 0 and 1. RiskMetrics selected $\lambda = 0.94$ for daily data and $\lambda = 0.97$ for monthly data. Although in theory, this choice could differ across the series, in practice using a common decay factor creates better properties for the covariance matrix.

The model can be also expressed in terms of all previous innovations. Taking the simple case of the variance, this gives

$$\sigma_{t+1}^2 = (1 - \lambda)(R_t^2 + \lambda R_{t-1}^2 + \lambda^2 R_{t-2}^2 + \dots) \quad (12)$$

which shows that the variance forecast is a weighted average of previous squared innovations, with exponentially declining weights on older observations. With $\lambda = 0.94$, the weight on the latest observation is 6%. The weight on the previous observation is $0.94 \times 6\%$, and so on. More than half of the weights is placed on the last 12 observations.

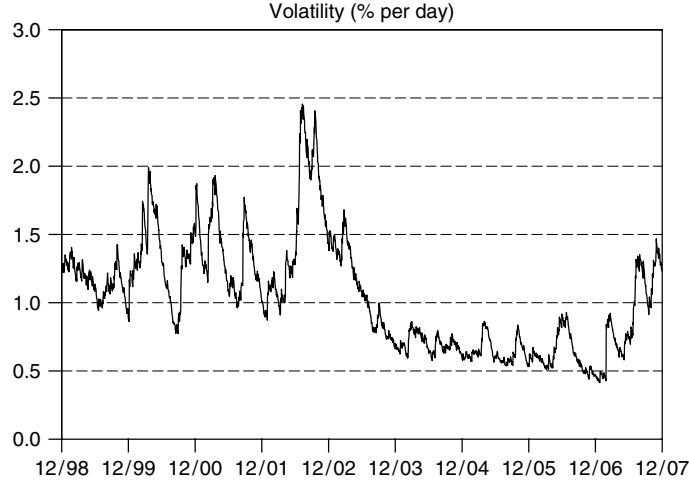

Figure 5 Forecast of daily volatility for S&P 500 Index using EWMA model

In summary, the main benefit of the delta-normal approach is its appealing simplicity. It provides a closed-form solution that is quick to compute. This analytical solution also lends itself well to a decomposition of VAR into its main risk drivers. This provides useful economic intuition.

This method, however, has drawbacks. It cannot account for nonlinear effects. Therefore, some of the risk will be missed for options or for instruments with imbedded options, such as mortgages. In addition, this method may also underestimate the occurrence of large losses because of its reliance on a normal distribution. In practice, most financial series have heavier tails than the normal distribution.

Historical Simulation Method

The historical simulation (HS) method applies current exposures to a time series of recent historical changes in the risk factors, for example, over the last 250 days. Define the current time as t ; we observe data from 1 to t . The current portfolio value is P_t , which is a function of the current N risk factors $f_{i,t}$:

$$P_t = P[f_{1,t}, f_{2,t}, \dots, f_{N,t}] \quad (13)$$

We sample the factor movements from the historical distribution, without replacement. The factor movements are drawn jointly for each day, which preserves the historical pattern of correlations. Call

Δf_i^k the hypothetical movement in risk factor i for the simulation numbered k . These are drawn from the historical distribution:

$$\Delta f_i^k \sim \{\Delta f_{i,1}, \Delta f_{i,2}, \dots, \Delta f_{i,t}\} \quad (14)$$

From this, we can construct hypothetical factor values, starting from the current one, $f_i^k = f_{i,t} + \Delta f_i^k$. This new set of risk factor values can be used to construct a hypothetical value of the current portfolio under the new scenario, $P^k = P[f_1^k, f_2^k, \dots, f_N^k]$ using full valuation.

We can now compute changes in portfolio values from the current position $R_p^k = (P^k - P_t)$, sort these returns, and pick the one that corresponds to the c th quantile, $R_p(c)$. The HS VAR is obtained from the difference between the average and the quantile,

$$\text{VAR}^{\text{HS}} = \text{AVE}[R_p] - R_p(c) \quad (15)$$

Often, the mean is ignored. The advantage of this method is that it is easy to explain. The method is intuitive because each return is associated to an actual realization of risk factors, which gives insight into what could go wrong. The method also appears “distribution-free”, because it makes no specific distributional assumption, other than assuming that the recent past is relevant. This is an improvement over the normal distribution because historical data typically contain fat tails. In addition, because the portfolio can be priced under full revaluation, this approach

can handle options and other nonlinear instruments. This explains why this is perhaps the most popular VAR method. It is also interesting to note that this apparatus can easily handle stress tests, where scenarios are prespecified by the risk manager instead of drawn from the recent history.

Historical simulation has drawbacks, however, as discussed by Finger [4]. It usually relies on a short historical moving window, such as one year, to infer movements in market prices. This may be too short to provide adequate representation of the risk space.

In addition, this method does not adequately track time variation in risk. Figure 5 indeed reveals long-term cycles in volatility. With a long window, the method is very slow to pick up changes in the risk environment. An alternative method, called *filtered simulation*, is proposed by Hull and White [5]. This consists of first fitting a time-series volatility model, such as the EWMA to each risk factor. This produces a series of returns scaled by their volatility forecast σ_t

$$\varepsilon_t = R_t / \sigma_t \quad (16)$$

Historical simulation is then applied to the sequence of scaled returns ε_t , which are then multiplied by the latest volatility forecast for the next day σ_{t+1} . The advantage of this approach is that it does not assume that the scaled returns follow a normal distribution. This method combines any fat tails in the data with the more recent volatility forecast, which should lead to more precise estimates of the risk forecasts. The disadvantage of these more reactive methods, however, is that they create a more volatile capital charge unless there is some smoothing of the daily VAR measures.

Monte Carlo Simulation Method

The MCS method is similar to historical simulation, except that the movements in risk factors are generated by drawings from some prespecified distribution:

$$\Delta f^k \sim g(\theta) \quad (17)$$

where g is the joint distribution (e.g., normal, Student's t , or other) with parameters θ . The risk manager samples pseudorandom values for the risk factors from this distribution. As in the case of historical simulation, these are used to price the portfolio for different scenarios. The returns are then sorted to produce the desired VAR.

This method is the most flexible, because it allows full revaluation as well as complex distributions for the risk factors. On the other hand, it is computationally more onerous. Monte Carlo methods also create inherent sampling variability because of the randomization process. Different sequences of random numbers will lead to different results. It may take a large number of iterations to converge to a stable VAR measure. Finally, the Monte Carlo method requires users to make detailed assumptions about the form and parameters of the stochastic process. The process makes the output less amenable to economic interpretation than other methods. Therefore, it is subject to model risk. Risk managers need to understand how sensitive the results are to the model assumptions.

Backtesting

Whichever method is used, it is essential to compare the risk forecasts with the actual distribution of revenues. This provides a reality check on the accuracy of models. Backtesting involves systematically comparing historical VAR measures with the subsequent daily returns. Each exceedance is called an *exception*. Assume, for example, that VAR is measured at the 99% level of confidence. If the model is well specified, we should observe on average 2.5 exceptions over the course of a year. This is because 100–99%, or 0.01×250 trading days gives 2.5. In practice, some deviation around this number is to be expected. If there are too many exceptions, however, the risk manager will have to conclude that the model is flawed. Such backtesting provides valuable feedback to users about the accuracy of the VAR system. The procedure can also be used to search for possible improvements in the models.

One final drawback of risk measurement models should be mentioned. All models assume that the current positions are frozen over the horizon. In practice, trading will occur, which can change the trading risk profile. More exceptions can occur if intraday risk is greater than at the close of the trading day. This is why exception tests should also be performed on a hypothetical return series. This represents a frozen portfolio, obtained from fixed positions applied to the actual returns on all securities, measured from close to close. This also abstracts from fee income or interest payments that are included

in actual revenues. A bank experiencing too many exceptions using both actual and hypothetical returns should conclude that its risk model is fundamentally flawed.

Conclusions

Quantitative approaches to measuring market risk have become widespread. Risk is now increasingly measured at the top level of the institution, which involves the large-scale aggregation of data across many instruments and types of financial risks.

In spite of its quantitative aspects, risk management is still largely an art form, however. The design of risk architecture involves many tradeoffs. The goal of risk systems should be to produce reasonably accurate estimates of risk at a reasonable cost and within a reasonable time frame. Most importantly, the risk manager needs to be keenly aware of limitations in quantitative risk measures.

PHILIPPE JORION

Models

When I was in grade school we used to build model airplanes out of kits. The frame was made out of precut pieces of balsa wood, each having been carefully pinned according to the plans along a preprinted arc to obtain the appropriate curvature, and then cemented, piece to piece, with airplane glue. The fuselage was made out of tissue paper, first glued to the balsa frame, trimmed, then dampened with water to shrink it taut, and finally, when dry, lacquered and painted to make it stiff and realistic. The engine was merely a long rubber band that ran the internal length of the fuselage, from propeller block at the nose to tail, wound up by rotating the propeller many times and then let loose to unwind for a flight of perhaps 10 seconds at best. If you were a really ambitious model builder, you followed the instructions very carefully: you were supposed to sand off any excess glue on the frame so as leave no imperfections at all.

What was “model” about the model airplane? The Zippy in the kit I remember building was smaller than a real Zippy (I presume there was somewhere in the world of real airplanes an actual Zippy); it was lighter; it was made out of totally different materials. But it did capture two essential features of the putatively real Zippy: appearance and flight. The model looked a lot like an airplane, and it could (briefly) fly.

Nevertheless, the model was not the Zippy. It was not the thing in itself. It was a model Zippy. It lacked seats, ailerons, proper windows, and doors among many other real-life details, and focused on only a few important features. What features are important depends on the model user. In my case, aged about 10, appearance and flight sufficed. At age three or four, crudely shaped wings, a body, and a throaty airplane engine noise might have been enough. A few years older and I would have wanted a combustion engine and radio control. But, however complex, none of these model Zippys would have been a Zippy.

What constrains the construction of a model Zippy?

First, the user and his needs. What aspects of the actual complex airplane and its surroundings is the user most interested in emulating, testing, playing, or tinkering with? An engineer needs a different

model than a child does. Second, engineering and construction: how to put together the model reliably and effectively, with as much accuracy in the key features as possible. Third, science: deep down below, even though the Wright Brothers probably did not know the partial differential equations of fluid flow, the possibility of heavier-than-air flight is built upon the science of mechanics and aerodynamics, on Newton’s laws and the Navier–Stokes equations.

Models in Physics

Scientific models are different. Resemblance is not enough. Scientific models aim at *divination*—foretelling the future—and controlling it, and there are two different approaches physicists use in creating such models.

Fundamental Models

The first approach is to aim at what physicists call a *fundamental model*, which, by nature, describes the *dynamics* behind events in the world. A fundamental model consists of a system of principles, usually formulated mathematically, that are then used to draw *causal* inferences about future behavior. *Dynamics* and *causality* are the essential characteristics. A fundamental model, particularly a successful one, is more of a theory than a model. To be a little pedantic, fundamental models proclaim that “These are the laws of the universe.” They describe the dynamics in God’s terms; they seek to state eternal truths, like Moses descending from the mountain.

An example all physicists are familiar with is Newton’s laws, which state that

$$F = ma \quad (1)$$

$$F = \frac{GMm}{r^2} \quad (2)$$

These are laws of cause and effect. Mass causes gravitational force. Force produces acceleration. Newton’s theory isolates the appropriate variables to use, and specifies a causal relationship between them.

The gap between a successful theory and the part of the universe it describes is virtually nonexistent:

the theory is the universe, not a model of the universe; the universe is the theory.

Phenomenological Models

The second type of model is what physicists call a *phenomenological* model. Phenomenological models are also used to make predictions, but they do not state absolute principles; instead they make pragmatic analogies between things you would like to understand and things you already do understand from more fundamental models. The analogies can be descriptive and useful, but analogies are self-limiting and there is often a toylike quality to them. In physics, one does not delude oneself into thinking of analogies as truth.

Phenomenological models do not say “This is a law.” Instead, they say “Approximately, you can think of this part of the world as being a lot like this other kind of thing you already understand more deeply.” Phenomenological models describe the world in man’s language rather than God’s.

A good example is the liquid drop model of the nucleus, where you think of an atomic nucleus as behaving much like an oscillating drop of fluid, even though you know that at a more reductionist level it is composed of protons and neutrons, themselves particles. Calibrating the liquid drop’s parameters to match the known properties of the nucleus, you can then use the model to compute and predict values of other yet unmeasured properties.

The gap between a successful phenomenological model and the part of the universe it describes is finite, actually, quite large. The model is an approximation, an effigy, a realistic-looking wax apple, Parrhasius’s painted curtain that fooled his fellow artist, a wonderful resemblance but not the thing itself.

Models in Finance

What is the point of a model in finance?

It takes only a little experience to see that it is not the same as the point of a model in physics or applied mathematics. Here is a simple but prototypical financial model. How do you estimate the price of a seven-room apartment on Park Avenue if someone tells you the market price of a typical two-room apartment in Battery Park City? Most likely,

you figure out the price per square foot of the two-room apartment. Then you multiply by the square footage of the Park Avenue apartment. Finally, you make some rule-of-thumb corrections for location, park views, light, facilities, and so on.

The model’s critical parameter is the implied price per square foot. You calibrate the model to Battery Park City. Then you use it to interpolate or extrapolate to Park Avenue. The price per square foot is *implied* from the market price of the Battery Park City apartments; it is not the construction price per square foot because there are other variables—exposure, quality of construction, neighborhood—that are subsumed into that one number.

The Aim of Financial Models

The way property markets use implied price per square foot illustrates the functions of financial models more generally.

Models are Used to Rank Securities by Value.

Implied price per square foot can be used to rank and compare many similar but not identical apartments. Apartments have manifold properties, as outlined above. Implied price per square foot provides a simple one-dimensional scale on which to *begin* ranking apartments by value. The single number given by implied price per square foot does not truly reflect the value of the apartment; it provides a starting point after which more qualitative factors must be taken into account.

Similarly, yield to maturity for bonds allows you to compare the values of many similar but not identical bonds, each with a different coupon and/or maturity, by mapping their yields onto a linear scale. The same applies to price/earnings (P/E) for stocks and option-adjusted spread (OAS) for mortgages or callable bonds. All of these metrics reduce a many-dimensional problem to a single-dimensional one. The Black–Scholes implied volatility of options provides a similar way of collapsing instruments with multiple qualities (strike, expiration, underlier, etc.) onto a single value scale and then making pragmatic modifications to it.

Models are Used to Interpolate from Liquid Prices to Illiquid Ones. In finance, models are used less for divination than to interpolate or extrapolate from the known dollar prices of liquid securities to

unknown dollar values of illiquid securities—in this case from the Battery Park City price to the Park Avenue value. Models in finance do not predict the future; instead they allow you to compare different prices in the present. Similarly, OAS is used to interpolate from relatively liquid bonds to less liquid ones. Correspondingly, the Black–Scholes model proceeds from a known stock price and a riskless bond price to the unknown price of a hybrid security, an option, similar to the way one estimates the value of fruit salad from its constituent fruits, or, inversely, the way one estimates the price of one fruit from the price of the other fruits and the salad.

None of these metrics are strictly accurate or correct, but they all provide immensely helpful ways of beginning to estimate value.

Models Transform Intuitive Linear Quantities into Nonlinear Dollar Values. In physics, a theory predicts the future. In finance, a model is also a means of translating intuition into dollar values. The apartment-value model transforms price per square foot into the dollar value of the apartment. It is intuitively easier to start from price per square foot (or per room) because it captures much of the variability of apartment prices. Similarly, P/E describes much of the variability of share prices. It is less easy to develop intuition about yield to maturity, option-adjusted spread, default probability, or return volatility than it is to think about price per square foot. Nevertheless, all of these parameters are clearly related to value and easier to think about than dollar value itself. They are intuitively graspable, and the more sophisticated you get, the richer your intuition. Models develop by leapfrogging from simple, intuitive, mental concepts (volatility, for example) to the mathematics that describes it (geometric Brownian motion and the Black–Scholes model) to richer mental concepts (the volatility smile) to experience-based intuition about them to newer models (stochastic volatility models, for example) that incorporate the newer concept.

In contrast to a fundamental or phenomenological model, the gap between a successful financial model and the correct value is nearly indefinable, because the fair value is finance’s *fata morgana*, undefined by prices, which themselves are not stationary, and so model success is temporary at best. If fair value were strictly calculable, there would be no markets.

Table 1 The aims of modeling

Field	Model aims
Physics	Reproduction, divination
Hobbyists	Resemblance
Finance	Ranking, interpolation, intuition

The qualities of models in different fields is summarized in Table 1.

The Foundations of Financial Engineering

Science—mechanics, electrodynamics, or molecular biology, for example—seeks to discover the fundamental principles that describe the world, and is usually reductive. Engineering is about using those principles, constructively, for a purpose.

Mechanical engineering is concerned with building devices based on the principles of mechanics (Newton’s laws) suitably combined with empirical rules about more complex forces (friction, for example) that are too difficult to derive from first principles. Electrical engineering is the study of how to create useful electrical devices based on Maxwell’s equations and solid-state physics. Bioengineering is the art of building prosthetics and other biologically active devices based on the principles of biochemistry, physiology, and molecular biology.

What about financial modeling, financial engineering, or quantitative finance? In a logically consistent world, financial engineering, layered above a base of solid financial science, would be the study of how to create functional financial devices—convertible bonds, warrants, credit default swaptions, and so on—that perform in desired ways, not just at expiration, but throughout their lifetime. Which brings us to financial science, the study of the fundamental laws of financial objects, whether they are stocks, interest rates, or whatever else a theory uses as atomic constituents. Here, unfortunately, lie dragons.

Brownian motion, the underpinning of much of quantitative finance, is indeed science, but it is accurate science only for small particles bumped around by invisible atoms. For stocks, the standard theory of geometric Brownian motion is an idealization that, while it captures some of the essential features of price uncertainty, is not a very good description of the detailed characteristics of their price

distributions. Markets are plagued and blessed with anomalies that disagree with standard and nonstandard theories. So, while we in financial engineering are rich in techniques (stochastic calculus, optimization, the Hamilton–Jacobi–Bellman equation, etc.), we do not (yet? ever?) have the right laws of science to exploit.

What solid laws and concepts do we have for building our ranking and translation models? In truth, only one.

The One Law of Financial Modeling

According to a legend, Hillel, a famous Jewish sage, was asked to recite the essence of God’s laws while standing on one leg. “Do not do unto others as you would not have them do unto you,” he is supposed to have said. “All the rest is commentary. Go and learn.”

You can summarize the essence of quantitative finance on one leg too: “If you want to know the value of a security, use the known price of another security that is as similar to it as possible. All the rest is modeling. Go and build.”

“Security” here refers not only to a single security but also to a portfolio of securities. The wonderful thing about this law—it is valuation by analogy—when compared with almost everything else in economics, is that it dispenses with utility functions, the unobservable hidden variables whose ghostly presence permeates most of *faux* quantitative economic theory. Financial economists refer to their essential principle as the *law of one price*, or the principle of *no riskless arbitrage*, which states that:

Any two securities with identical future payoffs, no matter how the future turns out, should have identical current prices.

The law of one price, this valuation by analogy, is the only genuine law we have in quantitative finance, and it is not a law of nature.^a It is a general reflection on the practices of human beings, who, when they have enough time and enough information, will grab a bargain when they see one. The law usually holds in the long run, in well-oiled markets with enough savvy participants, but there are always short- or even longer-lived and persistent exceptions.

How do you use the law of one price to determine value? If you want to estimate the unknown value of a target security, you must find some other replicating

portfolio, a collection of more liquid securities that, collectively, has the same future payoffs as the target, no matter how the future turns out. The target’s value is then simply the value of the replicating portfolio.

Where do models enter? It takes a model to show that the target and the replicating portfolio have identical future payoffs under all circumstances. To demonstrate payoff identity, (i) you must specify what you mean by “all circumstances”, for each security, and (ii) you must find a strategy for creating a replicating portfolio that, in each future scenario or circumstance, will have payoffs identical to those of the target. That is what the Black–Scholes options model does; it tells you exactly how to replicate or manufacture fruit salad—an option—out of fruit—stock and bonds. The appropriate price should be the cost of manufacture.

The tricky part of building these models is specifying what you mean by “under all circumstances.” In Black–Scholes all circumstances means a future in which stock returns are normally distributed and stock prices move continuously. Of course, that is not exactly true. Trying to specify “all circumstances” reminds me of the 1960s movie *Bedazzled*, starring Peter Cook and Dudley Moore. It retells the story of Faust, in which Dudley Moore plays a short-order cook in a Wimpy’s in London who sells his soul to the devil in exchange for seven chances to specify the circumstances under which he can achieve his romantic aims with the Wimpy’s waitress he covets. Each time the devil asks him to specify the romantic scenarios under which he believes he will succeed, he cannot get them quite specific enough. He says he wants to be alone with the waitress in a beautiful place where they are both in love with each other. He gets what he wants—a snap of the devil’s fingers and he and his mutually beloved are instantaneously transported a country estate, where he is a guest of the owner, her husband, whom her principles will not allow her to betray. In the final episode, he wishes for them to be alone together and totally in love in a quiet place where no one will bother them. He gets his wish: the devil makes them both nuns in nunnery where everyone has taken a vow of silence. This is the same difficulty you have specifying future scenarios in financial models—like the devil, markets always outwit you. Even if they are not strictly random, their

vagaries are too rich to capture in a few sentences or equations.

Model Risk

Risk is future uncertainty. A coin flip is risky. You know the current state of the coin, but not the future one. You can, however, perform an infinite number of mental flips and reliably calculate the probability distribution of heads and tails, which will match a physical coin's probability distribution to the extent that the coin is separable from its surroundings and uninfluenced by them.

In this sense, a liquid stock price is risky. You (more or less) know the current price and have no idea about the direction of its future change. But you cannot perform an infinite number of mental stock price moves with any reliability; the stock, the market and the world are not clearly separable and influence each other, so that the probability distribution of stock prices cannot be accurately known (and may not be time invariant). The history of the world does not affect a coin flip. The history of the world does have a bearing on the next change in a stock's price. The risk of a stock price is qualitatively different from the risk of a coin flip.

Financial models interpolate from liquid to illiquid prices by analogy, and must necessarily change over time as the economic environment changes or as market participants become more sophisticated. The Black–Scholes model, for example, used to be regarded as adequate for valuing exotic options prior to the market crash of 1987, but is now often replaced by a range of extended models that incorporate local volatility, stochastic volatility, or jumps. One does not know the truly correct current model, let alone the future one, and so the correct model is uncertain not only in the future but in the present too [3]. The word “risk” therefore inaccurately describes the indeterminate nature of financial models. If you want to describe this state of ignorance as risk, then do not forget that it is a shorthand term for uncertainty, for something much vaguer than probabilistic risk. There is no ensemble of models each with an associated known probability of being right.^b

Idolatry

The greatest danger in financial modeling is therefore the age-old sin of idolatry. Financial markets are alive

but a model is a limited human work of art. A model may be entrancing but no matter how hard you try, you will not be able to breathe true life into it. To confuse the model with the world is to embrace a future disaster driven by the belief that humans obey mathematical rules.

Financial modelers must therefore compromise, must firmly decide what small part of the financial world is of greatest current interest, decide on its key features, and make a mock-up of only those. A model cannot include everything. If you are interested in everything, you are interested in too much. A successful financial model must have limited scope; you must work with simple analogies; in the end, you are trying to rank complex objects on a low-dimensional scale. In physics there may one day be a Theory of Everything; in finance and the social sciences, you are lucky if there is a usable theory of anything.

Models are best regarded as a collection of parallel inanimate thought universes you can explore. Each universe should be consistent, but the actual financial and human world, unlike the world of matter, is going to be vastly more complex and vital than any model you make of it. You are always trying to shoehorn the real world into one of the models you have to see how usefully it approximates the key features you are concerned with.

The right way to engage with a model is, as a fiction reader does, to temporarily suspend disbelief, and then push it as far as you can. The success of the theory of options valuation, the best model economics can offer, is the story of a platonically simple theory, taken more seriously than it deserves and then used extravagantly, with hubris, as a crutch to human thinking. “If a fool would persist in his folly, he would become wise,” wrote Blake in *The Marriage of Heaven and Hell*. That is what options markets have done with options theory.

A little hubris is good. But catastrophes strike when hubris evolves into idolatry. Somewhere between these two extremes, a little north of common sense but still south of idolatry, lies the wise use of conceptual models.

Appendix: Avoiding Modeling Errors

- Expect neither miracles nor mechanical formulas; expect only aids to rational thinking.

- Many financial phenomena are not mathematically modelable in a useful way. You are worse off thinking you have a model and relying on it than simply realizing you do not, and then allowing for a margin of error.
 - Since financial models translate intuitive qualities into dollar values, and since financial data are often sparse, unreliable, and unstationary, models should be relatively simple. Complexity in the face of lack of highly detailed knowledge is pointless.
 - Deal with concepts first, then mathematical formulation, then calibration.
 - Markets are by definition vulgar, and correspondingly the most useful models are wisely vulgar too, using variables that the crowd uses to describe the phenomena they observe. In physics it pays to drop down deep, several levels below what you can observe (think of Kepler, Newton, Einstein, Schrodinger), formulate an elegant principle, and then rise back to the surface again to work out the observable consequences. In finance, which lacks deep scientific principles, it is better to use models that have as direct as possible a path between observation and consequences. (Of course, over time, crowds and markets get smarter and the definition of vulgarity changes to encompass increasingly sophisticated concepts.)
 - Markets learn from experience and proceed to adopt new paradigms and make new mistakes. What is a good model today may be inappropriate tomorrow. Be sure to understand what your model is assuming and what it is ignoring.
 - Regard models as interdisciplinary endeavors. Financial models are generally not back-of-the-envelope formulas handed over to “coders” to turn into executable instructions. Modeling is multidisciplinary: it touches on the practicality of doing business, on financial theory, on mathematical modeling and computer science, on computer implementation, and on the construction of user interfaces. Models end up as computational computer programs embedded in human and machine interfaces that are themselves computer programs. The risks lie in the knowledge of the business, the applicability of the financial model, the mathematics and numerical analysis used to solve it, the computer science used to implement and present it, and in the transmission of information and knowledge accurately from one part of the model, in the larger sense of the word, to the next. It helps to be knowledgeable in all of these areas in order to notice an error and then diagnose it.
 - To avoid errors, it is important to have modelers, programmers, and users who all work closely together, understand each other’s domains well enough to know what constitutes a warning symptom, and have a good strategy for testing a model and its limits. Too much specialization is harmful.
 - Test complex models in simple cases first. Often there are simple special-case known solutions; a deep-in-the-money call option is a forward, for example. Test the model at these boundaries first.
 - Do not ignore small numerical discrepancies. Track down their origin. Small disagreements often serve as warnings of potentially large disagreements and disastrous errors under other scenarios.
 - Usable financial models are software, and are subject to all the problems of writing, debugging, and maintaining large-scale software systems. Be reluctant to give up content for the sake of analytical elegance.
 - Work closely with end users (traders, salespeople, etc.) to embed the software in their environment in the most convenient way.
 - Informed and patient users who clearly comprehend both the model and the method of solution are invaluable in discovering model errors.
 - Efficient testing requires a good user interface.
 - Diffuse a new model slowly outward through the organization, from its developers to developers of other models to the end users.
 - Pride of ownership: one of the best defenses against modeling errors is to ensure that both models and systems are built by people who love what they do, take pride in their work, and are rewarded for doing it well.
- For a more detailed discussion of modeling errors and how to avoid them, see [2]. See also [4].

End Notes

^aThe time value of money, the benefits of diversification and the value of the right to choose are other useful principles. I thank Marcos Carreira for these comments.

Operational Risk

A basic ingredient of the Basel II guidelines of the Basel Committee on Banking Supervision is the introduction of the new risk class of operational risk (OR). OR is the risk of loss resulting from inadequate or failed internal processes, people, and systems or from external events. This definition includes legal risk, but excludes strategic and reputational risk. OR complements the more traditional risk classes of market risk (MR) and credit risk (CR), but it is more concerned with the overall quality assurance of banking operations, and as such borrows methodology more from such fields as reliability engineering and insurance mathematics. For the latter, see, for instance, McNeil *et al.* [17, Chapter 10] and Panjer [20]. The capital charge for OR may range from 10 to 20%, say, of overall risk capital and for some banks top the charge for MR. Under the so-called Pillar I of Basel II, banks can choose among three increasingly quantitative approaches for the measurement of OR. The first two, namely, the basic indicator (BIA) and the standardized (SA) approach, yield volume-based measures for OR: risk capital is charged in proportion to gross income, either companywide in the case of the BIA or averaged across a number (typically 7) of business lines (BL) for the SA.

Larger international banks have to use the so-called advanced measurement approach (AMA), which, upon introduction in January 2008, is mainly referred to as the *loss distribution approach* (LDA). Under the Basel II setup, banks using the LDA have to prove to the local regulator that they have the necessary quantitative risk management environment. Further, insurance of OR losses up to 20% is allowed. Capital estimates are to be based on internal, external, as well as expert opinion data. Essentially, banks are free to choose their own analytic approach for the calculation of an LDA-based capital charge for OR. In the second section, we review some of the approaches used. The third section contains some comments on further work.

The LDA Approach

Basel II prescribes the use of Value-at-Risk as a risk measure for OR, with a confidence level of 99.9% and a measurement horizon of 1 year. Hence,

denoting the total OR loss for the coming year T by L_T , the risk capital charge becomes

$$\text{RC}_{OR}^T = \text{VaR}_{99.9\%}^T(L_T) = F_{L_T}^{\leftarrow}(0.999) \quad (1)$$

where $F_{L_T}^{\leftarrow}$ denotes the generalized inverse of the distribution function (df) of the total loss random variable L_T . This function is also referred to as the *quantile function*. The variety of LDA models used by the industry now stems from the granularity of the stochastic frequency-severity models of L_T implemented, as well as from the extreme tail-fitting of F_{L_T} in order to estimate the 99.9% quantile.

For internal data of banks, the basic structure of the OR data warehouse is as follows:

$$\mathcal{X} = \{X_k^{T-i,b,r} : i = 1, \dots, n, \quad b = 1, \dots, B, \\ r = 1, \dots, R, \quad k = 1, \dots, N^{T-i,b,r}\} \quad (2)$$

where

i	stands for the number of past observation years;
B	stands for the different BL, typically $B = 8$;
R	denotes the different risk types (RT); often $R = 7$;
N	(frequency) denotes the number of losses in year $T - i$, BL b , and RT r ; and
X	(severities) denotes the successive loss amounts in these classes.

Finally, banks are allowed to cap the loss amounts recorded from below, for example, losses are only recorded above USD 20 000. As a consequence, the loss random variable (rv) to be modeled becomes

$$L_T = \sum_{b=1}^B \sum_{r=1}^R \sum_{k=1}^{N^{T,b,r}} X_{k,+}^{T,b,r} \quad (3)$$

where the “+” denotes the above capping: a daunting task indeed! It should be remarked at this point that the calculation of a capital charge for OR is methodologically very different from that for MR and CR. For MR, the confidence level is 99% and the modeling horizon is 10 days; this becomes 99.9% and 1 year for CR. Besides this, the underlying processes are totally different; for OR only losses are to be modeled and obviously, a bank does not “take positions” in OR. A consequence of this is that, in our opinion, regulators have moved a bit too fast up the hill of the ultimate risk management goal: a unified quantitative capital charge formula across all risk

classes. We firmly believe that, before reaching this ultimate goal, we have to walk up and down the quantitative risk management hill a couple of times. The final satisfaction with the results obtained may crucially depend on this.

What have we learned so far from the various quantitative impact studies (QIS) presented by the regulators (see [18] and [8])? First of all, severity data are very heavy-tailed. Moscadelli [18] even reports infinite-mean models for several of the BL-aggregated loss data. Data are furthermore very skewed. Finally, though frequency is no doubt important, it is mainly severity (“the one claim causes ruin”-type of paradigm) that calls the tune. In [18], extreme value theory (EVT) is used for the high-quantile estimation of $F_{L_T}^{\leftarrow}(0.999)$. On the other hand, Dutta and Perry [8] question the use of EVT, as the final capital charge may be very unstable with respect to the starting values of the resulting estimation procedure. See [5] and [19] for more information on this. Dutta and Perry [8] champion the use of the so-called *g-and-h* df as a flexible family of loss severity models for OR data. An rv X has a *g-and-h* df if for $Z \sim N(0, 1)$, and $a, b, g, h \in \mathbb{R}$,

$$X = a + b \frac{e^{gZ} - 1}{g} e^{1/2hZ^2} \quad (4)$$

For a comparison of EVT versus *g-and-h* based estimates of the OR capital charge, see [7], [6], and [15]. The first two references explain the methodological difficulties that would be present when using an EVT-based analysis for real *g-and-h* data, whereas the latter reference, based on the industry OR data, claims that EVT-based risk capital calculations work well till a confidence level of about 95%, whereas for higher confidence levels the *g-and-h* approach seems to deliver more reliable (acceptable) capital values. In our view, the jury is still out. For readers interested in a complete discussion of OR modeling in a large international bank, see [1]; in this article, various modeling issues that we had to omit here because of space constraint have been touched upon. For early contributions to the LDA, see for instance [2, 13, 14].

So far, we have only briefly mentioned the stochastic modeling of the internal OR loss data. The regulators require a combination of internal with external and expert opinion data. Several companies are providing industrywide OR loss data on which banks can calibrate their internal loss distribution

curves. At the moment, it is still early to comment on the validity and the ultimate effect of this. Furthermore, in the realm of OR, expert opinion is called for; it may be borne in mind that we are mainly estimating rare-frequency, high-severity events. As a consequence, a Bayesian approach presents itself. Within the (actuarial) realm of credibility theory, such an approach has for instance been worked out by Bühlmann *et al.* [4]. For a textbook treatment on credibility theory and its link to empirical Bayes, see [3]. Shevchenko and Wüthrich [21] and Lambrigger *et al.* [16] use the concept of conjugate priors within a Bayesian framework.

Further Work

The brief discussion above hopefully highlights some of the key issues/problems for the Pillar I quantitative modeling of OR. Our main concern is that for such extremely heavy-tailed data, VaR-based risk management is, at best breaking new ground and at worst not really applicable. This brings us to some of the recent research on using VaR as a one-fit-all-size risk management tool. For instance, many banks aggregate data BL-wise, estimate the resulting VaRs, $\widehat{\text{VaR}}_1, \dots, \widehat{\text{VaR}}_B$, and add these to obtain

$$\text{VaR}_+ = \sum_{b=1}^B \widehat{\text{VaR}}_b \quad (5)$$

Then they have to come up with a so-called diversification-based capital reduction argument to yield

$$\text{RC}_{\text{OR}}^T < \text{VaR}_+ \quad (6)$$

A more careful look at this issue shows that one is in danger of running head on into the wall of potential nonsubadditivity of the VaR, that is,

$$\text{VaR}(L_1 + L_2) > \text{VaR}(L_1) + \text{VaR}(L_2) \quad (7)$$

in cases important for OR practice; see [19] and the references therein for a discussion on this.

A related mathematical problem we would like to point out at this point is the following: suppose $X_1, \dots, X_d$ are d one-period risks, $\Psi : \mathbb{R}^d \rightarrow \mathbb{R}$ a function corresponding to a financial position $\Psi(X_1, \dots, X_d)$, and ρ a risk measure so that we want to calculate (estimate)

$$\rho(\Psi(X_1, \dots, X_d)) \quad (8)$$

Full determination of equation (8) requires the knowledge of the joint df $F_{X_1, \dots, X_d}$ which in many cases is not known. As a consequence, only upper and lower bounds on equation (8) can be calculated. This problem is dealt with in [9–11]. In [12], the authors discuss the difference between BL-wide aggregation of the VaR-estimates versus RT-wide aggregation. The final difference very much depends on the specific stochastic properties of the frequency-severity models for each cell of the OR loss data matrix.

Conclusion

The Pillar I based quantitative modeling of OR data still has numerous problems: lack of historical data, extreme heavy-tailedness leading to possible super-additivity of the VaR and hence, the questioning of diversification effects based on the VaR, and finally, the overall statistical uncertainty in the modeling of extremes for data of OR type. Before a sufficiently reliable method for OR capital estimation can be found, much more data-oriented work is needed.

Regulatory Capital

The Road to Basel II

Regulatory authorities impose minimum capital requirements and monitor banks through on- and off-site supervision to solve the asymmetric information problem created by the opacity of banks' business and their high leverage. Besides depositor protection, securing the banking sector's key role in the economy, including the monetary transmission process, the credit supply and the provision of payment systems, is an equally important motivation for bank regulation.^a

The development of the "1988 Basel Capital Accord", in short "Basel I", is closely linked to developments in the banking industry after the collapse of the fixed exchange rate system of Bretton Woods. Deregulation of the banking sector, high volatility of financial market prices, particularly exchange rates and interest rates, and increasing competition that fueled rapid lending growth, ultimately contributed to an increasing number of breakdowns in the banking industry. The failure of the German Herstatt Bank in 1974 was an early warning signal. Basel I was the regulatory answer to these developments and became the first common regulatory framework for large and internationally active banks.

The risk sensitivity of minimum capital requirements for credit risk is implemented (and limited) in Basel I by conditioning the risk weight on the borrower type. Loans to sovereigns or banks, for example, receive lower risk weights than corporate exposures. The securitization of financial claims, which has developed into a huge market over the last decade, was not covered at all by Basel I, although rules were often implemented on a national level. At the turn of the millennium, innovations in the financial industry and risk management practice in large, internationally active banks had outpaced the Accord by creating ample opportunities for regulatory capital arbitrage (see [28], for examples).

The 1996 amendment extends the unilateral focus of the Accord on credit risk by adding rules for market risks. Market risks comprise the risk of losses in on- and off-balance sheet positions caused by changes in market prices. More specifically, the amendment requires banks to hold capital for interest rate risk and equities risk in the trading book,

foreign currency risk, and commodities risk. It also introduces, for the first time, an option for banks to choose between a simpler, less risk-sensitive *standardized method* and a more *advanced internal models approach* that allows the use of banks' own *Value at Risk* models for calculating the required capital cushion.

Different approaches distinguished by the degree of risk sensitivity and individual complexity introduce an evolutionary aspect into the Basel II framework. Banks can migrate to a more complex approach with overall lower capital requirements provided they meet higher standards in risk management and risk measurement procedures. Its key objectives as stated by the Basel Committee on Banking Supervision were the focus on large, internationally active banks, the macroprudential focus on the stability of the banking system and the goal to enhance competitive equality.

An important way to promote both financial stability and a level playing field is to strengthen risk sensitivity of the minimum capital requirements. This reduces opportunities of *regulatory capital arbitrage*, which may otherwise encourage banks to carry out business transactions entailing risks that are not adequately captured by regulatory capital requirements and to avoid transactions that are overly burdened.

The risk sensitivity of the capital requirements for credit risk, for example, is increased in Basel II by replacing the static risk weights of Basel I with risk weights that either depend on external ratings or are based on a stylized credit risk model and require banks' own estimates of default probabilities as input. Furthermore, operational risk is included in the minimum capital requirements as a new risk category. This transition to model-based minimum capital requirements has not always been without its detractors. Indeed, concerns were raised about the limitations of quantitative models, advocating simpler approaches for regulatory purposes (see [17], especially, for market risk models).

Banking supervision operates somewhere between the two conceptual extremes of rules-based and principles-based regulation. Basel II contains important elements of both concepts. The calculation of a regulatory capital charge based on banks' own estimates of risk components which are inputs to regulatory risk-weight functions is an example of a rules-based approach. The regulatory approval of

internal models both for market risk in the trading book and for operational risk is an example of a principles-based approach. In the early stages of its development, a principles-based internal models approach for credit risk was still considered a viable option for the new framework [26]. On the basis of the results of an internal study, the Basel Committee acknowledged that the state of model development at that time could not ensure sufficient comparability across institutions and that a meaningful validation of model parameters and assumptions would be prevented by data limitations [5]. As a consequence, internal models are not eligible for the calculation of regulatory capital for credit risk. The risk-weight functions are defined in the new framework and only the risk components, for example, default probabilities, have to be estimated by banks' internal methods.

Basel II rests on three pillars, the first of these being the *minimum capital requirements*. The *supervisory review process*, which constitutes the second pillar, provides guidance for supervisory practice and banks' internal capital adequacy assessment processes. Whereas the first pillar is a typical rules-based approach, the second pillar is principles-based on account of its very purpose. The minimum capital requirements and guidance on the supervisory review process are complemented by disclosure requirements to enforce *market discipline*, the third pillar of the new framework.

Since this article is concerned with the methodological underpinnings of the new framework, its main focus is on the first pillar and here on the most risk-sensitive, model-based methods. The second pillar is only touched upon while the third is omitted altogether.

Capital Ratios as Solvency Indicators

The regulatory capital ratio links a bank's loss-absorbing capital in the numerator to its aggregated risks, measured by risk-weighted assets, in the denominator. If a bank has recognized internal models for market risk and operational risk, the *total capital ratio* (TCR), which should not fall below 8% is defined in Basel II as follows:

$$TCR = \frac{TC - RD_{CrR} - Ded}{RWA_{CrR} + 12.5 VaR_{MkR} + 12.5 VaR_{OpR}} \quad (1)$$

TC	: <i>total capital</i> consisting of core capital and supplementary capital
RD_{CrR}	: <i>regulatory difference</i> between expected loss and provisions for credit risk (only)
Ded	: deductions (e.g., certain investments in subsidiaries and securitization-related positions)
RWA_{CrR}	: <i>risk-weighted assets</i> for credit risk in the banking book
VaR_{MkR}	: <i>Value at Risk</i> for market risk in the trading book (internal models approach)
VaR_{OpR}	: <i>Value at Risk</i> for operational risk (advanced measurement approach).

Total capital can be decomposed into core capital (tier 1), for example, paid-up share capital, and supplementary capital (tier 2 and tier 3). Tier 2 capital consists of, for example, general loan loss reserves and subordinated debt (with a maturity of at least five years). Tier 3 capital consists of short-term subordinated debt and can cover market risk alone and this only if the bank has a recognized internal model. Besides the 8% minimum for the TCR, banks also need to set aside a minimum of 4% for their tier 1 ratio, which contains only tier 1 capital in the numerator.

Minimum requirements for credit risk in the banking book typically make the highest contribution to a commercial bank's total regulatory capital charge. They can be measured by two different approaches: the *revised standardized approach* (RSA) and the *internal ratings-based approach* (IRBA). The latter is further differentiated in the *foundation IRBA* and the more complex and risk-sensitive *advanced IRBA*. The RSA risk weights depend on the borrowers' external ratings, whereas the IRBA risk weights are model based and require banks' own estimates of the probability of default, the (expected) loss given default, and the maturity of the exposure. The parameterization of the risk-weight functions differs between asset classes, for example, sovereigns, corporates, and retail clients.

Its widespread use in the industry favors the *Value at Risk* (see **Value-at-Risk**) as the risk measure for the calculation of regulatory capital charges. The capital under a Value at Risk rule K_{VaR} is set sufficiently high so that it covers portfolio losses L

with a probability α over a one-year horizon:

$$K_{VaR} = \inf \{k \mid \Pr(L \leq k) \geq \alpha\} \quad (2)$$

The “confidence level” or solvency probability α for credit risk and operational risk, for example, is set to 99.9%. This value is consistent with empirical findings suggesting that large internationally active banks even reach higher target levels so that the new minimum requirements should not represent a binding constraint [27].

The Value at Risk of a credit portfolio can be decomposed into the *expected loss* (EL) and the *unexpected loss* (UL). Whereas EL is the mean of the loss distribution, UL is defined as the difference between an adverse quantile of the portfolio’s loss distribution (e.g., given by a confidence level of 99.9%) and EL. Expected losses are traditionally covered by general provisions (or general loss reserves) and also considered in the calculation of the interest rate margin whereas UL is covered by a capital cushion. In the IRBA, the risk-weighted assets cover only UL. Therefore, if EL is covered by provisions or revenues and if the model is correct, the likelihood that the bank stays solvent at the risk horizon is equal to the confidence level, consistent with equation (2).

The risk-weighted assets for credit risk in the IRBA are computed by aggregating over the UL-based capital charges UL_n of all N individual credit claims in the portfolio:

$$RWA_{CrR} = 12.5 \cdot \sum_{n=1}^N UL_n \quad (3)$$

To avoid distortions of the level playing field by differences in banks’ EL coverage by provisions, any shortfall needs to be deducted in equal shares from tier 1 and tier 2 capital in the numerator of the capital ratio. This shortfall or *regulatory difference* can be negative if the total eligible provisions (TEP) exceed EL. In this case, the regulatory difference RD_{CrR} is recognized in the tier 2 capital, but only up to a limit of 0.6% of risk-weighted assets for credit risk:

$$RD_{CrR} = \max \{EL - TEP, 0\} - \min \{\max \{TEP - EL, 0\}, 0.006 \cdot RWA_{CrR}\} \quad (4)$$

In the internal models approach for market risk and in the *advanced measurement approach* (AMA)

for operational risk, regulatory capital is measured by the Value at Risk and, therefore, the model output needs to be scaled by a factor of 12.5 to be consistent with the risk-weighted assets for credit risk in the denominator of the capital ratio in equation (1).

Capital Requirements for Credit Risk

Asymptotic Single-factor Model

The capital charge for a single asset measures its marginal contribution to the capital requirement for the total portfolio. A *decentralized capital rule*, often referred to as *portfolio invariance* property, requires that the capital charge for an asset depends only on its own risk characteristics and not on the composition of the rest of the portfolio. It is convenient for regulatory capital requirements because it makes it possible to compute the capital charge of a portfolio by adding up the independently calculated capital charges of its assets. This property generally does not hold under a Value at Risk based capital rule because the marginal contribution of a single asset depends on the correlation with the other assets in the portfolio. Therefore, any change in the portfolio composition can affect the capital charge of an individual asset (see **Economic Capital Allocation**).

Gordy [21] was able to show that portfolio invariance can be achieved for a limiting case given a single-factor version of a common credit risk model. In the following, we refer to this model as the *asymptotic single risk factor* (ASRF) model for reasons that will soon become clear. Large-sample approximations had already been used earlier for computational shortcuts but only with additional homogeneity assumptions for the portfolio ([39] and also see **Large Pool Approximations**).

The ASRF model is a stylized version of an asset value model that belongs to the class of *conditionally independent factor models* [38]. The key variable is the stochastic default-trigger or ability-to-pay variable Y_n of the n th firm, which is often loosely interpreted as the standardized asset value return of the borrower. Y_n depends on a single systematic risk factor X and an idiosyncratic risk factor U_n :

$$Y_n = \sqrt{\rho} X + \sqrt{1 - \rho} U_n \quad (5)$$

The parameter ρ denotes the asset correlation between any pair of firms. The risk factors X and U_n

are pairwise independent and standard normally distributed, such that Y_n is also standard normal. Default is triggered if Y_n falls below a default threshold c_n at the end of a risk horizon of (typically) one year. The (unconditional) probability of default is given by $\Phi(c_n)$ where $\Phi(\cdot)$ denotes the cumulative distribution function of the standard normal distribution.

Gordy [21] identifies the specific conditions for replacing L in equation (2) asymptotically by $\mathbb{E}(L|q_X(\alpha))$, which leads to a simple capital formula where $q_X(\alpha)$ denotes the $(1 - \alpha)$ -quantile of the distribution of X . Apart from technical conditions, such as the monotonicity of losses in X in the aggregate, two economically relevant conditions need to be fulfilled for a portfolio invariant capital rule. First, the dependence structure of the model is driven (solely) by the dependence of the default-trigger Y_n on the common systematic risk factor X . Second, portfolio invariance requires that the credit portfolio is perfectly fine grained, which means that the idiosyncratic risk has been eliminated by diversification.

Under these two assumptions, the required capital UL_n to cover the UL of the n -th asset over a one-year horizon is given by the following formula:

$$UL_n = EAD_n LGD_n [p_n(\Phi^{-1}(1 - \alpha)) - PD_n] \quad (6)$$

with

$$p_n(\Phi^{-1}(1 - \alpha)) = \Phi \left(\frac{\Phi^{-1}(PD_n) - \sqrt{\rho} \Phi^{-1}(1 - \alpha)}{\sqrt{1 - \rho}} \right)$$

The aggregation of UL_n over all assets gives the capital of the portfolio. The term $p_n(\Phi^{-1}(1 - \alpha))$ in equation (6) can be interpreted as the conditional default probability of the borrower, conditional on the value $\Phi^{-1}(1 - \alpha)$ of the systematic risk factor. The value of α is 0.999, implying a solvency probability of 99.9%. The asset correlation parameter ρ is defined dependent on the asset class.

The ASRF model's property of portfolio invariance ensures that the contribution of each asset to the UL capital of the portfolio requires the bank to estimate only three risk components as inputs to the risk-weight formula: the *exposure at default* (EAD), the *loss given default* (LGD), and the *probability of*

default (PD). For credit exposures with a time to maturity different from one year, UL_n from equation (6) is multiplied by a maturity adjustment factor, which requires the *effective time to maturity* as an additional parameter. These four risk components and the asset correlation parameter are further discussed in the following subsection.

The Risk Components EAD, LGD, and PD

The EAD is defined as the expected gross exposure upon default of the obligor and for on-balance sheet items as no less than the currently drawn amount. Credit conversion factors are applied in the case of noncash products such as undrawn credit commitments. In the advanced IRBA, banks use own estimates, whereas in the foundation IRBA, the draw-down factors of undrawn credit lines are given ([7], para. 474). Empirical and theoretical work on EADs in traditional bank lending is scarce. There appears to be some evidence that EAD decreases with credit quality. This may, however, also be the consequence of stricter limits and covenants for borrowers below investment grade [6].

LGDs are estimates of the loss severity of credit exposures upon default. They are estimated by the bank in the advanced IRBA and for retail exposures in the foundation IRBA as well. Mounting empirical evidence suggests that, at least in certain asset categories, loss severity can systematically fluctuate over time (see, e.g., [3] or [1]), inducing a correlation between default rates and recovery rates. Instead of incorporating this correlation in the ASRF model, banks have to account for systematic risk in their LGD estimates. Therefore, for exposures for which recovery rates are volatile over the economic cycle, the bank must estimate *downturn LGDs*, that is, estimates that are appropriate for an economic downturn if those are more conservative than the long-run average. In order to spare banks the estimation of two different LGDs, the downturn LGD is used in (6) also for subtracting EL, although EL depends in theory on the *unconditional* expectation of loss severity. For defaulted loans, banks have to compute a best-estimate LGD on the basis of current economic conditions and facility status ([7], para. 468 and 471).

The PD parameter measures the probability of the borrower entering default over a one-year horizon. The default event occurs either if the bank considers that the obligor is unlikely to pay its credit obligation

or if the obligor is past due more than 90 days ([7], para. 452). All banks adopting the IRBA must have an internal rating methodology through which every borrower is assigned a rating grade, which, in turn, determines the PD.

PD estimates of banks typically lie in a continuum between two methodological concepts: *point-in-time* PDs, which focus on current conditions and are often estimated from market prices, and *through-the-cycle* PDs, which account for the fluctuation of default rates over a business cycle. The exact definition of through-the-cycle PDs is controversial as are their pros and cons for regulatory capital purposes ([6], pp. 10–27 for a rigorous definition and discussion of different methodological concepts of internal ratings and PDs). Arguments in favor of point-in-time PDs are their consistency with a mark-to-market valuation of the portfolio and the easier validation owing to the shorter one-year horizon. Through-the-cycle PDs are, by construction, less volatile over time; this reduces cyclical effects of regulatory capital requirements. The Basel II framework gives banks some flexibility concerning their PD estimation, which mirrors the diversity of methodologies used in banks.

Asset Correlation

The asset-correlation parameter ρ in equation (6) fully determines the dependence between the asset value returns of two borrowers in the ASRF model and, in this way, the dependence structure of the portfolio. It is, therefore, by construction, a key driver of UL capital. During the development of Basel II, the original proposal of a flat asset correlation of 0.2 was replaced by the following function depending on the PD of the borrower:

$$\rho = \rho_{\max} - (\rho_{\max} - \rho_{\min})(1 - e^{-k PD_n}) \quad (7)$$

For wholesale lending, $\rho_{\max}$ and $\rho_{\min}$ are set to 0.24 and 0.12, respectively (with $k = 50$). For retail lending, the correlations are lower. Apart from reducing the steepness of the risk-weight curve, and, in this way, mitigating cyclical fluctuations of UL capital, the PD dependence of the asset correlation also reflects an on-average lower systematic/higher idiosyncratic risk of firms with a lower credit quality ([33] for empirical evidence).

In principle, the asset correlation can be estimated from historical data, such as stock returns, rating

migrations, or default rates. Empirical work on the estimation of asset correlations faces various limitations, for example, the scarcity of default events, missing traded equity for certain borrower types, and instability of correlations over time. As a consequence, it has produced quite diverse results (see **Correlation Risk** and for an overview of empirical results see [25]). Comparing the asset-correlation parameters in the risk-weighted functions with empirical correlation estimates is, however, misleading because the former are the result of the calibration of the ASRF model to credit risk portfolio models with a richer correlation structure, based on real credit portfolios (see the section Basel II Calibration and Procyclicality).

For small and medium enterprises in the corporate asset class, the asset-correlation parameter also increases with the size of the firm, which is measured by yearly turnover. The dependence on firm size reflects indicative empirical findings that systematic risk is higher for large firms than for small and medium enterprises (see, e.g., [18] or [33]).

Maturity Adjustments

The UL capital charge given by equation (6) captures only losses from default events over a one-year horizon. The market value of a loan with a longer maturity, however, is also sensitive to a change of the borrower's credit quality over this horizon. The maturity adjustment factor $M(T)$, which is a function of the loan's time to maturity T measured in years, accounts for the impact of migration risk by calibrating the model in a mark-to-market setting.

$$M(T) = \frac{1 + b(PD_n) \cdot (T - 2.5)}{1 - 1.5 b(PD_n)} \quad (8)$$

with

$$b(PD_n) = (0.11852 - 0.05478 \ln(PD_n))^2 \quad (9)$$

The adjustment factor $M(T)$ enters equation (6) as a multiplicative factor. It measures the relative change in required capital (per euro of the capital required for a 2.5-year loan) for a time to maturity greater than one year. For maturities between one and five years, $M(T)$ has been calibrated to a mark-to-market model. As a consequence, the capital figure obtained should be understood as the output of a mark-to-market model although the underlying model

structure of UL_n is that of a one-period default-mode model.

Since the maturity adjustment factor depends on the PD, the relative difference between capital charges for one and five years increases from 26% for a PD of 10% up to 242% for a PD of 0.03%. The size of the maturity adjustment has been criticized on the grounds that regulatory capital rules should focus on tail risk events rather than on migration risk. In fact, maturity adjustments quickly decrease for higher confidence levels as migration risk becomes less important [29]. Another criticism has been voiced from a macroprudential perspective. Relatively high values of the adjustment factor for long maturities and correspondingly low values for short maturities can provide incentives for short-term lending. Therefore, from a macro perspective, they can increase the risk of a credit crunch at times of stress and reinforce procyclical effects of the framework.

Credit Risk Mitigation

Compared with the previous Accord, the recognition of credit risk mitigation techniques has been greatly refined and expanded in Basel II, with respect to the methodology as well as the scope of eligible collateral. Two different methods are already available in the RSA to take account of risk mitigation. In the *simple approach*, the risk weights of the credit exposure are substituted by the risk weights of the protection provider. In the more risk-sensitive *comprehensive approach*, fluctuations in the value of the exposure as well as in the collateral are taken account of by the following formula, which defines the EAD after credit risk mitigation (E^*):

$$E^* = E(1 + H_e) - C(1 - H_c - H_{fx}) \quad (10)$$

- E : EAD without recognition of credit risk mitigation
- H_e : haircut for changes in the value of the credit exposure
- H_c : haircut dependent on the collateral
- H_{fx} : haircut for currency risk
- C : market value of the collateral.

The various haircuts in equation (10) are instrument dependent and either tabulated or can be estimated in more advanced approaches.

Credit derivatives and guarantees are typical instruments to address *counterparty credit risk* in

over-the-counter derivatives and security-financing transactions. This risk is driven by the joint effect of the uncertainty of the future exposure and the credit quality of the counterparty. A loss occurs only if the contract has a positive market value when the counterparty defaults; it also depends on the costs from replacing the contract by a similar transaction with a different counterparty. In this context, Basel II offers three approaches to address credit risk mitigation.

The most risk-sensitive approach is the *internal-model method*. In this approach, which is subject to regulatory approval, the EAD is the product of a multiplier and the *effective expected positive exposure (EPE)*. The effective EPE is defined as weighted average over time of effective expected exposures over the first year. Effective expected exposure, in turn, is the maximum expected exposure that occurs at a specific date or at a previous date ([7], para. 25–68).

In Basel II, the multiplier is set to 1.4. Subject to regulatory approval, it can also be estimated by the bank, recognizing a floor of 1.2. Applying a multiplier is important because the EPE can be interpreted as a loan-equivalent value only under certain assumptions: the portfolio needs to be infinitely granular and the exposures need to be mutually independent on a counterparty level and also from the counterparty's credit quality, that is, there is no wrong way risk. In addition, the EPE calculation assumes a static portfolio and does not consider *roll-over risk* from replacing transactions that mature before the one-year horizon. Canabarro et al. [15] and Wilde [40] explore the sensitivity of the multiplier against these assumptions.

Basel II Calibration and Procyclicality

The capital requirements under Basel II are the result of combining a bottom-up with a top-down calibration approach. In the bottom-up approach, appropriate risk weights for different asset classes are determined *relative* to each other to achieve consistency with banks' internal risk models. Figure 1 shows the risk-weight functions of selected asset classes. For a meaningful comparison, the LGD values represent average values from the fifth quantitative impact study of the Basel Committee [8]. Loans in asset classes with higher systematic risk and longer maturities generally carry higher risk weights for the

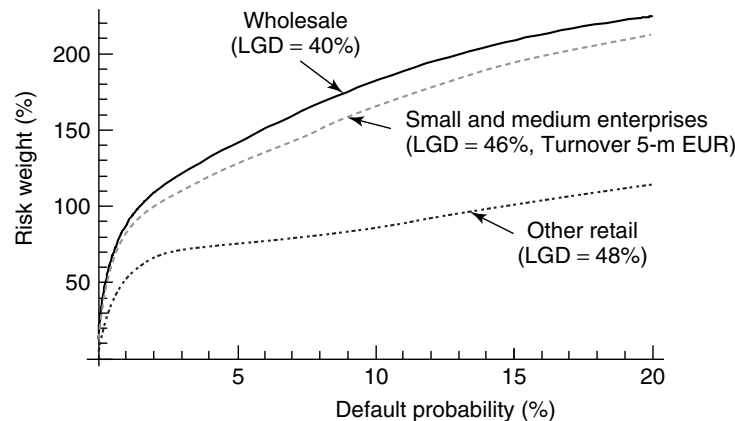

Figure 1 Risk-weight functions of different asset classes. This figure shows the risk-weight functions of three asset classes dependent on the probability of default. The loss given default (LGD) of every asset class is the average value for large, internationally active G10 banks, taken from the fifth quantitative impact study of the Basel Committee. The effective maturity for wholesale and small and medium enterprises is 2.5 years

same default probability (e.g., wholesale credit relative to retail credit).

Parallel to the bottom-up approach, the Basel Committee pursues a top-down approach with the goal to broadly maintain the level of capital requirements, while providing incentives for the more risk-sensitive approaches of the revised framework. The top-down approach was implemented by five quantitative impact studies in which banks were invited to compute the capital requirements for their current portfolios under the current accord as well as under the envisaged Basel II framework. One result of these exercises was the introduction of a scaling factor of 1.06 which is applied to risk weights for credit risk. Subsequent to the finalization of the Basel II framework, ongoing efforts have continued to monitor the level of capital requirements.

The dynamics of minimum capital requirements which are driven by the economic cycle, are not least as important as the level of capital. Since default rates and recovery rates are often systematically affected by the business cycle, banks adopting an IRBA might face higher capital requirements in an economic downturn. Stricter lending policies could then restrict the credit supply and generate negative feedback effects on the real economy, a phenomenon that is often described as *procyclicality*. In anticipation of the dynamic impact of the new IRBA, various mitigants have already been built into the new framework, for example, a flattening of the risk-weight functions

by a negative dependency of the asset correlation parameter on PD and the requirements to estimate downturn LGDs and to carry out procyclicality stress tests.

Empirical research has confirmed that fluctuations in regulatory capital requirements under the new framework are expected to be economically significant (see, e.g., [16] or [30]). Major empirical obstacles, for instance, uncertainties about the dynamic properties of PD and LGD estimates in real IRBA systems, have contributed to widely dispersed results. Furthermore, financial innovation, for example, the emergence of securitization and the originate-to-distribute model, has affected the traditional bank lending channel in ways that are difficult to predict. Procyclical effects, therefore, still pose a challenge for empirical research, risk management, and financial regulation.

Securitization Framework

Reducing the potential for regulatory capital arbitrage in securitization was a key target behind developing the new framework (see examples in [28]). For this purpose, regulators, in designing new rules, considered the level of capital held internally by banks for securitization exposures and set out to achieve capital neutrality between on-balance and off-balance sheet transactions as well as to ensure that capital charges for individual tranches capture the

relative distribution of risks across all tranches. At the same time, interfering in market segments where securitization was deemed a viable instrument of risk transfer needed to be avoided.

For banks following an IRBA, two methods are available in Basel II. If the tranches carry external ratings, they have to use the *ratings-based approach* (RBA). In this case, the risk weights are tied to ratings and account also for the granularity of the pool, measured by the effective number of exposures (or the inverse of the *Herfindahl—Hirschman Index*). If a specific tranche is unrated, its rating can be inferred from lower, more risky tranches.

Peretyatkin and Perraudin [35] compare the RBA capital charges with the model of Pykhtin and Dev [36, 37] on which they are based. They identify two simplified assumptions of the RBA that may have a significant effect on the capital charge: first, the missing differentiation between maturities and, second, not accounting for differences in correlation between the tranches exposures and exposures in the loan book.

The *supervisory formula approach* (SFA) provides an alternative for regulatory capital calculation if external ratings are not available and cannot be inferred. The SFA is based on a stylized model, similar to the ASRF model for traditional loans. If the required input data are unavailable, the exposure needs to be deducted from capital. In the special case of eligible liquidity facilities and credit enhancements in connection with ABCP (asset-backed commercial paper) programs, banks can determine the capital charge by their own internal assessment.

The conceptual underpinnings of the SFA are outlined in [23] and [22]. It strikes a balance between risk sensitivity and the tractability required for regulatory purposes. In the ASRF framework of the IRBA, the cumulative capital charge $K(\zeta)$ up to the enhancement level ζ is given by

$$K(\zeta) = \mathbb{E}[\min\{\zeta, L\} | X = q_X(\alpha)] \quad (11)$$

- ζ : share of the total amount of subordinate securitization exposures in the total
- : pool exposure
- L : book-value loss incurred in the pool as a share in the total pool exposure.

For a tranche of thickness Δ with enhancement level ζ , the capital in percent of the bank's exposure is

$$K(\zeta, \Delta) = \frac{K(\zeta + \Delta) - K(\zeta)}{\Delta} \quad (12)$$

By construction, the cumulative capital charge over all tranches equals K_{IRB} , which is defined as the sum of the UL capital from the ASRF model (6) and EL.

A direct application of the ASRF model to measure the risk of securitization tranches was not deemed as meaningful since the model implies relatively high capital charges for junior tranches, whereas at a certain level of protection the capital charge jumps to zero, depending also on the thickness of the tranche. This problem is solved by the *uncertainty in loss prioritization* assumption. By this assumption, the deterministic enhancement level ζ in equation (11) is replaced by the *effective* enhancement level $Z(\zeta)$. Specifying $Z(\zeta)$ as a Dirichlet process with parameter τ , the marginal distribution of $Z(\zeta)$ is $\text{Beta}(\tau \zeta, \tau(1 - \zeta))$. For $\tau \rightarrow \infty$, the model converges to the case of strict loss prioritization. The assumption that the exact level of protection of a tranche is uncertain can be motivated by the complexity of deal-specific contractual cash flows, often termed the *waterfall* of a securitization transaction, which cannot be explicitly modeled in the interest of tractability. In addition to the single risk factor assumption shared by the ASRF model, the SFA model assumes that the collateral pool is homogeneous and that LGDs are pairwise independent conditional on the systematic risk factor X and subject only to idiosyncratic risk.

Computing the SFA-based capital requirement for a tranche requires five inputs: two tranche-specific figures from the bank, namely, the nominal enhancement level ζ and the tranche thickness Δ , and three collateral pool-specific input values, namely, the *effective* number of exposures N , the exposure-weighted average expected *LGD*, and K_{IRB} . Since real portfolios are heterogeneous in exposure size, N is concentration-adjusted, that is, the inverse of the *Herfindahl—Hirschman Index*. To the extent that K_{IRB} contains maturity adjustments, maturity is also captured by the SFA. The parameter τ of the Beta distribution is set to 1000 in Basel II ([7], para. 623–634).

The model developed by Gordy and Jones assumes that a bank's exposure to every securitization is a negligible part of its total portfolio and that the collateral pool contains only loans or bonds but not that the collateral pool is infinitely fine grained. As an extension of the ASRF model, it does not capture the risk concentration if the same obligor is also part of other securitization transactions or of the traditional loan portfolio.

A level of conservatism is introduced by requiring deduction from capital for any protection level up to K_{IRB} . Furthermore, even for the most senior tranches, the capital charge cannot fall below the floor of 0.56%. Figure 2 shows the cumulative capital given by the SFA depending on the enhancement level ζ for collateral pools of 200, 50, and 5 exposures. Up to K_{IRB} , the capital charge increases almost linearly and afterward flattens out—the faster the flattening out, the less granular the collateral pool is.

Substantial losses were encountered from structured products in the wake of the 2007 subprime turbulence, particularly for previously highly rated tranches. This outcome supports allocating more capital for senior tranches than implied by direct application of the IRB model. In answer to the 2007 subprime turbulence, minimum capital requirements for securitizations were strengthened, particularly for *res securitizations*, that is, securitizations in

which at least one of the underlying exposures is already a securitization exposure itself, because of their higher systematic risk.

Capital Requirements for Other Risks in Pillar 1

Operational Risk

In Basel II, operational risk is, for the first time, a separate risk category subject to regulatory minimum capital requirements. It is defined as the risk of monetary losses “resulting from inadequate or failed internal processes, people and systems or from external events” ([7] para. 644.). It includes losses from failures in IT systems, fraud, natural catastrophes, and legal risk, but excludes losses from strategic and reputational risks. Ongoing developments in the financial industry, for example, the propagation of securitization and an increased reliance on rapidly evolving technology and complex financial products and strategies, support a new regulatory capital charge for operational risk.

Similar to other risk categories and consistent with the evolutionary concept of Basel II, different approaches characterized by increasing complexity and risk sensitivity are available to determine the regulatory capital charge for operational risk. The most advanced and technically most challenging method is

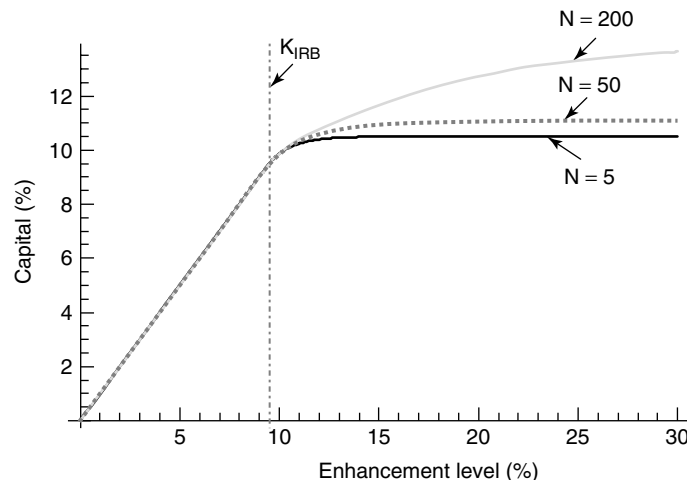

Figure 2 Capital requirements based on the supervisory formula. This figure shows the capital charge for securitizations under the supervisory formula approach for homogeneous collateral pools of $N \in \{200, 20, 5\}$ exposures. The default probability of every asset in the homogeneous pool is 2% and the loss given default 50%

the *advanced measurement approach*, which allows banks, subject to regulatory approval, to apply their own internal models for the calculation of regulatory capital (see **Operational Risk**). The resulting capital charge must capture potentially severe “tail” loss events. It needs to consider both EL and UL, with the UL defined for a one-year time horizon and a 99.9% confidence interval.

The loss distribution approach seems to have emerged as the most common modeling framework (see [4], as an example). Loss severity and loss frequency are typically modeled separately. Losses are aggregated over loss event types (e.g. external fraud or business disruptions and system failures) and business lines (e.g., corporate finance or retail banking). The Value at Risk figures of different business lines must be added, although banks can take into account correlation effects subject to regulatory approval.

Development of models for operational risk has been fast. *Extreme value theory* (EVT) is often applied, but these methods are still under development (see [20] for a critical examination of the use of EVT for operational risk modeling). The complex methods typically require an extensive set of historical loss data. The relative scarcity of high-impact, low-frequency events in individual banks has prompted the construction of external data bases. The outstanding methodological challenges and data restrictions in the modeling of operational risk are arguments in favor of complementing the quantitative risk measurement methodology with a self assessment, using, for example, scenario analyses and scorecards, a distinct pillar 2 review, and market discipline.

Market Risk

The 1996 amendment for market risk, which covered interest rate risk and equity risk in the trading book as well as foreign exchange and commodity risk, was integrated in Basel II. Since then, it has been possible to base the capital charge for market risk either on a standardized measurement method or – subject to regulatory approval – on the bank’s internal model for market risk (see **Market Risk**). Banks adopting the more risk-sensitive internal models approach are free to choose their own methodology, but to be recognized by the regulator, the internal

model has to meet various qualitative and quantitative requirements, including a regular backtesting program ([7], para. 718(LXX)–718(XCIX), and also see **Backtesting**).

The capital charge in the internal models approach is defined as follows:

$$MRC_t = \text{Max} \left\{ k \frac{1}{60} \sum_{i=1}^{60} VaR_{t-i}, VaR_{t-1} \right\} + SRC_t \quad (13)$$

where VaR_{t-1} is the Value at Risk of the portfolio over a 10-day horizon at a 99% confidence level ([7], para. 718). The second term, VaR_{t-1} , becomes binding if the portfolio composition has substantially changed.

The factor k in the first term of equation (13) is the sum of two components:

1. a multiplicative factor set by the local regulator with a floor of 3 that captures *inter alia* model risk, which stems, for example, from the assumptions of normality and stability of the distributions;
2. a *plus factor* that depends on the *ex post* performance, that is, the *backtesting* results, of the model.

The plus factor is based on mandatory quarterly backtesting with trading results of the last 250 days. The size of the plus factor depends on the number of Value at Risk exceptions and is given by a traffic-light table ([7], Annex 10, para. 27–61).

Various papers have advocated different backtesting methodologies (e.g., [31] or [13]). Accepting the imperfect nature of signals from backtesting results, supervisors have substantial leeway in how to assess the backtesting methodology of banks in their jurisdiction, for example, concerning the choice between a Value at Risk measure based on a “hypothetical profit and loss”, assuming a static portfolio, or on the “actual profit and loss”, which includes also commissions and intraday trading.

The *specific risk charge* SRC_t in equation (13) provides a buffer against idiosyncratic risk, including default risk and event risk. For banks that do not have methodologies in place to adequately capture event and default risks, a multiplicative factor of 4 instead of 3 applies. If the model captures only generic market risk, SRC_t is computed by the standardized approach.

The risk measurement approach of the 1996 amendment was challenged by financial innovation, which caused a shift of credit exposures from the banking book into the trading book when pools of traditional loans were packaged as tranches of collateralized debt obligations (CDO) and sold in the market. Although the risk of a credit exposure is not affected by transferring it between banking book and trading book, the risk measurement framework becomes different. Not only the different considered risk factors but also the shorter risk horizon and the lower confidence level drive a wedge between capital charges for the same exposure dependent on its assignment to the banking book or the trading book. As a consequence, making credit risk tradable by securitization created rich opportunities for regulatory capital arbitrage.

Recognizing the inherent risks of this development, the Basel Committee already decided in 2005 to reexamine the trading book treatment and issued two consultative documents with proposals for a revision in January 2009. An *incremental risk charge* is introduced for the internal models approach, which refines the treatment of specific risk and reduces the gap between regulatory capital charges in the banking book and in the trading book. It includes default risk and credit migration risk and also takes account of correlations between default events and migration events, which cause a clustering of both. Widening the definition beyond default risk alone reflects experience from the 2007 subprime turbulence that material credit-risk-related losses occurred without actual default events. Securitization positions cannot be incorporated into the incremental risk charge model on the grounds that a reliable quantification of diversification benefits is not possible given the current state of risk modeling. A standardized method applies instead.

Furthermore, a *stressed Value at Risk* is suggested that needs to be added to the Value at Risk in equation (13). For this purpose, a bank has to calibrate its model to historical data from a period of significant financial stress relevant to its portfolio. In summary, with the revised treatment of the trading book, the Basel Committee has addressed key limitations of previous capital requirements for the trading book and also incorporated lessons from the 2007 subprime turbulence.

Supervisory Review Process and Validation of Credit Risk Components

Whereas pillar 1 is concerned with regulatory minimum capital requirements, pillar 2 is about the internal capital adequacy assessment process. A bank has to ensure through its internal capital assessment that its capital basis is commensurate with its risk profile. The internal capital assessment has to address all material risks not captured in pillar 1, notably interest rate risk in the banking book, liquidity risk, and concentration risk. Banks' assessment of capital adequacy is evaluated in the supervisory review and evaluation process. This section is focused on two aspects that may require complex quantitative models, namely, the measurement of concentration risk in credit portfolios and stress testing.

Concentration Risk

Since lending is the primary activity of most banks, credit risk concentrations often present the most material risk concentrations ([7], para. 771). They are particularly important as they are not captured by the ASRF model, which is the basis of the regulatory capital requirements for credit risk in pillar 1. In a real bank portfolio with a finite number of assets, two of its assumptions, namely, that systematic risk is fully captured by a single factor and that the portfolio is infinitely granular, are not fulfilled. Deviations from this ideal case create *concentration risk*, which is not a different risk category but rather a key driver of credit risk. It can be decomposed into *single-name concentration* and *sectoral concentration*. Single-name concentration refers to an unbalanced exposure distribution across borrowers, whereas sectoral concentration refers to exposure concentration either in regional sectors or industry sectors ([9] gives an overview of various measurement tools for both kinds of risk concentrations).

Single-name concentration can generally be diversified away by increasing the number of exposures. A *granularity adjustment* for regulatory capital requirements to address single-name concentration was considered but not included in Basel II. Its computational burden was later significantly reduced by refined proposals in [34] and [24].

In the special case of a homogeneous portfolio (in terms of the risk components that enter the IRBA risk weight function), the granularity adjustment in

[24] computed from the loan volumes is linear in the Herfindahl—Hirschman Index. This gives a theoretical motivation for this popular but otherwise *ad hoc* concentration measure. *Ad hoc* measures generally use only information on exposure size in the portfolio. Model-based approaches consider also default probabilities and correlations and allow a risk quantification in terms of required capital. Therefore, model-based approaches have a higher informational value than *ad hoc* indicators.

Accounting for sectoral concentrations is technically more demanding than single-name concentrations since they drive the systematic risk through cross-sectoral default dependencies. At the same time, they are more relevant for typical credit portfolios of banks than name concentrations [19]. The asset-correlation parameter in the IRBA risk-weight functions was calibrated as an average correlation value, appropriate for portfolios that are very well diversified across sectors. Without further knowledge on this calibration procedure, it is, therefore, not possible to compute an adjustment of the ASRF model with as much rigor as the granularity adjustment in [24]. Contrary to the ASRF model, standard portfolio models for credit risk automatically account for risk concentrations. Therefore, the internal capital adequacy assessment process should be well suited to ensure that risk concentrations are adequately captured by capital.

Stress Tests

The inability to capture extreme events or “tail risk” is a commonly known shortcoming of standard risk models, which was confirmed by the market disruptions in the wake of the 2007 subprime turbulence. Therefore, the transition to model-based capital rules has increased the importance of stress tests (*see Stress Testing*). Initially introduced as compulsory in the 1996 amendment for internal market risk models, market risk is still the area in which stress testing methodologies are most advanced (see, e.g., [2, 12], and [32]).

Stress tests of credit portfolios are an essential element of the new framework. Stress scenarios should consider economic downturns, market-risk events, and liquidity conditions ([7], para. 434–437). They need to be integrated into the risk management framework of the institution and, therefore, they are typically based on institution-specific stress scenarios and

use internal risk models. At least one out of different components of a credit risk model are usually stressed: PD, LGD, volatility and correlation parameters, or the systematic risk factors. Feeding “stressed” PDs or LGDs into the ASRF model is a common approach that provides valuable information on the potential impact of the stress scenario on regulatory capital requirements. Its informational value for risk management decisions, however, is constrained by the stylized structure of the ASRF model, for example, its insensitivity to risk concentrations.

Stress tests of credit portfolios can serve three different purposes. First, they allow to assess the capital adequacy in selected stress scenarios. Second, they can help validate a model. Finding, for example, that a model does not react meaningfully to stressed conditions could be a warning signal. Third, they can help dampen the time variation of minimum capital requirements and to mitigate procyclical effects. This purpose can be achieved if stress tests are used to determine a dynamic capital buffer that is accumulated under benign and run down under adverse economic conditions.

Stress tests are typically either carried out for a broad economic scenario affecting the total portfolio or with stress scenarios confined to one or few industry sector(s). Particularly in the first case, the link between the credit risk drivers, modeled at the micro or portfolio level and the macroeconomic level, still poses a significant methodological and data challenge. Stress tests with sector-specific or borrower-specific scenarios can be useful to detect *hidden risk concentrations* in credit portfolios, which affect portfolio risk through elevated default correlations between certain (groups of) borrowers [14].

Outstanding Challenges to Future Regulation

Risk measurement in the context of future regulation faces at least three major challenges that have also gained in prominence in the 2007 subprime turbulence. The first is the need to broaden the scope of covered risks, in particular, by giving more attention to liquidity risk. The second is to further improve the risk assessment methodology, for example, by better taking into account linkages between different risk categories. The third is the need to strengthen a system-oriented *macroprudential* approach to bank regulation.

The first challenge pertains to liquidity risk [10], which played a prominent role in the 2007 subprime turbulence. An imminent shortage in funding liquidity due to unexpectedly high liquidity demands from liquidity facilities granted to special purpose vehicles is a case in point.

As a second challenge, the 2007 subprime turbulence uncovered weaknesses in modeling the economic risk of specific financial instruments as well as between different risk categories. One example is the collective increase of market risk, credit risk, and liquidity risk, which suggests a more integrated treatment in internal capital modeling [11].

The third major challenge is a more prominent role of a macroprudential perspective in regulation. Strategic interactions among market participants, for example, herding behavior, played an important role when the 2007 subprime turbulence unfolded into a major financial crisis. Their consequences and the resulting endogeneity of risk are not well captured either by regulatory minimum capital requirements or by statistical risk models currently used in financial institutions. Potential procyclical effects of risk-sensitive capital rules can provide another example that the micro- and the macroprudential perspectives do not necessarily coincide. Hence, supplementing regulation with a stronger macroprudential dimension still poses a formidable challenge.

Economic Capital

Role of Capital in Financial Institutions

In contrast to a typical corporation, the key role of capital in a financial institution is not primarily one of providing a source of funding for the organization.^a For example, banks usually have ready access to funding through their deposit-taking activities, which can be increased fairly fluidly. Instead, the primary role of capital in a bank, apart from the transfer of ownership, is to act as a buffer to

- absorb large unexpected losses;
- protect depositors and other claim holders; and
- provide confidence to external investors and rating agencies on the financial health and viability of the firm.

Typically, the sources of financial risk are classified as (*see Risk Exposures*)

- *credit risk*—losses associated with the default (or credit downgrades and upgrades) of an obligor (a counterparty, borrower, or debt issuer);
- *market risk*—losses associated with changes in market values; and
- *operational risk*—losses associated with operating failures.

Other types of risk faced by a financial institution include *liquidity risk*, *business* (or *strategic*) *risk*, *legal risk*, *insurance* and *liability risks*, etc. Capital provides a metric for aggregating risks across both different asset classes and across different risk types.

We can broadly classify capital into three types:

- *Book capital*—the actual physical capital held. While in its strictest definition this should be simply *equity capital*, more generally this might also include other assets such as liquid debt or hybrid instruments.
- *Regulatory capital*—the capital that a bank is required to hold by regulators in order to operate; this is defined by the regulatory authorities to act as a proxy for economic capital (EC).
- *Economic capital*—an estimate of the minimum level of capital that a firm requires to operate its business with a desired target solvency level. Sometimes this is also referred to as *risk capital*.^b

EC is meant to reflect the true “fair market” value differential between assets and liabilities. In contrast, regulatory capital may be commonly defined in terms of accounting book value measures rather than market values.^c The objectives of regulatory capital requirements are to safeguard the security of the financial system as a whole and to ensure its ongoing viability, as well as to create a level playing field across all institutions.

Economic Capital Definitions

Economic Capital as a Buffer for Unexpected Losses

EC represents the minimum buffer that provides protection against all risks faced by an institution at a target confidence level. Since it would be too costly to cover losses at the 100% level, EC is set at a lower confidence level (e.g., 99.9%). The choice of this level involves a trade-off between providing high returns on capital for shareholders and providing protection to the debt holders and other claim holders, such as depositors, while achieving a desired rating. For example, a firm’s probability of default over one year should be at most 0.5% to achieve a BBB rating by S&P. Thus, it must have enough capital to sustain a “0.5% worst-case loss” over a one-year time horizon.

The approach commonly taken by practitioners is to define EC to absorb only *unexpected losses* up to a certain confidence level, with *reserves* set aside to absorb *expected losses* (EL). Thus, EC is estimated as the *Value at Risk* (VaR) (*see Value-at-Risk; Market Risk*) at an $\alpha\%$ confidence level less the expected loss (*see Figure 1*):

$$EC_{\alpha} = VaR_{\alpha} - EL \quad (1)$$

Subtracting *EL* from the worse-case losses represents a simplifying approximation to estimate *EC* and generally leads to conservative estimates. More precisely, *EC* should measure loss relative to the portfolio’s initial mark-to-market (MtM) value and *not* relative to the *EL* of its end-of-period distribution, and should account for the interest payments that must be made on the funding debt:

$$EC = A_0 - \frac{VaR_{\alpha}(A_1)}{(1 + r_D)} \quad (2)$$

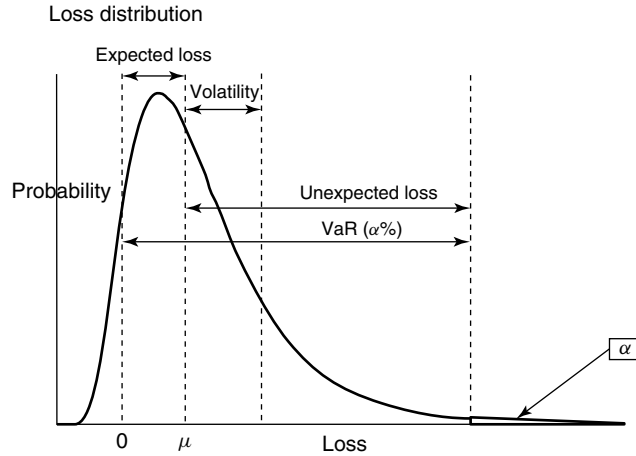

Figure 1 Loss distribution and capital

where A_0 is the market value of the assets at time 0, and r_D the nominal return on the liabilities. The estimation of the interest compensation factor and of the MtM value of the portfolio generally requires the use of an asset pricing model.^d

Economic Capital or “Risk Capital” as Insurance for the Value of the Firm

Some economists have used the term *risk capital* to refer to the smallest amount that can be invested to insure the value of the firm’s net assets against loss in value relative to a risk-free investment [4, 5]. For example, the risk capital of a long US Treasury bond position is the value of a *put option* with strike equal to the forward price of the bond.

Economic Capital as a Management Tool

EC provides a consistent metric to determine risk aggregation, asset and business allocation, as well as performance measurement.

In addition to computing the total EC for a portfolio, it is important to *attribute* this capital *a posteriori* to various subportfolios such as the firm’s activities, business units, counterparties or even individual transactions, and to *allocate* it *a priori* in an optimal manner, to maximize risk-adjusted returns (see **Economic Capital Allocation**). EC provides a useful basis for *risk-adjusted performance measurement* (RAPM), also referred to as *risk-adjusted return on*

capital (RAROC) (see **Risk-adjusted Return on Capital (RAROC)**) since it defines a consistent metric that spans all asset and risk classes, thereby providing an “apples-to-apples” benchmark for evaluating the performance of alternative business opportunities. Each asset can be assessed on a consistent basis, with returns adjusted appropriately in the context of the amount of risk assumed.

Economic Capital Calculation

Methods for calculating EC can be classified as *top-down* or *bottom-up* approaches. In addition to statistical methods, practitioners also commonly use *stress-testing* methods (see **Stress Testing**).

Top-down Approaches

EC can be estimated based on the aggregate information of the firm’s performance. Such “top-down approaches” generally use information on either *earnings* or *stock prices*.

The earnings-based approach typically makes the simplifying assumption that the market value of capital is equal to the value of a perpetual stream of expected earnings. As the determination of EC is based on the ability to sustain a worst-case loss at a given confidence level, this leads to

$$EC_0 = EaR/k \quad (3)$$

where EaR is the difference between expected earnings and the earnings under the worst-case scenario at a confidence level, and k is the required return associated with the riskiness of the earnings. Often, this approach is used with the additional assumption that earnings are normally distributed; thus, the confidence level is determined as a multiple of the volatility (see [7]).

Limitations of the earnings approach include its requirement of reliable historical performance data, and its inability to link EC directly to the sources of risk.

An alternative top-down approach is based on the *Black-Scholes-Merton* option pricing framework (see **Structural Default Risk Models**). It assumes that the market value of capital can be modeled as a *call option* on the value of the firm's assets where the strike is the notional value of the debt. An advantage of this approach is the availability of stock market data. However, several simplifications regarding the capital structure and model assumptions must be made to apply this tool in practice. A key limitation is that it does not allow the allocation of capital into different risks or business lines.

Bottom-up Approaches

EC is estimated by modeling the individual transactions and businesses and then aggregating the risks using advanced statistical portfolio models and stress testing. The bottom-up approaches have now become the best practice and provide greater transparency in isolating risks and allocating capital.

The estimation of EC at the firm level requires consolidation of risks at two levels.

- First, one computes the market risk, credit risk, operational risk, and so on, at the enterprise level. To achieve this, a firm might use separate VaR models for market risk, credit risk, and operational risk.
- Then, at the second level, the firm consolidates the capital across these risks.

A simple method to aggregate capital in the second step is to add up the credit risk capital, market risk capital, and operational risk capital. This produces a conservative capital measure (essentially, assuming that the risks are perfectly correlated). More advanced approaches apply *copula functions* (see **Copulas**:

Estimation) to aggregate risks, and many firms devote considerable effort to measure the correlations between these risks.

Stress Testing and Economic Capital

In addition to the VaR-based approaches, practitioners usually use stress testing as an important part of their EC methodology. Commonly, this involves the development of several specific adverse extreme scenarios and the assessment of portfolio losses against them. Stress scenarios may be based on historical experience or management judgment.

The combination of stress testing and statistical measures to develop EC measures is generally *ad hoc*, largely based on management's judgment. For example, an institution might assign the EC for market risk as 50% times the 99% VaR plus 50% the loss outcome from some stress scenarios (see **Stress Testing**).

End Notes

^aFor a more detailed discussion of economic capital, see [1, 6] and the references cited therein.

^bAlternatively, Matten [3] defines $EC = \text{risk capital} + \text{goodwill}$.

^cIn some cases, accounting practice allows items to be reported on a market value basis.

^dThis equation is derived by assuming that assets A_0 are funded by debt, L_0 , and equity, E_0 : $A_0 = L_0 + E_0$. The amount owed at maturity will be $L_0 \times (1 + r_D) = (A_0 - E_0) \times (1 + r_D)$. To match a given default probability α , EC is E_0 chosen so that this expression matches $\text{VaR}_\alpha(A_1)$, the α percentile of the final asset value. For a detailed discussion, see [1, 2].

Risk-adjusted Return on Capital (RAROC)

Maintaining credit worthiness is a cost of doing business for a bank. In a multibusiness bank, senior management faces the problem of allocating capital to the different businesses in order to maximize the market value of the bank to existing shareholders, subject to the constraint that it maintain its desired level of creditworthiness. The capital structure of the bank is set so that the bank's equity provides a buffer for the bank to maintain its desired level of creditworthiness. We refer to this buffer as the *economic capital* (see **Economic Capital**) of the bank. Traditional approaches to capital budgeting define the risk of a project in terms of a project's systematic risk with market factors. Such a measure does not address the concerns of senior management about how the project affects the overall risk of the bank. If a project increases the probability of default, to restore the bank's creditworthiness, the bank must increase its economic capital. The cost of the marginal increase in the economic capital should be allocated to the project and an adjusted net present value determined. The value additivity principle will not hold, as economic capital is not additive, as noted by Merton [8] (see **Convex Risk Measures; Expected Shortfall**).

In determining whether to add or eliminate a business from a bank's portfolio, a marginal approach is often advocated for determining the economic capital. The standard assumption is that the business is "small" in comparison with the existing portfolio. If this is not the case, the whole nature of the bank and its capital structure are affected, implying that the determination of the marginal effects is problematic. Merton and Perold [9] show that simply aggregating the marginal economic capital of individual businesses underestimates the total economic capital and the error can be substantial. Apart from these theoretical concerns, the actual determination of the marginal capital is fraught with many practical difficulties.

Each business within the bank contributes to the overall credit risk of the bank. The economic capital of the bank is less than the aggregate economic capital of the individual businesses on a stand-alone basis, owing to the fact that businesses are correlated.^a We

refer to the difference between the economic capital of the bank and the aggregate stand-alone value as the *portfolio effect*. This raises a number of challenging issues. The first is the measurement of economic capital. If economic capital is estimated on a stand-alone basis, does the bank own the portfolio effect or individual businesses? If businesses, how should economic capital be allocated? Given the allocation of capital to each business within the bank, how should it measure the performance of each business, recognizing that each business affects the overall creditworthiness of the bank and the cost of funding? What benchmark should be used to judge the performance of a business? How should the performance of a business be measured, if it does not fully utilize its allocated capital? These questions hint at some of the difficulties in measuring the performances of the businesses within the bank.

Practitioners have addressed the issue of an appropriate performance metric with the use of a risk-adjusted rate of return on capital (RAROC).^b A generic RAROC takes the form

$$RAROC = \frac{ER - EL - Costs}{EC} \quad (1)$$

where ER denotes the expected revenue, EL the expected losses, $Costs$ the funding cost associated with the project, and EC the economic capital attributed to the project.^c The economic capital is usually defined as the capital necessary to cushion against unexpected losses, operational, and market risks, and is often referred to as a *Value at Risk* (see **Value-at-Risk; Market Risk**). There are both practical and theoretical issues with the use of this type of metric. The first is the myopic nature of the measure. The second is the issue of how to measure economic capital for a business. The third is what benchmark to use to judge whether the risk-adjusted return is acceptable. The fourth is that economic capital is not a sufficient statistic for the measurement of risk. It is known from the work of Wilson [17], Froot and Stein [4], and Crouhy *et al.* [2] that economic capital does not incorporate the systematic risk of a business and serious errors can occur if projects are solely ranked on the basis of RAROC.^d

Froot and Stein (FS) [4] assume that there are no agency issues—the management acts in the best interests of existing shareholders. In their three-period model, risk management arises endogenously from

the need to avoid an adverse selection problem associated with costly external financing in the last period. They show that the expected excess rate of return for a new project depends on two terms. The first term depends on the covariance of the cash flow with the market portfolio and the second depends on the covariance of the project's cash flow with the nontradable cash flows of the bank multiplied by the price of nontradable risk. As FS observe, it is not clear how to estimate this term.

Banks are opaque to outsiders. Any outside assessment of the creditworthiness of a bank is out of date even when issued. Banks are translucent if not opaque to insiders, with information flows restricted across businesses inside the bank and even within businesses.^c Perold [10] describes a single-period model that incorporates the deadweight costs generated by the opaqueness of banks. Stoughton and Zechner [14] examine the question of capital allocation among businesses of a bank, assuming information asymmetry between the different business managers and senior management in a single-period model. The investment in risky technologies is financed with debt. Equity is used to satisfy a Value-at-Risk constraint. They derive a type of RAROC performance metric for each business, the hurdle rate being driven by the cost of debt, the distribution associated with the information asymmetry, and the outside employment opportunities for managers. Implication and measurement issues are not addressed.

None of these papers attempt to address the myriad of practical issues facing banks. A start is made in [15]. Each business within the bank is assumed to have its own balance sheet. This necessitates making some assumptions about the capital structure of the business. The risky assets of the business are financed with debt. The bank lends the business an amount of debt and charges the business an interest rate reflecting the expected maturity of the project and the credit risk of the bank. The required economic capital depends on the nature of the risks associated with project over its expected duration, giving rise to a *term structure of required economic capital*.^f This is taken as exogenous. The economic capital is assumed to be financed *via* equity. The business invests the economic capital in a short-term default-free asset. The costs associated with economic capital arise from taxation. The resulting hurdle rate depends on the systematic risk associated with the risky

investment and a second factor due to the requirement to hold costly economic capital. The weights of the two factors can be estimated, implying that it is possible to establish a required benchmark for performance measurement. If the term structure of economic capital allocated to the business is done on a marginal basis, the required rate of return on the business depends on the variance of the return on the business, the variance of the return on the remaining part of the bank, and the covariance between the two returns. If done on a stand-alone basis, it depends on the variance of the return on the business.

End Notes

^aMany different methods, from bottom-up to top-down, have been advocated for the allocation of capital. See [6, 16, Chapter 6] for brief descriptions.

^bMatten [5, Chapter 7], describes many different types of performance metrics used by practitioners, as well as references to the history of RAROC. In a recent survey of chief risk officers of financial firms—see [11]—nearly 90% stated that they used risk-adjusted performance measures, with RAROC being the dominant measure.

^cSee [1, Chapter 14; 12, Chapter 7] for a detailed description of how to apply RAROC.

^dSee [3] for a discussion on the pitfalls of RAROC.

^eThe issue of opaqueness in financial institutions is discussed in [13, 7].

^fA simple example would be a foreign currency swap. Principal is exchanged in this type of swap and this increases the credit risk. Initially, this is low risk, though as the swap approaches maturity, more economic capital is required.

Stress Testing

It is widely recognized that the most popular statistical financial risk measure, Value at Risk (VaR), is not, except under highly restrictive conditions, a sufficient statistic for describing risk in portfolios of financial assets. It is slightly ironic that nonstatistical techniques increasingly have come to be relied upon as tools for overcoming the deficiencies in VaR, signaling an (implicit) rejection of a risk epistemology based on objective principles and deductive reasoning in favor of a subjective alternative reliant on inductive reasoning. The prescriptions of regulatory authorities have added significant impetus to this trend. Partly as a result of this exogenous motivating force, these tools have experienced an incomplete ontogeny. Although various mathematical techniques of stress testing and scenario analysis have been developed, an axiomatic treatment justifying the incorporation of these tools into economic decision making is still missing.

Stress testing and scenario analysis aim to elicit information about how risk assessments are affected by extreme changes in either valuation-driving factors or exogenously determined parameters. Scenario analysis generally involves a more holistic approach, in which many factors are assumed to change simultaneously. Stress testing usually refers to techniques in which a single factor or parameter is changed, possibly repeatedly. Unfortunately, the two sobriquets are frequently used interchangeably.

These techniques are widely used in banks and other financial institutions. Some financial regulation requires regulated entities to use these techniques in risk measurement as a condition for allowing the use of (more favorable) risk-based capital calculations.

Historical Origins

Following several, high profile, financial derivatives-related trading losses incurred by financial and nonfinancial firms in the early 1990s, various government-sponsored studies seeking ways to ameliorate future adverse events called for improved risk assessment. An increased focus on stress testing and scenario analysis was among the specific recommendations therein.

The earliest of these recommendations came from the Group of Thirty's Report of the Global Derivatives Study Group (1993). Recommendation six of the report states, "Dealers should regularly perform simulations to determine how their portfolios would perform under stress conditions." The most detailed prescriptions came from the Basel Committee for Banking Supervision in its (1996) "Amendment to the Capital Accord to Incorporate Market Risks". For example, the document states, "Banks should subject their portfolios to a series of simulated stress scenarios . . . for example, the 1987 equity crash, the ERM crises of 1992 and 1993, or the fall in the bond markets in the first quarter of 1994." The perceived importance of these techniques continues to wax large in the regulatory agenda. For example, in 2006 the Committee of European Banking Supervisors issued a consultative paper on stress testing in which it opined, "Stress testing is a valuable risk management technique whose potential applications are quite varied . . ." A comprehensive system of stress testing and scenario analysis is generally a required concomitant to risk-based methods for regulatory capital adequacy determination.

Stress Testing

Stress testing, as the name suggests, seeks to gauge risk by examination of extreme changes in the underlying random factors that affect valuation. By factor, we mean a source of random variation in the price of a financial instrument. For example, two random factors affect the value of an exchange traded equity call (or put) option, variation in the market price of the underlying equity and variation in the volatility of the underlying equity.

In its basic form, stress testing involves changing one factor at a time only, holding all others constant. This technique can be applied to a portfolio of instruments or to a single position.

Factor-push

One common flavor of this sort of stress test is called *factor-push*, because the stress test outcome is the result of "pushing" each factor in the direction resulting in portfolio loss. This approach can be implemented mechanically as follows.

First, a "push" size must be selected. This push size will be applied sequentially to each factor, i ,

where f_i refers to the current value of the i th factor. The push size is subjective. One way it may be given a heuristic justification is if, for each factor, it is taken to be a constant, c , multiplied by the factor's standard deviation, s_i .

Second, every position under consideration is valued twice, using the following two alternative values for the factor:

$$f_i^+ = f_i(1 + cs_i), \quad f_i^- = f_i(1 - cs_i) \quad (1)$$

The value for the factor that results in the larger total portfolio reduction in value is retained, whereas the other is discarded. This process is then repeated for the remaining factors.

Third, every position is valued once more, this time simultaneously using all the factor changes that were retained during the previous step.

As noted earlier, there is no rigorously defensible rationale for the selection of any particular size for the push factor. This method can introduce other undesirable effects into the final portfolio stress loss estimate as well.

Because the ultimate step uses factor changes that are each chosen independently, the set of factor changes may make no economic sense, if viewed together as a single economic scenario. Also, to the extent that the portfolio contains instruments that have nonzero second-order cross-factor sensitivities, these will be ignored in developing the final set of factor changes.

If the portfolio contains some instruments whose values are either nonlinear or discontinuous functions of some of the factors, then for any given scheme for determining the push size, it can be shown that the resulting portfolio stress loss may not be greater than alternative schemes that have a strictly smaller push size. Such would be the case, for example, if the portfolio consisted of only a long position in an option straddle.

Another variation of the factor-push method is used by some derivatives exchanges and over the counter (OTC) market dealers for the determination of the customers' portfolio margin requirements. In this method, each factor is allowed to take on a range of values. For example, the current factor level may be scaled up or down in increments of 1 standard deviation until the increment reaches c standard deviations. A zero factor change is included (for a reason which will shortly be obvious), giving in this case $2c$ alternative values for each factor.

In this method, all factors are allowed to change simultaneously. Therefore, if there are n factors and $2c + 1$ possible values for each, then $(2c + 1)^n$ portfolio revaluations are performed, and the one yielding the greatest portfolio loss is taken to be the stress loss.

The factor-push method is also related to a common method for managing trading portfolio risk when the portfolio includes instruments whose values are a nonlinear function of the factors driving pricing. A *sensitivity ladder* is a set of possible changes specified for each factor, where the instruments are revalued (and typically first-order sensitivities recalculated as well) for each specified change in a factor.

Maximum Loss

A stress testing technique that attempts to account for the deficiencies in the factor-push type of stress test is called *maximum loss* and was first developed by Studer [8].

Maximum loss is defined as the n -tuple of factor changes for which the corresponding portfolio loss is a maximum, subject to the factor changes being a member of a feasible set. Studer defines the feasible set of factor changes with respect to a (continuous) joint distribution of factor returns. Specifically, he requires that the likelihood of any feasible n -tuple of factor returns must exceed some given probability.

This approach is difficult to implement. For an arbitrary portfolio of financial instruments, this approach requires evaluating every feasible point, both boundary and interior points, in the space of factor returns. Random or quasirandom methods might be employed to create a practical implementation of this method. Any sampling technique would potentially run into problems with portfolios that exhibit nonlinear sensitivities to the factors. With detailed knowledge of the instruments in the portfolio, it may be possible to construct a computationally efficient search algorithm that samples only from areas of the factor return distribution that are likely to result in the maximum loss.

Stress Testing of Correlation Matrices

This technique focuses on the impact of changing the joint dynamics of factors affecting portfolio valuation. It is common belief that volatile market environments are characterized by different correlation

dynamics. Several authors have argued inconclusively for a mixture of normals as description of factor returns over time.

To implement stress testing for changes in a correlation matrix, a “shocked” matrix is used to calculate the change in portfolio value. Typically, the shocked matrix is intended to represent a “high correlation” environment. The shocks are typically specified based on subjective rules similar to those used in the techniques discussed earlier. However, because the covariance matrix must be positive definite, shocks that can be validly applied to the correlations are constrained.

The usual technique to deal with this issue is to apply the subjectively determined shocks, then manipulate the resulting covariance matrix to ensure positive definiteness with the goal of departing minimally from the intended shocks. Much has been written on the problem of determining the closest positive definite matrix to a given matrix by elimination of the negative eigenvalues from the stressed correlation matrix, for example, see [7].

Scenario Analysis

The intent of scenario analysis is to analyze the performance of a portfolio when subjected to an ensemble of factor changes intended to represent a specific market event, one typically characterized as extreme but plausible and relevant.

The “extremeness” of a scenario may be defined in two ways. First, it may be measured with respect to the magnitude of factor changes considered. In this case, there is no guarantee that the scenario will correspond to a significant loss in portfolio value. Alternatively, it may be measured with respect to the magnitude of the change in portfolio value resulting from factor changes, that is, an ensemble of factor changes that corresponds to a portfolio loss greater than a threshold level.

The concept of plausibility is usually judged in reference to the set of factor changes, not the portfolio positions. No standards of plausibility exist. However, Breuer and Krenn [5] propose to define the plausibility of a given scenario as the cumulative probability, under the assumption that factor returns are distributed multivariate normal, of all the scenarios with probability less than or equal to the given scenario. To justify this criterion, Basel Committee on Banking Supervision [3] refers to its intuitive appeal.

Without an arbitrary definition of plausibility, it may not be possible to establish necessary conditions for a scenario to be deemed plausible. For example, no-arbitrage and nonnegative price conditions may be violated under severe market stresses. As illustrations, note that during the equity market crash of 1987, the arbitrage relationship between the US equity index cash market and index futures prices did not hold at all times. Similarly, negative yields for discount bills of the US Treasury were observed at times during the market crisis of 2007–2008.

Relevance is defined with respect to the positions in the portfolio and the current market environment. For example, an “oil embargo” scenario might be thought not relevant to a portfolio containing only interest rate derivatives. There is no objective method for evaluating (or ranking) relevance. Therefore, relevance is incorporated into scenario selection by judgment.

The selection of factor changes used in the scenario selection is, therefore, in the final analysis, a subjective exercise. Scenarios are typically modeled in one of the two ways. First, an actual historical period is used as the basis for the scenario. Historical scenarios may be generally agreed “events” or may be selected mechanically, for example, by “data-snooping” histories of factor changes, selecting as candidate scenarios those dates where more than a minimum number of factor changes exceeds a given threshold. Also, financial regulators have identified certain historical events, which they have deemed to be suitable stress scenarios, such as the equity market crash of 1987 (see, e.g. [3]).

Given the chosen period, factor returns from that period are collected and applied to the current levels of market factors, yielding “shocked” factor values. For market factors that did not trade during the chosen period, a proxy must be used to create an estimated shock. Changes in the dynamical properties of factors, arising, for example, from market microstructure changes between the historical period chosen and the present, are typically ignored, and the factor shocks applied as if those changes would have no effect in a replay of the scenario. Finally, the shocked factor values are used to revalue the portfolio and a stress loss (or profit) is calculated.

Second, an ensemble of factor changes is created by employing (explicitly or implicitly) a structural or reduced form model of market dynamics to generate a hypothetical scenario. The result may yield

quantitative shocks for only a subset of the market factors relevant to a portfolio. The remaining factor shocks are set based on judgment. A variation on this approach employs scenarios in which a subset of factors are shocked in highly stylized ways (e.g., see [6]), such as by a parallel move in yields or a change in all equity market prices of a single percentage amount. Historical scenarios claim general assent to plausibility because they have actually happened. However, the claim may sometimes be questioned, for, as noted above, the passage of time may render an historical scenario increasingly artificial, as reliance on proxies for shocks and the extent of changes in market dynamics increase.

It has been documented in the experimental psychology literature that individuals systematically underestimate the probability of rare events, and they overestimate probabilities for events that have occurred more recently. The subjective nature of scenario selection may therefore *ipso facto* lead to systematic biases in scenario selection.

It is claimed by some that scenario analysis will provide incremental knowledge about the risk of a portfolio beyond which it might be available using other risk measures, such as VaR. The arguments in support of this claim are not rigorous. In the absence of a probability model, what may be extreme and plausible can only be evaluated subjectively. Thus, if one individual claims some quantum of knowledge derived from evaluating a scenario, then a general assent as to the claim may be difficult to achieve (beyond the trivial sense in which all would agree with the statement, “if these shocks are applied in this way to this set of mathematical relations describing portfolio value, then this change in portfolio value is observed”).

Even if the problem of intersubjectivity is put aside, it is not obvious how to measure the increment to knowledge from scenario analysis. A scenario maps an n -tuple of factor changes to a single value for the portfolio return. If the space of factor changes is continuous and the set of possible (extreme) values for portfolio return is continuous, it can be argued that the measure of the information from a scenario is zero, unless a not-small (subjective) probability is assigned to the specific set of factor changes considered. This conclusion might be modified if it can be shown that (i) small perturbations in the n -tuple of factor changes from the base case scenario result in portfolio returns that are close the return

in the base case and (ii) small perturbations in the portfolio return map to only n -tuples of factor changes that are “close” to the base case set of factor changes. For a large and complex portfolio containing instruments, whose price is nonlinear or discontinuous in terms of factor changes, neither of these conditions can be guaranteed.

It has been shown in [1, 2] and related research that a scenario can be interpreted as a worst-case loss on a countable, finite event space, and as such satisfies the axioms of a coherent risk measure. It has also been shown that a coherent risk measure can be obtained from scenarios. These results place scenario analysis squarely within the framework of risk theory. In limited contexts, it is possible to construct decision-theoretic justifications for rules based on stress scenarios. The key element in so doing is the ability to completely specify the event space of portfolio outcomes. This can be accomplished self-referentially, as when a decision maker, regulator, and so on, defines the set of relevant outcomes, where any other outcome not included in (or derivable from) this set of predefined outcomes is ignored or declared irrelevant. A widely cited example is the Standard Portfolio Analysis of Risk (SPAN) margining system used by many derivatives exchanges in which a given set of scenarios is deemed to be relevant for determining capital adequacy for a market participant.

Historical scenarios are typically constructed to mimic factor moves that span multiple trading days in order to encompass an entire period of market disturbance. The identification of either a beginning or ending date may be ambiguous, if the goal is to capture peak-to-trough factor changes, as these may not be synchronous across all markets. A subjective choice of dates to be employed must be made in such cases.

In general, no allowances are made for time-related valuation effects in a scenario, such as cash flows, time decay (“theta”), expiration, and reinvestment of net cash inflows. However, long horizon (e.g., several months to over one year) scenario analyses, such as the one performed by some financial firms for nontrading books, do include these effects.

The static portfolio assumption is most often justified by the argument that illiquidity would make it very difficult and costly either to trade out of any positions or to put on hedge positions during the market event. To some extent, this can be observed in markets undergoing stress.

This static approach to scenario-based stress testing does not allow for an active assessment of liquidity risk, which is greatest during a crisis. Only a dynamic scenario can capture the losses resulting from portfolio adjustment subsequent to a change in market liquidity, as manifest in widening of bid-ask spreads, and an increase in the price impact of trades.

The potential usefulness of a given historical scenario will fall over time, making scenario analysis a dynamic process; over time it is necessary to replace or revise scenarios. The deterioration has several origins. Market microstructure changes will affect factor price dynamics. Examples are the switch from eighths to decimals on the US equity exchanges in 2001 and the replacement of floor execution with electronic trading systems. Also, the set of traded instruments changes as a result of bankruptcy, merger, financial innovation, and so on. Changes in market liquidity (perhaps arising from the entrance or exit of new market participants) will affect price dynamics as well. Even large changes in price levels can adversely affect the usability of an historical scenario, potentially causing the historical factor changes to defy common sense by being large or too small.

Since 2001 the International Monetary Fund, in cooperation with member central banks, has conducted model-based scenario analysis for certain member countries. In each country, *macro stress testing* employs a central-bank model of the entire banking system and focuses on factor changes and their impacts on balance sheets, which might result in a system-wide event, for example, contagious default

and systemic contraction of lending to preserve capital. These factors might include the change in corporate defaults, changes in counterparty default, or changes in foreign exchange (FX) rates, trade balance or FX reserves, or shocks to asset prices, such as real estate. For a survey of these methods, see [4].

Model Validation

One important way to mitigate model risk (*see Models*; for a more detailed discussion of model risk and how to mitigate model risk, see Crouhy *et al.* [1], chapter 14) is to invest in research to improve models and to develop better statistical tools, either internally at the bank or externally at a university (or at an analytically oriented consulting organization).

An even more vital way of reducing model risk is to establish a process for the independent vetting of how models are both selected and constructed. This should be complemented by independent oversight of the profit and loss (P&L) calculation. In this article, we address the *ex ante* validation of pricing models developed for the front office of a trading institution. *Ex post* validation of risk models, or back testing, is addressed in **Backtesting**.

The role of vetting is to offer assurance to the firm's management that any model proposed by, say, a trading desk for the valuation of a given security, is reasonable. In other words, the model offers a reasonable representation of how the market itself values the instrument, and that the model has been implemented correctly. Vetting should consist of the following phases:

1. Documentation

The vetting team should ask for a full documentation of the model, including both the assumptions underlying the model and its mathematical expression. This should be independent of any particular implementation, such as a spreadsheet or a C++ computer code, and should include the following:

- The term sheet or, equivalently, a complete description of the transaction.
- A mathematical statement of the model, which should include the following:
 - An explicit statement of all the components of the model: stochastic variables and their processes, parameters, equations, and so on.
 - The payoff function and/or any pricing algorithm for complex structured deals.
 - The calibration procedure for the model parameters.
 - The hedge ratios/sensitivities.

- Implementation features, that is, inputs, outputs, and numerical methods employed.
- A working version of the implementation.

2. Soundness of model

An independent model vetter needs to verify that the mathematical model is a reasonable representation of the instrument that is being valued. For example, the manager might reasonably accept the use of a particular model (e.g., the Black model) for valuing a short-term option on a long maturity bond, but reject (without even looking at the computer code) the use of the same model to value a two-year option on a three-year bond. At this stage, the risk manager should concentrate on the finance aspects, and not become overly focused on the mathematics.

3. Independent access to financial rates

The model vetter should check that the bank's middle office has independent access to an independent market risk management financial rates database (to facilitate independent parameter estimation).

4. Benchmark modeling

The model vetter should develop a benchmark model based on the assumptions that are being made and on the specifications of the deal. Here, the model vetter may use a different implementation from the implementation that is being proposed. A proposed analytical model can be tested against a numerical approximation technique or against a simulation approach. (For example, if the model to be vetted is based on a "tree" implementation, one may instead rely on the partial differential equation approach and use the finite element technique to derive the numerical results.) The results of the benchmark test can be then compared with those of the proposed model.

5. Health check and stress test the model

Also, make sure that the model possesses the basic properties that all derivatives models should possess, such as put-call parity and other nonarbitrage conditions. Finally, the vetter should stress-test the model. The model can be stress-tested by looking at some limit scenario, in order to identify the range of parameter values for which the model provides accurate pricing. This is especially important for implementations that rely on numerical techniques.

6. Build a formal treatment of model risk into the overall risk management procedures, and periodically reevaluate models

Also, reestimate parameters using best-practice statistical procedures. Experience shows that simple, but robust models tend to work better than more ambitious, but fragile models. It is essential to monitor and control model performance over time.

Backtesting

The term *backtesting* is used in several ways in finance. Most commonly, backtesting denotes either (i) an assessment of the hypothetical historical performance of a suggested trading strategy or (ii) the evaluation of financial risk models using historical data on risk forecasts and profit and loss realizations. The following discussion is about the evaluation of risk models.

The procedure is to consider the daily *ex ante* risk measure forecasts from a model and test it against the daily *ex post* realized portfolio loss. The risk measure forecast could take the form of a Value-at-Risk (VaR), an expected shortfall, or a distributional forecast. The goal is to be able to backtest any of these risk measures of interest. The backtesting procedures can be seen as a final diagnostic check on the risk model carried out by the risk management team that constructed the risk model, or they can be used by external model evaluators such as bank supervisors.

Evidence on actual bank VaRs and their backtesting performance can be found in [7, 22, 28, 29, 31]. The regulatory considerations involved in backtesting are detailed by the Basel Committee on Banking Supervision [2–4]. Lopez [24] analyzes the regulatory approach to backtesting and Campbell [9] provides a survey of backtesting that includes a discussion of regulatory considerations. Backtesting of credit risk models is investigated in [25].

First, we discuss procedures for backtesting the VaR metric (*see Value-at-Risk; Market Risk*). Second, we consider increasing backtesting power by using explanatory variables to backtest the VaR. Third, we consider the increasing power by backtesting risk measures other than VaR, and we discuss various other issues in backtesting.

Backtesting VaR

By now, VaR is by far the most popular portfolio risk measure used by risk management practitioners. The VaR revolution in risk management was triggered by JP Morgans RiskMetrics approach launched in 1994. Supervisory authorities immediately recognized the need for methods to backtest VaR and the first research on backtesting was published soon after in

[21, 23]. Christoffersen [10] extended Kupiec’s test of unconditional VaR coverage to tests of conditional VaR coverage. These concepts are defined later.

Defining the Hit Sequence

First, define VaR_{t+1}^p to be a number constructed on day t such that the portfolio losses on day $t + 1$ will only be larger than the VaR_{t+1}^p forecast with probability p . If we observe a time series of past *ex ante* VaR forecasts and past *ex post* losses, PL , we can define the “hit sequence” of VaR violations as

$$I_{t+1} = 1 \quad \text{if} \quad PL_{t+1} > VaR_{t+1}^p \quad (1)$$

$$= 0 \quad \text{if} \quad PL_{t+1} < VaR_{t+1}^p \quad (2)$$

The hit sequence returns a 1 on day $t + 1$ if the loss on that day is larger than the VaR number predicted in advance for that day. If the VaR is not exceeded (or violated), then the hit sequence returns a 0. When backtesting the risk model, we construct a sequence $\{I_{t+1}\}_{t=1}^T$ across T days, indicating when the past violations occurred.

The Null Hypothesis

If we use the perfect VaR model, then given all the information available to us at the time the VaR forecast is made, we should not be able to predict whether the VaR will be violated. We should be expecting a 1 in the hit sequence with probability p and we should be expecting a 0 with probability $1 - p$ and the occurrences of the hits should be random over time.

We say that a risk model has correct *unconditional* VaR coverage if $\Pr(I_{t+1} = 1) = p$ and we say that a risk model has correct *conditional* VaR coverage if $\Pr_t(I_{t+1} = 1) = p$. Roughly speaking, correct *unconditional* VaR coverage just means that the risk model delivers VaR hits with probability p on average across the days. Correct *conditional* VaR coverage means that the risk model gives a VaR hit with probability p on every day given all the information available on the day before. Note that correct conditional coverage implies correct unconditional coverage but not *vice versa*.

We can think of VaR backtesting as testing the hypothesis:

$$H_0 : I_{t+1} \sim \text{i.i.d. Bernoulli}(p) \quad (3)$$

If p is one half, then the i.i.d. Bernoulli distribution describes the distribution of getting a head when tossing a fair coin. When backtesting risk models, p will not be one half but instead on the order of 0.01 or 0.05 depending on the coverage rate of the VaR. The hit sequence from a correctly specified risk model should look like a sequence of random tosses of a coin that comes up heads 1 or 5% of the time depending on the VaR coverage rate.

Note that, in general, the expected value of a binary sequence is simply the probability of getting a 1:

$$\begin{aligned} E_t [I_{t+1}] &= \Pr_t (I_{t+1} = 1) 1 + \Pr_t (I_{t+1} = 0) 0 \\ &= \Pr_t (I_{t+1} = 1) \equiv \pi_{t+1|t} \end{aligned} \quad (4)$$

We denote this conditional hit probability by $\pi_{t+1|t}$ and its unconditional counterpart is defined $E [I_{t+1}] \equiv \pi$.

We can therefore construct the following null hypothesis of correct conditional coverage for the hit sequence from a VaR model

$$H_0 : E_t [I_{t+1}] = \pi_{t+1|t} = p \quad (5)$$

namely that the conditionally expected value of the hit sequence at time $t + 1$, given all the information available at time t is the promised VaR coverage rate p .

Unconditional Coverage Testing

First, we want to test if the unconditional probability of a violation in the risk model, π , is significantly different from the promised probability, p . We call this the *unconditional coverage hypothesis*. We can write $H_0 : E [I_t] \equiv \pi = p$.

The expected value of the hit sequence can be estimated by the sample average, $\hat{\pi} = \frac{1}{T} \sum_{t=1}^T I_t = T_1/T$, where T_1 is the number of 1s in the sample. Note that if the null hypothesis is true, we have that $E [\hat{\pi}] = E \left[\frac{1}{T} \sum_{t=1}^T I_t \right] = p$. Assuming that the observations on the hit sequence are independent over time, the variance of the $\hat{\pi}$ estimate is $1/T \text{Var} (I_t)$ where $\text{Var} (I_t)$ can be estimated as the sample variance of the hit sequence. The hypothesis that $E [I_t] = p$ can therefore be tested in a simple means test

$$MT = \sqrt{T} \frac{\hat{\pi} - p}{\sqrt{\text{Var} (I_t)}} \sim N(0, 1) \quad (6)$$

We can also implement the unconditional coverage test as a likelihood ratio test. For this, we write the likelihood of an i.i.d. Bernoulli(π) hit sequence:

$$L(\pi) = \prod_{t=1}^T (1 - \pi)^{1-I_{t+1}} \pi^{I_{t+1}} = (1 - \pi)^{T_0} \pi^{T_1} \quad (7)$$

where T_0 and T_1 are the number of 0s and 1s in the sample. We can easily estimate π from $\hat{\pi} = T_1/T$, that is, the observed fraction of violations in the sequence. Plugging the ML estimates back into the likelihood function gives the optimized likelihood as

$$L(\hat{\pi}) = \left(1 - \frac{T_1}{T}\right)^{T_0} \left(\frac{T_1}{T}\right)^{T_1} \quad (8)$$

Under the unconditional coverage null hypothesis that $\pi = p$, where p is the known VaR coverage rate, we have the likelihood

$$L(p) = \prod_{t=1}^T (1 - p)^{1-I_{t+1}} p^{I_{t+1}} = (1 - p)^{T_0} p^{T_1} \quad (9)$$

And we can check the unconditional coverage hypothesis using a likelihood ratio test

$$LR_{uc} = -2 \ln \left[\frac{L(p)}{L(\hat{\pi})} \right] \sim \chi_1^2 \quad (10)$$

Asymptotically, that is, as the number of observations, T , goes to infinity, the test will be distributed as a χ^2 with one degree of freedom.

The choice of significance level comes down to an assessment of the costs of making two types of mistakes: we could reject a correct model (type I error) or we could fail to reject (that is accept) an incorrect model (type II error). Increasing the significance level implies larger type I errors but smaller type II errors and *vice versa*. In academic work, a significant level of 1, 5, or 10% is typically used. In risk management, type II errors may be very costly so that a significance level of 10% may be appropriate.

Often, we do not have a large number of observations available for backtesting, and we certainly will typically not have a large number of violations, T_1 , which are the informative observations. It is, therefore, often better to rely on Monte-Carlo-simulated P values rather than those from the χ^2 distribution. Christoffersen and Pelletier [14] discuss how

to implement the [17] Monte Carlo P -values in a backtesting setting.

Independence Testing

There is strong evidence of time-varying volatility in daily asset returns as surveyed in [1]. If the risk model ignores such dynamics, then the VaR will react slowly to the changing market conditions and VaR violations will appear clustered in time. Pritsker [30] illustrates this problem using VaRs computed from historical simulation. If the VaR violations are clustered, then the risk manager can essentially predict that if today has a VaR hit, then there is a probability larger than p of getting a hit tomorrow, which violates that the VaR is based on an adequate model. This is clearly not satisfactory. In such a situation, the risk manager should increase the VaR in order to lower the conditional probability of a violation to the promised p .

The most common way to test for dynamics in time series analysis is to rely on the autocorrelation function and the associated portmanteau or Ljung–Box-type tests. We can implement this approach for backtesting as well. Let γ_k be the autocorrelation at lag k for the hit sequence. Plotting γ_k against k for $k = 1, \dots, m$ will give a visual impression of the correlation of between a hit in one of the last m trading days and a hit today. The Ljung–Box test provides a formal check of the null hypothesis that all of the first m autocorrelations are zero against the alternative that any of them is not. The test is easily constructed as

$$LB(m) = T(T+2) \sum_{k=1}^m \frac{\gamma_k^2}{T-k} \sim \chi_m^2 \quad (11)$$

where χ_m^2 denotes the chi-squared distribution with m degrees of freedom. Berkowitz *et al.* [6] find that setting $m = 5$ gives good testing power in a realistic daily VaR backtesting setting.

Independence testing can also be done using the likelihood approach. Assume that the hit sequence is dependent over time and that it can be described as a first-order Markov sequence with transition probability matrix:

$$\Pi_1 = \begin{bmatrix} 1 - \pi_{01} & \pi_{01} \\ 1 - \pi_{11} & \pi_{11} \end{bmatrix} \quad (12)$$

These transition probabilities simply mean that conditional on today being a nonviolation (i.e., $I_t = 0$) then the probability of tomorrow being a violation (i.e., $I_{t+1} = 1$) is π_{01} . The probability of tomorrow being a violation given today is also a violation is $\pi_{11} = \Pr(I_t = 1 \text{ and } I_{t+1} = 1)$. The probability of a nonviolation following a nonviolation is $1 - \pi_{01}$ and the probability of a nonviolation following a violation is $1 - \pi_{11}$.

If we observe a sample of T observations, then we can write the likelihood function of the first-order Markov process as

$$L(\Pi_1) = (1 - \pi_{01})^{T_{00}} \pi_{01}^{T_{01}} (1 - \pi_{11})^{T_{10}} \pi_{11}^{T_{11}} \quad (13)$$

where T_{ij} , $i, j = 0, 1$, is the number of observations with a j following an i . Taking first derivatives with respect to π_{01} and π_{11} and setting these derivatives to zero, one can solve for the maximum likelihood estimates:

$$\hat{\pi}_{01} = \frac{T_{01}}{T_{00} + T_{01}}, \quad \hat{\pi}_{11} = \frac{T_{11}}{T_{10} + T_{11}} \quad (14)$$

Then using the fact that the probabilities have to sum to one, we have $\hat{\pi}_{00} = 1 - \hat{\pi}_{01}$, $\hat{\pi}_{10} = 1 - \hat{\pi}_{11}$.

Allowing for dependence in the hit sequence corresponds to allowing π_{01} to be different from π_{11} . Positive dependence is a matter of concern, which amounts to the probability of a violation following a violation (π_{11}) being larger than the probability of a violation following a nonviolation (π_{01}). If, on the other hand, the hits are independent over time, then the probability of a violation tomorrow does not depend on today being a violation or not and we write $\pi_{01} = \pi_{11} = \pi$. We can test the independence hypothesis that $\pi_{01} = \pi_{11}$ using a likelihood ratio test

$$LR_{\text{ind}} = -2 \ln \left[\frac{L(\hat{\pi})}{L(\hat{\Pi}_1)} \right] \sim \chi_1^2 \quad (15)$$

where $L(\hat{\pi})$ is the likelihood under the alternative hypothesis from the LR_{uc} test.

Other methods for independence testing based on the duration of time between hits can be found in [14].

Backtesting with Information Variables

The preceding tests are quick and easy to implement. However, as they only use information on past VaR

hits, they might not have much power to detect misspecified risk models. To increase the testing power, we consider using the information in past market variables, such as interest rate spreads or volatility measures. The basic idea is to test the model using information that may explain when violations occur. The advantage of increasing the information set is not only to increase power but also to help us understand the areas in which the risk model is misspecified. This understanding is key in improving the risk models further.

If we define the q -dimensional vector of information variables available to the backtester at time t as X_t , then the null hypothesis of a correct risk model can be written as

$$H_0 : \Pr(I_{t+1} = 1|X_t) = p \Leftrightarrow E[I_{t+1} - p|X_t] = 0 \quad (16)$$

The hypothesis says that the conditional probability of getting a VaR violation on day $t + 1$ should be independent of any variable observed at time t and it should simply be equal to the promised VaR coverage rate, p . This hypothesis is equivalent to the conditional expectation of the hit sequence less p being equal to 0.

Engle and Manganelli [18] develop a conditional autoregressive VaR by regression quantiles approach. For backtesting, they suggest the following dynamic quantile test:

$$DQ = \frac{(I - p)' X (X' X)^{-1} X' (I - p)}{Tp(1 - p)} \sim \chi_q^2 \quad (17)$$

where X is the $T \times q$ matrix of information variables, and $(I - p)$ is the $T \times 1$ vector of hits where each element has been subtracted by the desired covered rate p .

Berkowitz *et al.* [6] find that implementing the DQ test using simply the lagged VaR from a GARCH model as well as the lagged hit gives good power in a realistic daily VaR experiment. Smith [31] also finds good power when applying the DQ test. A regression-based approach to backtesting is also used in [11, 12]. Christoffersen *et al.* [13] develop tests for comparing different VaR models.

Smith [31] further suggests a probit approach where the potentially time-varying probability of a hit is modeled using the normal cumulative density

function and where Lagrange multiplier tests are used.

When backtesting with information variables, the question of which variables to include in the vector X_t immediately arises. It is difficult to give a general answer as it depends on the particular portfolio at hand. It is likely that variables that are thought to be correlated with the future volatility in the portfolio are good candidates. In equity portfolios option, implied volatility measures such as the VIX would be an obvious candidate. In FX portfolios option, implied volatility measures could be constructed as well. In bond portfolios, variables such as term spreads and credit spreads are likely candidates as are variables capturing the level, slope, and curvature of the term structure.

Other Issues in Backtesting

When correctly specified, the one-day VaR measure tells the user that there is a probability p of losing more than the VaR over the next day. Importantly, it does not, for example, say how much one can expect to lose on the days where the VaR is violated. Thus, the VaR only contains partial information about the distribution of losses. This limitation of the VaR is reflected in the definition of the hit variable in equation (1), which in turn limits the possibilities for backtesting in the VaR setting. We can only backtest on the hit occurrences and not, for example, on the magnitude of the losses when the hits occur because the VaR does not promise hits of a certain magnitude.

Backtesting Expected Shortfall

The limitations of the VaR as a risk measure suggest alternative risk measures, most prominently expected shortfall (ES), also referred to as *conditional VaR* ($CVAR$) (see **Value-at-Risk; Market Risk**), which denotes the expected loss on the days where the VaR is violated. We can define it formally as

$$ES_{t+1}^p = E_t[PL_{t+1}|PL_{t+1} > VaR_{t+1}^p] \quad (18)$$

Note that ES provides information on the expected magnitude of the loss whenever the VaR is violated. We now consider ways to backtest the ES risk measure.

Consider again a vector of variables, X_t , which are known to the risk manager and which may help explain potential portfolio losses beyond what is explained by the risk model. The ES risk measure promises that whenever we violate the VaR, the expected value of the violation will be equal to ES_{t+1}^p . We can therefore test the ES measure by checking if the vector X_t has any ability to explain the deviation of the observed shortfall or loss, PL_{t+1} , from the expected shortfall on the days where the VaR was violated. Mathematically, we can write

$$PL_{t+1} - ES_{t+1}^p = b_0 + b_1' X_t + e_{t+1} \quad \text{for} \\ t + 1 \text{ where } PL_{t+1} > VaR_{t+1}^p \quad (19)$$

where $t + 1$ now refers only to days where the VaR was violated. The observations where the VaR was not violated are simply removed from the sample. The error term e_{t+1} is assumed to be independent of the regressor, X_t .

To test the null hypothesis that the risk model from which the ES forecasts were made uses all information optimally ($b_1 = 0$) and that it is not biased ($b_0 = 0$), we can jointly test that $b_0 = b_1 = 0$.

Note that now the magnitude of the violation shows up on the left-hand side of the regression. However, note that we can still only use information in the tail to backtest. The ES measure does not reveal any particular properties about the remainder of the distribution, and therefore we only use the observations where the losses were larger than the VaR.

Further, discussion of ES backtesting can be found in [26].

Backtesting the Entire Distribution

Rather than focusing on particular risk measures from the loss distribution such as the VaR or the expected shortfall, we could instead decide to backtest the entire loss distribution from the risk model. This would have the benefit of potentially increasing further the power to reject bad risk models.

Assuming that the risk model produces a cumulative distribution of portfolio losses, call it $F_t(*)$. Then at the end of every day, after having observed the actual portfolio loss (or profit), we can calculate the risk model's probability of observing a

loss below the actual. We denote this probability by $p_{t+1} \equiv F_t(PL_{t+1})$.

If we use the correct risk model to forecast the loss distribution, then we should not be able to forecast the risk model's probability of falling below the actual return. In other words, the time series of observed probabilities p_{t+1} should be distributed independently over time as a Uniform(0,1) variable. We therefore want to consider tests of the null hypothesis:

$$H_0 : p_{t+1} \sim \text{i.i.d. Uniform}(0, 1) \quad (20)$$

The Uniform(0,1) distribution function is flat on the interval 0–1 and 0 everywhere else. As the p_{t+1} variable is a probability, it is a must that it should lie in the 0–1 interval. Constructing a histogram and checking if it looks reasonably flat provide a useful visual diagnostic. If systematic deviations from a flat line appear in the histogram, then we would conclude that the distribution from the risk model is misspecified. A detailed discussion of this approach is found in [16].

Unfortunately, testing the i.i.d. uniform distribution hypothesis is cumbersome due to the restricted support of the uniform distribution. However, we can transform the i.i.d. Uniform p_{t+1} to an i.i.d. standard normal variable, z_{t+1} , using the inverse cumulative distribution function, $z_{t+1} = \Phi^{-1}(p_{t+1})$. We are then left with a test of a variable conforming to the standard normal distribution, which can easily be implemented. The i.i.d. property of z_{t+1} can be assessed *via* the autocorrelation functions and by using the $LB(m)$ test in equation (4) on z_{t+1} and $|z_{t+1}|$, for example. The normal distribution property can be tested using the method of moments approach in [8]. Regression-based tests using information variables can also be constructed. Further analysis of distribution backtesting can be found in [5, 15].

Dirty Profits and Losses

The backtesting procedures compare the *ex ante* forecast from a risk model to the *ex post* profit and losses (P/L). It is therefore obviously essential, but unfortunately not always the case, that the *ex post* recorded P/L arise directly from the portfolio used to make the *ex ante* model predictions.

The risk model will typically produce a risk forecast for the loss distributions of a particular portfolio of assets. The *ex post* profits and losses should only contain cash flows directly related to the portfolio of assets assumed in the risk models. However, the total *P/L* of a trading desk may contain trading commission revenues as well as costs that are not directly related to holding the portfolio of assets assumed in the risk model. This extraneous cash flows should be stripped from the *P/L* before backtesting.

The daily *P/L* may also include cash flows from intraday transactions, that is, the *P/L* from selling an asset that was bought the same day. Such cash flows are not directly related to the end-of-day portfolio entered into the risk model and should ideally be stripped away as well. A detailed discussion of these issues can be found in [27].

Multiple-day Horizons and Changing Portfolio Weights

The backtesting procedures described earlier can be relatively easily adopted to the multiday risk-horizon setting. If, for example, a 10-day VaR forecast is observed daily along with the *ex post* 10-day *P/L*, then the hit sequence can be constructed daily as in equation (1). The 10-day VaR horizons implies that 9-day autocorrelation is to be expected in the hit sequence and that this should be allowed for when constructing its variance as in equation (6). Similarly, in the *DQ* test as in equation (17), one should use information variables available 10 days before the observed *P/L*. Smith [31] discusses backtesting with multiday VaRs.

Allowing for Risk Model Parameter Estimation Error

In the discussion so far, we have abstracted from the fact that the risk models in use most likely contain parameters that are estimated with errors. This parameter estimation error will in turn render the hit sequence observed with error. As a consequence when backtesting the risk model, we may reject the “true” risk model just because its parameters were estimated with error. As discussed in [18], this is mainly an issue when the risk model is evaluated in-sample, that is, when the model is evaluated on the same data it was estimated on. In typical external

backtesting applications, the backtesting procedures are used in a more realistic out-of-sample manner where the model is estimated on data until day t and then used to forecast risk for day $t + 1$. In this setting, parameter estimation error is less likely to be critical. Parameter estimation issues in relation to VaR modeling has been analyzed in detail in [19, 20].

Copulas: Estimation

Copulas are a tool for modeling and capturing the dependence of two or more random variables (rv's). In the work of Sklar [22], the term *copula* was used for the first time; it is derived from the Latin word *copulare*, which means to connect or to join. Similarly, Hoeffding had already studied distributions under “arbitrary changes of scale” in the 1940s; see [7].

The main purpose of a copula is to disentangle the dependence structure of a random vector from its marginals. A d -dimensional copula is defined as a function $C : [0, 1]^d \rightarrow [0, 1]$, which is a cumulative distribution function (cdf) with uniform^a marginals. On one hand, this leads to the following properties:

1. $C(u_1, \dots, u_d)$ is increasing in each component $u_i, i \in \{1, \dots, d\}$.
2. $C(1, \dots, 1, u_i, 1, \dots, 1) = u_i$ for all $1 \leq i \leq d$.
3. For $a_i \leq b_i, 1 \leq i \leq d$, C satisfies the *rectangle inequality*

$$\sum_{i_1=1}^2 \dots \sum_{i_d=1}^2 (-1)^{i_1+\dots+i_d} C(u_{1,i_1}, \dots, u_{d,i_d}) \geq 0,$$

where $u_{j,1} = a_j$ and $u_{j,2} = b_j$.

On the other hand, every function satisfying (1)–(3) is a copula. Furthermore, $C(1, u_1, \dots, u_{d-1})$ is again a copula and so are all k -dimensional marginals with $2 \leq k < d$.

The construction of *multivariate* copulas is difficult. There is a rich literature on uni- and bivariate distributions but many of these families do not have obvious multivariate generalizations.^b Similarly, it is not at all straightforward to generalize a two-dimensional copula to higher dimensions. For example, consider the construction of three-dimensional copulas. A possible attempt is to try $C_1(C_2(u_1, u_2), u_3)$ where C_1, C_2 are bivariate copulas. However, already for $C_1 = C_2 = \max\{u_1 + u_2 - 1, 0\}$ (the countermonotonicity copula, introduced in the section *Important Copulas*) this procedure fails. See [18, Section 3.4] for further details. Also Chapter 4 in [11] gives an overview of construction of multivariate copulas with different concepts. In particular, it discusses the construction of a d -dimensional copula given the set of $d(d-1)/2$ bivariate margins.

The class of Archimedean copulas (see also the section Archimedean Copulas) is an important class for which the construction of multivariate copulas can be performed quite generally. A common example of a three-dimensional Archimedean copula is given by the following exchangeable Archimedean copula:

$$C(u_1, u_2, u_3) = \phi^{-1}(\phi(u_1) + \phi(u_2) + \phi(u_3)) \quad (1)$$

with appropriate generator ϕ . However, for appropriate ϕ_1, ϕ_2 ,

$$\phi_1^{-1}(\phi_2 \circ \phi_1^{-1}(\phi_1(u_1) + \phi_1(u_2)) + \phi_2(u_3)) \quad (2)$$

also gives a three-dimensional copula (see [14], Section 5.4.3). It is of course possible that ϕ_1 and ϕ_2 are generators of different types of Archimedean copulas.

The key to the separation of marginals and dependence structure is the *quantile transformation*. Let U be a standard uniform rv and $F^{-1}(y) := \inf\{x : F(x) \geq y\}$ be the generalized inverse of F . Then

$$P(F^{-1}(U) \leq x) = F(x) \quad (3)$$

This result is frequently used for simulation: the generation of uniform rv's is readily implemented in typical software packages and if we are able to compute F^{-1} , we can sample from F using equation (1).

On the contrary, the *probability transformation* is used to compute copulas implied from distributions, see the following section Copulas derived from Distributions. Consider X having a continuous distribution function F_2 , then $F(X)$ is standard uniform.^c

Sklar's Theorem

It is not surprising that every distribution function inherently embodies a copula function. On the other hand, any copula entangled with some marginal distributions in the right way leads to a proper multivariate distribution function. This is the important contribution of Sklar's theorem [22]. Ran F denotes the range of F .

Theorem Consider a d -dimensional cdf F with marginals $F_1, \dots, F_d$. There exists a copula C such that

$$F(x_1, \dots, x_d) = C(F_1(x_1), \dots, F_d(x_d)) \quad (4)$$

for all x_i in $[-\infty, \infty]$, $i = 1, \dots, d$. If F_i is continuous for all $i = 1, \dots, d$ then C is unique; otherwise, C is uniquely determined only on $\text{Ran } F_1 \times \dots \times \text{Ran } F_d$. On the other hand, consider a copula C and univariate cdf's $F_1, \dots, F_d$. Then F as defined in equation (4) is a multivariate cdf with marginals $F_1, \dots, F_d$.

It is important to note that for discrete distributions, copulas are not as natural as they are for continuous distributions; compare [8].

In the following, we therefore concentrate on continuous F_i , $i = 1, \dots, d$. It is interesting to examine the consequences of representation (2) for the copula itself. Using that $F \circ F^{-1}(y) = y$ for any continuous CDF F , we obtain

$$C(\mathbf{u}) = F(F_1^{-1}(u_1), \dots, F_d^{-1}(u_d)) \quad (5)$$

While relation (4) is usually the starting point for simulations that are based on a given copula and given marginals, relation (5) rather proves to be the theoretical tool to obtain the copula from any multivariate distribution function. This equation also allows to extract a copula directly from a multivariate distribution function.

Invariance Under Transformations

An important property of a copula is that it is invariant under strictly increasing transformations: for strictly increasing functions $T_i : \mathbb{R} \rightarrow \mathbb{R}$, $i = 1, \dots, d$ the rv's $X_1, \dots, X_d$ and $T_1(X_1), \dots, T_d(X_d)$ have the same copula.

Bounds of Copulas

Hoeffding and Fréchet independently derived that a copula always lies in between certain bounds; compare Figure 1. This is because of the existence of some extreme cases of dependency, co- and countermonotonicity. The so-called *Fréchet–Hoeffding bounds* are given by

$$\max \left\{ \sum_{i=1}^d u_i + 1 - d, 0 \right\} \leq C(\mathbf{u}) \leq \min \{u_1, \dots, u_d\} \quad (6)$$

which holds for any copula C . Although a comonotonic copula exists in any dimension d , there is no countermonotonicity copula in the case of dimensions greater than two.^d

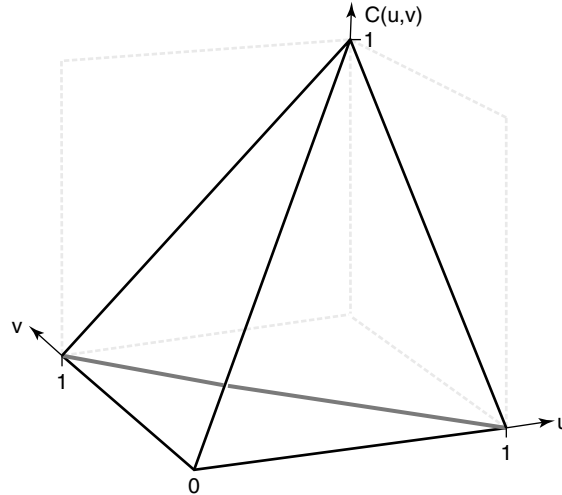

Figure 1 According to the Fréchet–Hoeffding bounds, every copula has to lie inside of the pyramid shown in the graph. The surface given by the bottom and back side of the pyramid (the lower bound) is the countermonotonicity copula $C(u, v) = \max \{u + v - 1, 0\}$, while the front side (the upper bound) is the comonotonicity copula, $C(u, v) = \min(u, v)$

Important Copulas

First, the *independence copula* is given by

$$\prod_{i=1}^d u_i \quad (7)$$

Random variables are independent if and only if their copula is the independence copula.

The *comonotonicity copula* or the *Fréchet–Hoeffding upper bound* is given by

$$\min\{u_1, \dots, u_d\} \quad (8)$$

Random variables $X_1, \dots, X_d$ are called *comonotonic*, if their copula is as in equation (8). This is equivalent to $(X_1, \dots, X_d)$ having the same distribution as $(T_1(Z), \dots, T_d(Z))$ with some rv Z and strictly increasing functions $T_1, \dots, T_d$. Therefore, comonotonicity refers to perfect dependence in the sense where all rv's are, in an increasing and deterministic way, depending on Z .

The other case of perfect dependence is given by countermonotonicity. The *countermonotonicity copula* reads

$$\max\{u_1 + u_2 - 1, 0\} \quad (9)$$

Two rv's with this copula are called *countermonotonic*. This is equivalent to (X_1, X_2) having the same distribution as $(T_1(Z), T_2(Z))$ for some rv Z and T_1 being increasing and T_2 being decreasing or vice versa. However, the *Fréchet–Hoeffding lower bound* as given in equation (6) is *not* a copula for $d > 2$; see [14], Example 5.21.

Copulas Derived from Distributions

The probability transformation^e allows to obtain the copula inherent in multivariate distributions: for a multivariate cdf F with continuous marginals F_i , the inherent copula is given by

$$C(\mathbf{u}) = F(F_1^{-1}(u_1), \dots, F_d^{-1}(u_d)) \quad (10)$$

For example, for a multivariate normal distribution, the implied copula is called *Gaussian copula*. For a d -dimensional rv X , the correlation matrix^f Γ is obtained from the covariance matrix by scaling each component to variance 1. Therefore, Γ is given by the entries $\text{Corr}(X_i, X_j)$, $1 \leq i, j \leq d$ (see **Correlation**

Risk). For such a *correlation matrix* Γ the Gaussian copula is given by

$$\Phi_{\Gamma}(\Phi^{-1}(u_1), \dots, \Phi^{-1}(u_d)) \quad (11)$$

In a similar fashion, one obtains the *t-copula* or the *Student copula*

$$t_{v,\Gamma}(t_v^{-1}(u_1) \dots, t_v^{-1}(u_d)) \quad (12)$$

where Γ is the correlation matrix, t_v is the cdf of the one dimensional t_v distribution, and $t_{v,\Gamma}$ is the cdf of the multivariate $t_{v,\Gamma}$ distribution. The mixing nature of the t -distribution leads to a dramatically different behavior in the tails, which is an important property in applications. See the section *Tail Dependence*.

Archimedean Copulas

An important class of analytically tractable copulas are the *Archimedean copulas*. For the bivariate case, consider a continuous and strictly decreasing function $\phi : [0, 1] \rightarrow [0, \infty]$ with $\phi(1) = 0$, called the *generator*. Then $C(u_1, u_2)$ given by

$$\begin{cases} \phi^{-1}(\phi(u_1) + \phi(u_2)) & \text{if } \phi(u_1) + \phi(u_2) \leq \phi(0) \\ 0 & \text{otherwise} \end{cases} \quad (13)$$

is a copula if and only if ϕ is convex; see [18], Theorem 4.1.4. If $\phi(0) = \infty$ the generator is said to be *strict* and $C(u_1, u_2) = \phi^{-1}(\phi(u_1) + \phi(u_2))$.

For the multivariate case, there are different possibilities of generalization. A relatively special case is when the copula is of the form

$$\phi^{-1}(\phi(u_1) + \dots + \phi(u_d)) \quad (14)$$

These are the so-called exchangeable Archimedean copulas and [15] give a complete characterization of such ϕ leading to a copula of the form (7). One may also consider asymmetric specifications of multivariate Archimedean copulas; see [14] Section 5.4.2 and 5.4.3. We present some examples of Archimedean copulas in bivariate case: from the generator $(-\ln u)^\theta$ one obtains the bivariate *Gumbel copula* or *Gumbel–Hougaard copula* as follows:

$$\exp\left(-\left[(-\ln u_1)^\theta + (-\ln u_2)^\theta\right]^{\frac{1}{\theta}}\right) \quad (15)$$

where $\theta \in [1, \infty)$. For $\theta = 1$ it coincides with the independence copula, and for $\theta \rightarrow \infty$, it converges

4 Copulas: Estimation

to the comonotonicity copula. The Gumbel copula has tail dependence in the upper right corner.

The *Clayton copula* is given by^g

$$(\max \{u_1^{-\theta} + u_2^{-\theta} - 1, 0\})^{-\frac{1}{\theta}} \quad (16)$$

where $\theta \in [-1, \infty) \setminus \{0\}$. For $\theta \rightarrow 0$ it converges to the independence copula, and for $\theta \rightarrow \infty$ to the comonotonicity copula. For $\theta = -1$ we obtain the Fréchet–Hoeffding lower bound. The generator $\theta^{-1}(u^{-\theta} - 1)$ of the Clayton copula is strict only if $\theta > 0$. In this case

$$C_{\theta}^{Cl}(u_1, u_2) = (u_1^{-\theta} + u_2^{-\theta} - 1)^{-\frac{1}{\theta}} \quad (17)$$

The generator $\ln(e^{-\theta} - 1) - \ln(e^{-\theta u} - 1)$ leads to the *Frank copula* given by

$$-\frac{1}{\theta} \ln \left(1 + \frac{(e^{-\theta u_1} - 1) \cdot (e^{-\theta u_2} - 1)}{e^{-\theta} - 1} \right) \quad (18)$$

for $\theta \in \mathbb{R} \setminus \{0\}$.

The *generalized Clayton copula* is obtained from the generator $\theta^{-\delta}(u^{-\theta} - 1)^{\delta}$:

$$\left([(u_1^{-\theta} - 1)^{\delta} + (u_2^{-\theta} - 1)^{\delta}]^{\frac{1}{\delta}} + 1 \right)^{-\frac{1}{\theta}} \quad (19)$$

with $\theta > 0$ and $\delta \geq 1$. Note that for $\delta = 1$ the standard Clayton copula is attained; compare [18], Example 4.19.

Further examples of Archimedean copulas may be found in [18], and in particular one may consider Table 4.1 therein as well as Sections 4.5 and 4.6 (Table 1).

Table 1 List of some copulas. For the Gumbel, Clayton, Frank and the Marshall–Olkin copula, only the bivariate versions are stated. References to the multivariate versions are given in the text. Further copulas may be found in [18], Table 4.1 (p. 94) and Sections 4.5 as well as 4.6

Name	Copula	Parameter range
Independence or product copula	$\Pi(\mathbf{u}) = \prod_{i=1}^d u_i$	
Comonotonicity copula or Fréchet–Hoeffding upper bound	$M(\mathbf{u}) = \min \{u_1, \dots, u_d\}$	
Countermonotonicity copula or Fréchet–Hoeffding lower bound	$W(u_1, u_2) = \max \{u_1 + u_2 - 1, 0\}$	
Gaussian copula ^(a)	$C_{\Gamma}^{Ga}(\mathbf{u}) = \Phi_{\Gamma}(\Phi^{-1}(u_1), \dots, \Phi^{-1}(u_d))$	
<i>t</i> - or Student copula ^(a)	$C_{v, \Gamma}^t(\mathbf{u}) = t_{v, \Gamma}(t_v^{-1}(u_1), \dots, t_v^{-1}(u_d))$	
Gumbel copula or Gumbel–Hougaard copula	$C_{\theta}^{Gu}(u_1, u_2) = \exp \left(- [(-\ln u_1)^{\theta} + (-\ln u_2)^{\theta}]^{\frac{1}{\theta}} \right)$	$\theta \in [1, \infty)$
Clayton copula ^(b)	$C_{\theta}^{Cl}(u_1, u_2) = (\max \{u_1^{-\theta} + u_2^{-\theta} - 1, 0\})^{-\frac{1}{\theta}}$	$\theta \in [-1, \infty)$
Generalized Clayton ^(b) copula	$C_{\theta, \delta}^{Cl}(u_1, u_2) = \left([(u_1^{-\theta} - 1)^{\delta} + (u_2^{-\theta} - 1)^{\delta}]^{\frac{1}{\delta}} + 1 \right)^{-\frac{1}{\theta}}$	$\theta \geq 0, \delta \geq 1$
Frank copula ^(b)	$C_{\theta}^{Fr}(u_1, u_2) = -\frac{1}{\theta} \ln \left(1 + \frac{(e^{-\theta u_1} - 1) \cdot (e^{-\theta u_2} - 1)}{e^{-\theta} - 1} \right)$	$\theta \in \mathbb{R}$
Marshall–Olkin copula or generalized Cuadras–Augé copula	$C_{\alpha_1, \alpha_2}(u_1, u_2) = \min \{u_2 \cdot u_1^{1-\alpha_1}, u_1 \cdot u_2^{1-\alpha_2}\}$	$\alpha_1, \alpha_2 \in [0, 1]$

^(a)Here Γ is a correlation matrix, that is, a covariance matrix where each variance is scaled to 1

^(b)For the (generalized) Clayton and the Frank copula, the case $\theta = 0$ is given as the limit for $\theta \rightarrow 0$, which leads to the independence copula in both cases

The Marshall–Olkin Copula

The *Marshall–Olkin copula* is a copula with singular component. For intuition, consider two components that are subject to certain shocks that lead to failure of either one or both the components. The shocks occur at times that are assumed to be independent and exponentially distributed. Denote the realized shock times by Z_1, Z_2 and Z_{12} . Then we obtain for the probability that the two components live longer than x_1 and x_2 , respectively,

$$P(Z_1 > x_1)P(Z_2 > x_2)P(Z_{12} > \max\{x_1, x_2\}) \quad (20)$$

This extends to the multivariate case in a straightforward way; compare [4] and [18]. The related copula equals

$$\min\left\{u_2 \cdot u_1^{1-\alpha_1}, u_1 \cdot u_2^{1-\alpha_2}\right\} \quad (21)$$

with $\alpha_i \in [0, 1]$. A similar family is given by the *Cuadras-Augé* copulas

$$\min\{u_1, u_2\} \cdot (\max\{u_1, u_2\})^\alpha \quad (22)$$

$\alpha \in [0, 1]$; see [3].

Measures of Dependence

Measures of dependence summarize the dependence structures of rv's. There are three important concepts: linear correlation, rank correlation, and tail dependence. A further concept of dependence is *association*; see [6, 17].

Linear Correlation

Linear correlation is a well-studied concept. It is a dependence measure, which is useful only for *elliptical distributions* (see **Multivariate Distributions**). This is because elliptical distributions are fully described by mean vector, covariance matrix, and a characteristic generator function. As mean and variances are determined by the marginal distributions, the copulas of elliptical distributions depend only on the covariance matrix and the generator function. Linear correlation, therefore, has a distinguished role in this class, which it does not have in other multivariate models.

Rank Correlation

Rank correlations describe the dependence structure of the ranks, that is, the dependence structure of the considered rv's when transformed to uniform marginals using the probability transformation. Most importantly, this implies a direct representation in terms of the underlying copula; compare equation (5). We consider *Kendall's tau* and *Spearman's rho*, which also play an important role in nonparametric statistics.

For rv's $\mathbf{X} = X_1, \dots, X_d$ with marginals $F_i, i = 1, \dots, d$, *Spearman's rho* is defined by

$$\rho_S(\mathbf{X}) := \text{Corr}(F_1(X_1), \dots, F_d(X_d)) \quad (23)$$

Corr is the correlation matrix whose entries are given by $\text{Corr}(F_i(X_i), F_j(X_j))$.

Consider an independent copy $\tilde{\mathbf{X}}$ of $\mathbf{X}$. Then *Kendall's tau* is defined by

$$\rho_\tau(\mathbf{X}) := \text{Cov}\left[\text{sign}(\mathbf{X} - \tilde{\mathbf{X}})\right] \quad (24)$$

For $d = 2$,

$$\begin{aligned} \rho_\tau(X_1, X_2) &= P\left((X_1 - \tilde{X}_1) \cdot (X_2 - \tilde{X}_2) > 0\right) \\ &\quad - P\left((X_1 - \tilde{X}_1) \cdot (X_2 - \tilde{X}_2) < 0\right) \end{aligned} \quad (25)$$

which explains this measure of dependency.

Both measures have values in $[-1, 1]$; they are 0 for independent variables (while there might also be nonindependent rv's with zero rank correlation) and they equal 1 (−1) for the comonotonic (countermonotonic) case. Moreover, they can directly be derived from the copula of $\mathbf{X}$; see [14], Proposition 5.29. For example,

$$\rho_S(X_1, X_2) = 12 \int_0^1 \int_0^1 (C(u_1, u_2) - u_1 u_2) du_1 du_2 \quad (26)$$

In the case of a bivariate Gaussian copula one obtains^h $\rho_S(X_1, X_2) = \frac{6}{\pi} \arcsin \frac{\rho}{2}$ and a similar expression for ρ_τ .

For other examples and certain bounds that interrelate those two measures, we refer the reader to [18],

Sections 5.1.1–5.1.3. For multivariate extensions see, for example, [21] and [23].

Tail Dependence

We distinguish between *upper* and *lower* tail dependence. Consider two rv's X_1 and X_2 with marginals F_1, F_2 and copula C . *Upper tail dependence* means intuitively that with large values of X_1 also large values of X_2 are expected. More precisely, the *coefficient of upper tail dependence* is defined by

$$\lambda_u := \lim_{q \nearrow 1} P(X_2 > F_2^{-1}(q) | X_1 > F_1^{-1}(q)) \quad (27)$$

provided the limit exists and $\lambda_u \in [0, 1]$. The *coefficient of lower tail dependence* is
